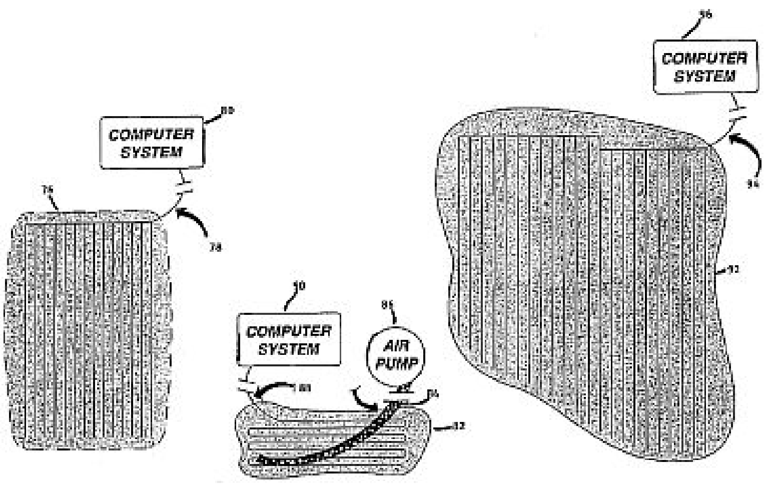
FIGURE 5



DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Reference will now be made in detail to the present preferred embodiments of the present invention, examples of which are illustrated in the accompanying drawings.

Whenever possible, the same reference numbers will be used throughout the drawings to refer to the same or like parts.

Shown in Fig. 1 is a first preferred embodiment of the present invention. It illustrates the application of pulsed electromagnetic energy to any aquatic setting. Shown generally at 10, this embodiment includes a water reservoir 12, such as an aquarium, pool, pond or other body of water. Below water reservoir 12 is placed electric wiring 16. Although in Fig. 1 electric wiring 16 is shown in a continuous open ended coil of wiring, electric wiring 16 can be positioned in a discontinuous fashion having a main line and a plurality of other lines extending from the main line. The electrical wiring 16 is placed over a substantial area of water reservoir 12, from 1 to 30 inches below the bottom surface of the water reservoir 12 and is insulated from the surrounding elements and cross currents from other cables. If water reservoir 12 has sides, such as in a pool, electric wiring 16 can also be placed behind the surface of the sides of reservoir 12. Electric wiring 16 is insulated by neutral materials, such as plastics, that will insulate electric wiring 16, yet not produce a charge in the surrounding soil or substance. Further, highly shielded electrical wire is not desired as it decreases the capacity of diffusion of the pulsed electromagnetic energy. The pulsed electromagnetic energy is supplied to electric wiring 16, and is controlled by an electromagnetic energy generator 14.

Optionally, an air pump 18 and perforated air hose 20 may be included in the system embodied in Figure 1. Air pump 18 and air hose 20 provide an oxygen source to the water with in reservoir 12, thus, aerating the water and increasing the oxygen concentration of the water.

In use, pulsed electromagnetic energy is applied to the electric wiring 16 by an electromagnetic energy generator 14. Various electronic components maybe utilized to generate electromagnetic energy for use in this system, such as a computer system or a electromagnetic wave generator for example. Preferably, the electromagnetic energy has a magnetic field component in the range of 0.5 to 30 Gauss, and the frequency range of the pulses between 0.5 and 30 Hertz. Concurrently, air pump 18 pumps air through hose 20 to increase the oxygen concentration of the water. The water in free motion around the air bubbles is energized to a higher state because of the application of the pulsed electromagnetic energy, and thus becomes even more saturated with oxygen.

Application of the electromagnetic energy to reservoir 12 provides for application of electromagnetic energy to both plants and animals situated within the aquatic system. The affected plants and animals exhibit enhanced physiologic effects such as increased growth and overall health for example. Furthermore, the highly oxygenated and energized water can then be utilized for watering plants which are not directly exposed to electromagnetic energy.

Optionally the system and method of the present invention contemplates the sustained or intermittent introduction of acoustic energy into the aquatic setting or the environment of other embodiments of the present invention. Many forms of soothing sounds may provide enhanced benefit but most preferred is the use of symphonic music or sounds, preferably with minimal or no dischord. The introduction of such can be accomplished through a sound system 100 as is schematically illustrated in Fig. 6. Sound system 100 comprises a power supply 102, which may be independent or shared with other systems utilized in the environment, that is operably connected to a sound control panel 104 from which one may control the selection and characteristics of the sounds broadcast by sound system 100 into the surrounding environment of the present invention. Control panel 104 is connected to one or more speakers 106 for broadcasting the generated sound. In aquatic settings underwater speakers are contemplated.

Although not required, one or more microphones 108 for receiving sound from the aquatic setting or other environment is contemplated. Such sounds may be recorded as is known in the art.

Additionally the sustained or intermittent introduction of orgone or radionic energy into the aquatic setting of the environment or other embodiments of the present invention, especially but not necessarily in pulsed form, is contemplated. Such radionic energy is supplied through one or more radionic generators or collectors as are lcnown and available in the art. Exposure time and intensity may be varied.

Referring now to Fig. 2, there is shown a second embodiment of the present invention, illustrating the application of pulsed electromagnetic energy to livestock animal pens. In this embodiment, there is a stock pen 24 which can be used to retain any type of livestock animal or poultry. Further, it should be understood that such a stock pen can be enclosed in buildings or open fields. Electrical wiring 26 extends below the surface and laterally across first stock pen 24 to cover at least a substantial area of stock pen 24. As in the first embodiment, electrical wiring 26 is comprised of electrical wiring having neutral insulating materials, and is placed under the surface of the selected area at a preferred depth of 1 to 30 inches. Electromagnetic energy generator 28 generates and transmits electromagnetic energy to electric wiring 26. Optionally, this system may also include a water tank 34 for watering of the animals. An air pump 30 may be utilized to pump air into the water tank 34 through hose 32. Aeration of water tank 34 by pump 30 increases the oxygen concentration of the water held within water tank 34.

If the stockyard is enclosed, the electric wiring is buried at a depth between 1 and 30 inches within the dirt or other flooring material, such as concrete, for example.

Now referring to Fig. 3, there is shown a third embodiment of the present invention illustrating the application of electromagnetic energy to a plant bio-system 46, such as a garden.

The plant based bio-system may include, for example, a grain plot 48, fruit or other trees 56, plants 58 and/or flowers 60. The plants may either be grown within the ground itself or within planting containers such as pots and the like. The system 46 may optionally also include a water reservoir 50, which is aerated by hose 52 and air pump 54 to increase the oxygen concentration of the water held within reservoir 50. Electromagnetic energy is generated by an electromagnetic energy generator 64 and applied to system 46 via electric wiring 62. Electric wiring 62 is position to cover at least a substantial portion of system 46, and is placed below the surface of system 46, at a depth of 1 to 30 inches. The plants affected by the application of the electromagnetic energy exhibit improved physiological effects such as improved and more rapid growth, and better overall health for example.

Shown in Fig. 4 is yet another embodiment of the present invention, illustrating applying electromagnetic energy to an athletic playing surface 68, such as, for example a basketball court, a football field, a soccer field, a swimming pool, playgrounds or other playing surfaces.

Electrical wiring 70 is placed below playing surface 68 at a preferred depth of between 1 and 30 inches. Electromagnetic energy generator 72 generates and conducts electromagnetic energy through electric wiring 70 to diffuse the electromagnetic energy throughout playing surface 68.

The electromagnetic energy is applied to those persons playing or competing on playing surface 68. Upon application of the electromagnetic energy, humans experience higher energy levels for longer periods of time, reduced fatigue, less muscle strain and soreness, in addition to increased concentration and precision in playing the particular sport.

Referring now to Fig. 5, there is shown yet another embodiment of the present invention, illustrating application of electromagnetic energy to a golf course hole. This embodiment includes a tee box 76, a green 92 and/or optionally a water reservoir 82. Below tee box 76 is placed electrical wiring 78, which is placed at a depth of 1 to 30 inches. Electrical wiring 94 is also placed below golf green 92 at a preferred depth of 1 to 30 inches. If water reservoir 82 is utilized, electrical wiring 88 is positioned below the bottom of reservoir 82 at a depth of 1 to 30 inches for emission of electromagnetic energy. Treated water from reservoir 82 may be used to water the golf course fairways, greens, or other plants associated with the course as to achieve the benefits as described above in relation to the plant based bio-system embodiment.

Electromagnetic energy generators 80,90 and 96 produce and emit electromagnetic energy through electrical wiring 78,88 and 94 respectively. Optionally, a single electromagnetic generator can control the emission of electromagnetic energy through electrical wiring 78,88 and 94. As with the above described embodiments, electromagnetic energy generators 80,90 and 96 emit electromagnetic energy having a magnetic field component in the range of 0.5 to 30 Gauss, and the frequency range of the pulses between 0.5 and 30 Hertz.

Effects seen through application of the electromagnetic energy to a grass surfaces such as soccer fields, play grounds, football fields, golf greens and tee boxes include more rapid and healthier growth of grass, faster regeneration or repair of divots and ball marks, fewer attacks to these grasses by pests as the grasses are healthier. The human players experience gentle invigoration, increased energy, greater concentration, and less muscle soreness or strain.

Increased mental activity and faster healing of wounds has also been noted.

Sporting equipment such as golf clubs are not affected by the application of electromagnetic energy because no sustained electrical current is conducted to the metal portions of the clubs.

In use with any of the above embodiments, the characteristics of the electromagnetic energy remain the same, that is electromagnetic energy having a magnetic field component in the range of 0.5 to 30 Gauss, and the frequency range of the pulses between 0.5 and 30 Hertz. The cycling/hertz of the electromagnetic energy is varied slowly during a 24 hour period. In application of pulsed electromagnetic energy to humans, the magnetic field strength is adjusted to be within 4 to 8 Gauss. The placement of the electrical wiring below the surface of the selected area is adjusted to accommodate these parameters. Further, it is important to note that the spacing of the electric wiring in the above described embodiments may be altered to achieve desired effects.

Although the principles, preferred embodiments and preferred operation of the present invention have been described in detail herein, this is not to be construed as being limited to the particular illustrative forms disclosed. They will thus become apparent to those skilled in the art that various modifications of the preferred embodiments herein can be made without departing from the spirit or scope of the invention as defined by the appended claims.

http://en.wikipedia.org/wiki/Carl_Baugh

Carl Baugh

Born Carl Edward Baugh
October 21, 1936 (age 77)
Kenedy, Texas, USA

Carl Edward Baugh (born October 21, 1936) is an American young earth creationist. Along with others, Baugh claims to have discovered human footprints alongside dinosaur footprints near the Paluxy River in Texas, but never provided evidence for his alleged findings.[1][2][3] Baugh is a national television host, purporting to present science supporting creationism on the program Creation in the 21st Century on the Trinity Broadcasting Network. His claims have been debunked by the scientific community and other creationists as pseudoscience.[4] His educational credentials have also been called into question.[5] He was also the president and a graduate of Pacific International University, an unaccredited university located in Springfield, Missouri.

Biography

Born in Kenedy, Texas, Baugh graduated in 1955 from Abilene High School in Abilene, Texas[citation needed]. He currently appears on Trinity Broadcasting Network program Creation in the 21st Century.[6] Baugh was also the president and a graduate of the Pacific International University, which was a non-accredited organisation.[7][8]

In 1984, Baugh started the Creation Evidence Museum in a double-wide trailer in Glen Rose, Texas, near Dinosaur Valley State Park, to promote creationism.[4] All of the museum exhibits have been strongly criticized as incorrectly identified dinosaur prints, other fossils, or outright forgeries.[9][10] In 2008, a descendant of a family that found many original Paluxy River dinosaur tracks in the 1930s claimed that her grandfather had faked many of them.[11] Others, such as purported dinosaur claws, were identified by University of Texas at Austin paleontologist Wann Langston as crocodile teeth.[12]

In 1996, Baugh presented his "man-tracks" in the controversial program The Mysterious Origins of Man.[13] Creationist Ken Ham, of Answers in Genesis, criticized the claims in a review titled "Hollywood's 'Moses' Undermines Genesis," regarding Baugh: "According to leading creationist researchers, this evidence is open to much debate and needs much more intensive research. One wonders how much of the information in the program can really be trusted!"[14] He also has been given television exposure by the tele-evangelist Kenneth Copeland. He has authored several self-published books[4] on such topics as the age of the universe, dinosaurs coexisting with humans and critiques of evolution.[15]

In 2001 Baugh and Creation Evidence Museum were featured on The Daily Show where Baugh likened human history to The Flintstones and the show poked fun at his claims about the hyperbaric biosphere, pterodactyl expeditions, and dinosaurs.[16]

He is a promoter of intelligent design. In 2002 he appeared with William A. Dembski at a conference in Texas and has built his more recent web material around ID and Dembski.[17]

The Accelerated Christian Education schools teach his theories as fact in some of their High School science workbooks.

Claims and criticism

Both scientists and creationists have criticized Baugh's claims. In 1982–1984, several scientists, including J.R. Cole, L.R. Godfrey, R.J. Hastings, and S.D. Schafersman, examined Baugh's purported "mantracks" as well as others provided by creationists in the Glen Rose Formation.[12] In the course of the examination "Baugh contradicted his own earlier reports of the locations of key discoveries" and many of the supposed prints "lacked human characteristics."[12] After a three-year investigation of the tracks and Baugh's specimens, the scientists concluded there was no evidence of any of Baugh's claims or any "dinosaur-man tracks".[12]

On September 27, 1984, Al West, a Baugh co-worker for two years, who followed the mantrack claims since 1974, and friend of Glen Kuban, publicly announced that Baugh "never had evidence for manprints as claimed.[12] Gayle Golden, writer for The Dallas Morning News, reported that Baugh "paid $10,000 for his Moab skeleton and confirmed that Baugh knew at their purchase that the bones had already been dated at 200-300 years. However Baugh later claimed that the bones were found in Cretaceous deposits."[12]

One of Baugh's more famous claims, aside from the dinosaur tracks, is an alleged out of place artifact of an "18th century miner's hammer" found in million-year-old Ordovician rock (he has also claimed it is in Cretaceous rock) found in 1934 from London, Texas.[18][19] Baugh asserted this as evidence against scientifically known ways that rocks form.[18] However, laboratory tests discounted his claim about the hammer's being formed in the rock.[18][19] J.R. Cole wrote, "The stone concretion is real, and it looks impressive to someone unfamiliar with geological processes. How could a modern artifact be stuck in Ordovician rock? The answer is that the concretion itself is not Ordovician. Minerals in solution can harden around an intrusive object dropped in a crack or simply left on the ground if the source rock (in this case, reportedly Ordovician) is chemically soluble."[20]

In July 2008, Baugh was in contact with Alvis Delk and James Bishop, who claimed to have found a dinosaur-human print fossil.[21] Baugh bought the "fossil" from Delk who used the money to pay his medical bills.[22] On the authenticity of the claims, reporter Bud Kennedy noted, "since no scientists were involved, about all we really know so far is that the museum has a new rock."[23] This was deemed "not a convincing human footprint in ancient rock" by biologist Glen J. Kuban and called a "blatant fake" by biologist PZ Myers.[24]

Creationist organizations such as Answers in Genesis have criticized Baugh's claims saying he "muddied the water for many Christians. . . . People are being misled."[4] Don Batten, of Creation Ministries International wrote: "Some Christians will try to use Baugh's 'evidences' in witnessing and get 'shot down' by someone who is scientifically literate. The ones witnessed to will thereafter be wary of all creation evidences and even more inclined to dismiss Christians as nut cases not worth listening to."[25] Answers in Genesis (AiG) lists the "Paluxy tracks" as arguments "we think creationists should NOT use" [emphasis in original].[26] Also Answers In Creation reviewed Baugh's museum and concluded "the main artifacts they claim show a young earth reveal that they are deceptions, and in many cases, not even clever ones."[27]

In his 1992 book Panorama of Creation, Baugh claims that a layer of metallic hydrogen surrounded the early earth. Furthermore, he professes that hexagonal water, or, "Creation water" as he calls it, is capable of healing. Such claims have been addressed by scientists as pseudoscience,[8] and his hypotheses and credentials are not accepted in academia.

Baugh has claimed several college degrees, at one point professing to earning three doctorates, when no evidence exists that he even graduated from high school.[28] All three "doctorates" are from unaccredited "schools." One is an honorary "Doctor of Philosophy in Theology" from the non-accredited California Graduate School of Theology. His claimed 1989 "doctorate" and masters degrees in Archaeology come from the non-accredited Pacific International University, of which Baugh was also the president.[28] His dissertation titled "Academic Justification for Voluntary Inclusion of Scientific Creation in Public Classroom Curricula, Supported by Evidence that Man and Dinosaurs Were Contemporary" was reviewed by Brett Vickers who criticized its "descriptions of his field-work on the Paluxy river 'man-tracks', speculation about Charles Darwin's religious beliefs and phobias, and biblical evidence of Adam's mental excellence."[29] In 2005, Baugh claimed to have completed yet another doctorate in theology from the unaccredited diploma mill known as Louisiana Baptist University.[30]

[57] **ABSTRACT**

The Cloaking System is designed to operate in the visible light spectrum, utilizes optoelectronics and/or photonic components to conceal an object within it, and employs analog or digital control feedback resulting in camouflage adaptable to a changing background. The system effectively conceals either a still or moving object from view by the interposing of a shield between an observer and the object and recreating a full color synthetic image of the background on the shield for viewing by observer, thus creating the illusion of transparency of both the object and the Cloaking System. This system consists of four major elements: a sensor; a signal processor; a shield; and a means of interconnecting, supporting, and safely enclosing the aforementioned elements along with the concealed object.

4. U.S. Pat. No. 4,962,420.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The need for this invention arises out of the present state of the art of military camouflage in the visible light spectrum. This invention is designed for the purpose of concealing both stationary and moving objects from view. The term "cloaking" as used in the title of this invention and elsewhere herein refers to concealing such objects.

2. Prior Art

The techniques in use today largely involve painting, coloring, and/or contour shaping to allow an object to better blend in with the background. Such techniques are rather primitive and do little to conceal a moving object as it is not possible with present fixed state camouflage techniques to cause an object to continually blend in with a changing background. In order to effectively camouflage a moving object, its appearance must be constantly controlled from the viewpoint of the observer to blend in with the changing background from the observer's perspective. Little has been done to utilize modern advancements in optoelectornics, computers, or microminiature components to camouflage an object. The proposed system was conceived with the view in mind of effectively concealing a stationary or moving object such as a man, vehicle, or aircraft from view by utilization of this technology. This invention will find practical application in military and law enforcement where field commanders find it useful to conceal such an object from view.

SUMMARY OF THE INVENTION

This system is designed to interrupt energy in the visible light electromagnetic spectrum to effectively conceal an object from view by an observer. This is accomplished by insertion of a shield between an observer and the object being concealed and recreating a full color synthetic real-time image of the background on the shield for view by an observer, thus creating the illusion of transparency of the object. The basic concept for the application consists of four basic building blocks: a sensor, a signal processor, and a shield which are interconnected through an analog, digital, of fiber optic data bus, and a supporting structure for all system elements, the object being concealed being interposed between the background and the shield.

The signal processor formats the image of the background as viewed by the sensor and presents a synthetic image of the background on the shield for view by an observer. The object is placed behind or within the shield which is of opaque construction, and having a nonspecular display surface thus concealing the object from view by the observer and yet creating an illusion of transparency of the complete Cloaking System and the enclosed object. In its nonactivated state, the shield would have minimum light reflectivity. Although either an analog signal processor or digital signal processor may be used, the latter is described herein as one specific embodiment. The digital signal processor constantly compares the synthetic image in the shield with the reference image within the sensor and makes corrections to the synthetic image to correspond with the actual image being sensed. Data on the data bus blows in both directions. Special software or embedded firmware will also be utilized in the signal processor to make changes in the image presented on the shield to correct for distance and angle of the observer with respect to the object being concealed; the source of intelligence information pertaining to an observer is beyond the scope of this invention but is mentioned here only for clarification.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. **1** is a pictorial representation of the invention and is intended to illustrate the basic concept of the invention;

FIG. **2** is a pictorial isometric view of the system block diagram implementing the basic concept;

FIG. **3** is a pictorial perspective view of the invention and illustrates how an object can be concealed within a 360° shield;

FIG. **4** is a perspective view of the invention and illustrates how an object can be concealed within a sphere; and

FIG. **5** is an orthographic view that illustrates a simple concept demonstration model.

DESCRIPTION OF ONE EMBODIMENT OF THE INVENTION

The basic concept of the Cloaking System **10** is illustrated in FIG. **1** wherein the background **14** is displayed on the shield **24** as a synthetic image **26** on its nonspecular display surface, when viewed from the front. FIG. **2** illustrates how the basic concept is implemented. The digital signal processor **12** is the brain and controls all operations, digitally formats the image of the background **14** as viewed by the sensor **16**, establishes a reference image matrix **18** within the sensor **16**, and transmits the background image signal via the data bus **20** to a synthetic image matrix **22** within the shield **24**, thus causing a synthetic image **26** to be displayed on the surface of the shield **24** as seen from the direction of observation **28**. The object **30** to be concealed is placed behind the shield **24** to prevent its being observed. The digital signal processor **12** constantly compares the synthetic image matrix **22** with the reference image matrix **18** and makes corrections to the synthetic image matrix **22** which in turn corrects the synthetic image **26** to correspond with the actual background image **14** being sensed, thus minimizing distortion and maintaining realism of the synthetic image **26**. Data on the data bus **20** flows in both directions. The primary purpose of the system is to present on the shield **24** a near identical image of the background behind said object **30** so as to create the illusion of transparency of both said object **30** and the Cloaking System **10**; a secondary purpose of the system is to alter the synthetic image **26** to create an illusion of a background that does not exist; while such a deceptive method goes beyond the scope of simply creating an illusion of transparency of the object it would be very useful for special missions or difficult scenario conditions where it would be more effective to depict an artificial background than to display a representation of the actual background. Any such alterations in the synthetic image **26** would be accomplished by software or embedded firmware and is considered part of the tactical strategy to be employed, thus emphasizing the flexibility of the invention and its potential interaction with the operating environment.

The basic concept or cell unit depicted in the preceding FIG. **2** may be expanded to combine as many cells as desired to provide 360° coverage. Referring to FIG. **3**, a cylindrical shield **24***a* is illustrated with a cutaway view showing object **30** along with the digital signal processor **12**, data bus **20**, and sensors **16**, all supported by a suitable attachment means **32**. The digital signal processor **12** organizes and presents a different synthetic image **26** on the appropriate sector of the shield **24***a* utilizing signals from appropriate sensors **16**, together with tactical data concerning potential points of observation. The appropriate size and number of sectors would be determined by the optimal design for a given operational mission. Although shown here as separate components for clarity, the present state-of-the-art would allow incorporation of the an embedded circuitry digital signal processor **12** and sensors **16** into the shield **24***a* to provide a cylindrical smart skin to wrap around the object. The shield may also incorporate backplanes for mounting embedded sensors, processors and bus circuitry.

Carrying the basic concept a step further, the shield **24***b* may be formed into a spherical shape as illustrated in FIG. **4**. A cutaway view is again presented showing object **30**, sensors **16**, digital signal processor **12**, data bus **20**, and a spherically shaped shield **24***b*. As with the cylindrical shape, the digital signal processor **12** organizes and presents a different synthetic image **26** on the appropriate sector of the shield **24***b* utilizing both tactical data and signals from appropriate sensors **16**. In this configuration there would be considerably more sectors, as compared with the cylindrical shape, and the programming would be more complex to provide a high degree of realism in the image.

Irregular shapes for the shield may also be employed utilizing conformal smart skins which would be thin digital signal processor circuits embedded within the shield display surface. However, in order to reduce distortion of the image, either a circular, cyclindrical, or spherical shape would allow uniform algorithms to be employed in the embedded processor programs in the digital signal processor **12** to correct for circular or spherical aberration. Some distortion may appear as ripples or waves in the image, depending upon the shape of the shield, relative position and motion of the observer, and complexity of background images. However, in the algorithms could be developed, such as those required for irregular or conformal shields for military vehicles, to minimize such distortion.

ALTERNATE TECHNOLOGIES AND EMBODIMENTS

Several alternate technologies and methods of implementing this invention may be utilized.

One alternate technology employs the simplest method of implementing the Cloaking System concept which would utilize a conventional analog signal processor, a specially designed liquid crystal display to present the background image on the shield, and a conventional video camera for the sensor. Since this method utilizes conventional analog technology, this method is limited to flat plane or semicircular displays and would not lend itself to image correction as could be achieved by the digital options. However, this method would allow the construction of a prototype model within a year or two to demonstrate the basic cloaking concept.

Another alternate technology employs a digital option; the main differences between this method and the first-described analog method consists of the conversion of all analog video signals to digital signals, the usage of a digital signal processor to direct all operations, and higher technology used in constructing the shield and the sensor. Because of the high flexibility of the digital method, a great variety of shapes could be used for the shield and various compensation software or embedded firmware schemes could be employed to minimize distortion in the image; hence the digital method was selected and described in the preceeding section in considerable detail as one embodiment of the invention.

In still another method, photonic materials could be used for constructing the shield and sensor which would be capable of directly manipulating light signals and transmitting these signals on a higher speed fiber optic data bus. These light signals could be then digitized and further manipulated by a digital signal processor to perform necessary system functions but without the encumbrance of the slower speed of a digital data bus. The selection of either optoelectronic or photonic building blocks for the shield, sensor, and data bus would depend upon such factors as size and shape of the object to be shielded, speed of the object relative to the background, and environment. Usage of either optoelectronic or photonic materials in extremes such as that encountered in combat would require extensive testing and development. However, for more benign applications, a state-of-the-art system could be developed within three to five years utilizing currently available materials and components.

Any one of several available commercial or military digital process and bus architectures could be used depending upon the application and program requirements. IBM-PC integrated circuits and bus standards such as RS-232 (Serial), RS-422 (Parallel), or IEEE 488 (Parallel could be used for lower cost and benign environments. In more rigorous combat environments Very High Speed Integrated Circuit (VHSIC) architecture and Military standards such as MIL-STD-1553, MIL-STD-1750, or MIL-STD-1760 could be used for complex interfaces between men and machines. Sophisticated and advanced models using fiber optic technology and a high speed data bus would have advantages in terms of small size and conformal shape adaption of the shield.

CONCEPT DEMONSTRATION MODEL

A simple Concept Demonstration Model could be constructed utilizing any of the above-described technologies and methods. This model is shown in FIG. **5**; the object **30**, such as a vehicle, is shown in a top view with a semicircular shield **24***c* secured by an attachment means **32**, such as supporting struts. Sensors **16** view the wall **38** and the analog signals are subsequently displayed on the shield **24***c* facing the point of observation **28** behind line **36** which is fifty feet from the vehicle **30**. The vehicle **30** is moving to the left as shown by the arrow **34**. When the system is operating properly, the vehicle **30** would never be observed; only the wall **38** behind said vehicle **30** would be seen. For simplicity and to establish a reference, the wall **38** would probably be initially monochromatic and color patterns added later to present more difficult scenarios and to measure system limitations.

I claim:

1. A system for concealing an object from view by an observer through use of a background scene and comprising:

means for sensing a background scene and for generating a video image signal therefrom;

means for creating a processed image of said background video image signal for display purposes; and

means for displaying an image represented by said processed image signal, the generated image being part of the sensed field of view, the object located between the means for sensing and the means for displaying, the object thereby being substantially camouflaged by the image displayed.

2. A concealing system according to claim **1** wherein said background scene sensing means comprises means for converting background light images electrical analog image signals for processing by an analog signal processor.

3. A concealing system according to claim **1** wherein said background scene sensing means for converting background light images to electrical digital image signals for processing by a digital signal processor comprises;

means for responding to digital commands from a digital signal processor;

means for storing digital image signals in a reference background image matrix array within the sensor upon command by the digital signal processor; and

means for providing digital information from said array upon said command from said digital signal processor.

4. A concealing system according to claim **1** wherein said sensing means for sensing a background scene produces fiberoptic image signals for said processed image.

5. A concealing system according to claim **1** wherein a processing subsystem, including said background sensing means, has the means for processing digital image signals for the purpose of presentation to a shield subsystem comprising:

means for formatting digital image signals from said sensing means;

means for receiving and commanding said sensing means to store digital image signals in a reference background image matrix therein;

means to receive and transmit digital image signals from the reference background image matrix to a synthetic image matrix within a shield subsystem;

means to compare the digital information stored in the reference background image matrix in the sensor with that stored in the synthetic image matrix;

means coupled to said means to compare digital information for correcting or altering the image displayed on the shield subsystem by providing commands to the shield subsystem;

means for converting analog video signals from said correcting means to digital image signals;

means for converting created optical image signals to digital image signals;

means for formatting digital image signals from said optical image creating means into a form suitable for presentation to the shield subsystem; and means for receiving and commanding the display at information stored in the synthetic image matrix.

6. A shield for concealing an object from view of an observer comprising:

means for providing a light absorbing opaque and nonspecular display surface which, in its nonactivated state, has minimum light reflectivity;

means for receiving and commanding the display of information from an analog signal processor;

means for providing in said display's activated state the display of a near-identical full color image of the background or other scene for view on the shield surface facing an observer as directed by said analog signal processor, said shield including means to obstruct visual sight of an adjacent concealed object;

means associated with said object for support thereof; and

means to support said analog processor, at least one sensor, and circuitry therefor.

7. A shield for concealing an object from view comprising:

means for providing a light absorbing opaque and nonspecular display surface that, in its nonactivated state, has minimum light reflectivity;

means for obstructing visual sight of an object in said shield, concealed adjacent thereto from view;

means for receiving and commanding the display of information from a digital signal processor;

means for providing in its activated state the display of a near-identical full-color image of a screen for view on the shield surface being viewed as directed by said digital signal processor;

means for storing digital image signals in an array within a synthetic image matrix;

means for display of said digital image signals in the form a full-color image of the background as stored in said synthetic image matrix, said full-color image to be presented on said surface being viewed;

means associated with said object for support thereof; and

means to support said digital signal processor and at least one sensor in association with said shield including backplanes for mounting embedded components, embedded sensors, and embedded data busses.

8. A shield according to claim **7** wherein said shield is constructed from fiberoptic materials and has means for responding to commands from said digital signal processor.

9. A shield according to claim **7** including an integral support structure for said shield, said signal processor, and an object to be concealed, said shield including backplanes for mounting embedded components, embedded sensors, and embedded data buses.

10. A shield according to claim **8** including an integral support structure for said sensor, said signal processor, and an object to be concealed, said shield including backplanes for mounting embedded components, embedded sensors, and embedded data buses.

(57) ABSTRACT

A linear metamaterial comprises a transmission line, having a linear dimension, and is loaded with capacitors, and shunted with an inductor such that for an electromagnetic wave, having a wavelength greater than the linear dimension and traveling along the axis of the transmission line, the effective permeability and permittivity of the metamaterial are simultaneously negative. Applications for the metamaterial are also disclosed.

METAMATERIALS FOR CONTROLLING AND GUIDING ELECTROMAGNETIC RADIATION AND APPLICATIONS THEREFOR

CROSS-REFERENCE TO RELATED APPLICATIONS

The present application claims the benefit of U.S. Provisional Patent Application No. 60/384,080 filed on May 31, 2002, which is hereby incorporated by reference herein.

FIELD OF THE INVENTION

The present invention relates generally to the control and guidance of electromagnetic radiation and in particular to a left-handed metamaterial for controlling and guiding electromagnetic radiation and to applications therefor.

BACKGROUND OF THE INVENTION

The concept of a negative index of refraction, originally proposed by Veselago in the 1960s, suggested the possibility of materials in which the permittivity and permeability could be made simultaneously negative. Veselago termed these left-handed media (LHM), because the vectors E, H, and k would form a left-handed triplet instead of a right-handed triplet, as is the case in conventional, right-handed media (RHM). In such a material the phase velocity and Poynting vector are antiparallel. Recently, novel 3-dimensional (3-D) electromagnetic materials have successfully demonstrated negative refraction by synthesizing a negative refractive index. These artificial dielectrics (metamaterials) consist of loosely coupled unit cells composed of thin wire strips and split-ring resonators to synthesize negative permittivity and permeability, respectively. In these metamaterials, the choice of operating frequency is restricted to the region of the resonance, which results in a highly dispersive, narrow and behaviour with strong associated absorption losses.

Other structures with magnetic properties to refract electromagnetic radiation at negative angles have also been considered. For example, International PCT Application No. WO 00/41270 discloses a structure that exhibits magnetic properties when it receives incident electromagnetic radiation. The structure is formed from an array of capacitive elements, each of which is smaller, and preferably much smaller, than the wavelength of the incident electromagnetic radiation. Each capacitive element has a low-resistance conducting path associated with it and is such that a magnetic component of the incident electromagnetic radiation induces an electrical current to flow around a path and through the associated capacitive element. The creation of the internal magnetic fields generated by the flow of the induced electrical current gives rise to the structure's magnetic properties.

International PCT Application No. WO 02/03500 discloses a microstructured magnetic material having a magnetic permeability of negative value but unity magnitude over a particular radio frequency range.

Although the above references disclose structures with magnetic properties to refract electromagnetic radiation at negative angles, improved materials exhibiting negative refractive indices are desired.

It is therefore an object of the present invention to provide a novel left-handed metamaterial for controlling and guiding electromagnetic radiation and novel applications therefor.

SUMMARY OF THE INVENTION

According to one aspect of the present invention there is provided a planar metamaterial comprising:

two substantially orthogonal, coplanar sets of transmission lines, said transmission lines being spaced with a periodicity, loaded with capacitors with said periodicity, and shunted with inductors with said periodicity such that for an electromagnetic wave, having a wavelength greater than said periodicity and traveling along the plane of said transmission lines, the effective permeability and permittivity of said metamaterial are simultaneously negative.

According to another aspect of the present invention there is provided a linear metamaterial comprising:

a transmission line, having a linear dimension, and being loaded with capacitors, and shunted with an inductor such that for an electromagnetic wave, having a wavelength greater than said linear dimension and traveling along the axis of said transmission line, the effective permeability and permittivity of said metamaterial are simultaneously negative.

According to yet another aspect of the present invention there is provided a planar resonance cone metamaterial comprising:

a first set of transmission lines, spaced with a periodicity, and loaded with capacitors with said periodicity;

a second set of transmission lines, substantially orthogonal and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said periodicity, and loaded with inductors with said periodicity, said first and second sets of transmission lines exhibiting characteristics such that for an electromagnetic wave, having a wavelength greater than said periodicity by an order of magnitude, and traveling along the linear axis of said first set of transmission lines, the effective permittivity of said metamaterial is positive such that for an electromagnetic wave, having a wavelength greater than said periodicity by an order of magnitude and traveling along the linear axis of said second set of transmission lines, the effective permittivity of said metamaterial is negative.

According to yet another aspect of the present invention there is provided a planar resonance cone metamaterial comprising:

a first set of transmission lines, spaced with a first periodicity, and loaded with capacitors with a second periodicity;

a second set of transmission lines, substantially orthogonal and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said second periodicity, and being loaded with inductors with said first periodicity whereby for an electromagnetic wave, having a wavelength greater than said first and second periodicities by an order of magnitude and traveling along the longitudinal axis of said first set of transmission lines, the effective permittivity of said metamaterial is positive and for an electromagnetic wave having a wavelength greater than said first and second priodocities and traveling along the longitudinal axis of said second set of transmission lines, the effective permittivity of said metamaterial is negative.

According to yet another aspect of the present invention there is provided a near field focusing device comprising:

a first set of transmission lines, said first set of transmission lines being spaced with a first periodicity and loaded with capacitors with a second periodicity;

a second set of transmission lines, substantially orthogonal to, and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said second periodicity, loaded with capacitors with said first periodicity, and shunted with inductors, said first set of transmission lines intersecting said second set of transmission lines such that for an electromagnetic wave, having a wavelength greater than said first or second periodicity by an order of magnitude, and traveling along the plane of said transmission lines, the effective permeability and permittivity of said metamaterial are simultaneously negative; and

a planar waveguide, having a flat extent, coupled to said transmission lines, such that said flat extent is parallel to one set of transmission lines.

According to yet another aspect of the present invention there is provided a phase-shifting device comprising:

a transmission line, having a linear dimension and characteristic impedance;

capacitors loaded on said transmission line; and

an inductor shunting said transmission line, said transmission line exhibiting characteristics such that for an electromagnetic wave, having a wavelength greater than said linear dimension by an order of magnitude and traveling along the axis of said transmission line, the effective permeability and permittivity of transmission are simultaneously negative and such that said transmission line provides a continuous passband for said electromagnetic wave along said transmission line.

According to yet another aspect of the present invention there is provided a near field focussing device comprising:

a parallel-plate waveguide; and

a negative refractive index metamaterial in line with said waveguide and forming an interface therewith.

According to yet another aspect of the present invention there is provided a coupled-line coupler comprising:

a microstrip line; and

a left-handed material coupled to an edge of said microstrip line.

The present invention provides advantages in that the metamaterial is capable of internal positive and negative wave refraction, and guided wave beam formation, steering, and focusing over regions that are smaller than the wavelength of incident electromagnetic radiation. Moreover, the beam steering capability can be extended beyond the physical boundaries of the metamaterial into the surrounding space to produce a controllable radiation pattern.

BRIEF DESCRIPTION OF THE DRAWINGS

Embodiments of the present invention will now be described more fully with reference to the accompanying drawings in which:

FIG. **1** shows phase matching at an interface between a right-handed material (RHM) and a generic material i.e. a right-handed material or a left-handed material;

FIG. **2** is a two-dimensional (2-D) loaded left-handed transmission line unit cell;

FIG. **3** shows a plane wave illuminating a RHM/LHM interface at 2 GHz;

FIG. **4** illustrates the focusing effect at an interface between right-handed and left-handed media;

FIG. **5** shows a point source illuminating a RHM/RHM interface at 2 GHz;

FIG. **6** shows a point source illuminating a RHM/LHM interface at 2 GHz;

FIG. **7** shows a focusing device including a negative refractive index metamaterial interfaced with a parallel-plate waveguide at 1.5 GHz;

FIG. **8** shows experimental data demonstrating focal regions observed in the focusing device of FIG. **7** at 1.55 GHz and 1.65 GHz and the lack thereof at 2.55 GHz when operating beyond the left-handed frequency band;

FIG. **9** shows a planar resonance cone metamaterial including a square-celled transmission-line network containing inductors and capacitors oriented orthogonally and positioned over a ground plane;

FIG. **10** shows one side of the square-celled transmission-line network of FIG. **9** illustrating attached coaxial connectors;

FIG. **11** shows an opposite side of the square-celled transmission-line network of FIG. **9**, with chip capacitors and meander-line inductors in place.

FIG. **12** shows single-stage, 2-stage, 4-stage and 8-stage 0° phase-shifting circuits;

FIG. **13** is a schematic diagram of a 1-D phase-shifting unit cell;

FIG. **14** shows an unmatched dispersion relation for the phase-shifting unit cell of FIG. **13**;

FIG. **15** shows a matched dispersion relation for the phase-shifting unit cell of FIG. **13**;

FIG. **16** shows phase responses of a +10° phase-shifting device, a −350° transmission line, a −10° phase-shifting device and +10° L-C line;

FIG. **17** shows phase responses of one-stage, 4-stage and 8-stage 0° phase-shifting devices;

FIG. **18** shows phase and magnitude responses of +10° and −10° 4-stage phase-shifting devices;

FIG. **19** shows a 4-stage +10° phase-shifting device;

FIG. **20** is a plasma parameter diagram showing elliptic and hyperbolic regions;

FIG. **21** is a schematic diagram of a focusing device in the form of a uniform anisotropic planar L-C grid over ground, with corner feed and resistive edge-loading;

FIG. **22** shows a uniform-grid moment-method simulation displaying corner-fed resonance cones at eight frequencies;

FIG. **23** shows node voltage across 50Ω terminating resistors at numbered points around the edge of the grid of FIG. **21**, derived from the simulation data displayed in FIG. **22**;

FIG. **24** shows a focusing device in the form of a non-uniform L-C grid, wherein the inductors and capacitors have been transposed in the upper part of the grid and wherein the transition region includes a row of elongated cells;

FIG. **25** shows the physical layout of the grid of FIG. **24**;

FIG. **26** shows resonance cone refraction at 1.2 GHz;

FIG. **27** shows a focusing simulation at 1.3 GHz showing the grid-to-ground voltage magnitude;

FIG. **28** shows focusing measurements at 1.3 GHz showing the normalized **S21** magnitude;

FIG. **29** shows a focusing simulation at 1.7 GHz showing the grid-to-ground voltage magnitude;

FIG. **30** shows focusing measurements at 1.7 GHz showing the normalized **S21** magnitude;

FIG. **31** shows a MS/LHM coupled-line coupler and schematic of a coupler unit cell;

FIG. **32** shows a dispersion diagram for MS and LHM lines used in the coupler of FIG. **31** and photograph of a MS/LHM coupler and a conventional MS/MS coupler of the same length, line spacing and propagation constant;

FIG. **33** shows a spatial Fourier transform of line voltages on the MS line and LHM line of the MS/LHM coupled-line coupler of FIG. **31**;

FIG. **34** shows the coherence length of the MS/LHM coupled-line coupler of FIG. **31**;

FIG. **35** shows a comparison of a MS/MS coupler with a MS/LHM coupler of the same length, line spacing and propagation constant for coupled power, isolation, reflection, and arbitrary coupling;

FIG. **36** shows MS/LHM branch-line couplers;

FIG. **37** shows even/odd mode equivalent circuits of a type **1** MS/LHM branch-line coupler;

FIGS. **38***a* to **38***d* show scattering parameters of type **1** MS/LHM branch-line couplers compared to a regular branch-line coupler and scattering parameters of a type **2** MS/LHM branch-line coupler;

FIG. **39** shows a planar transmission-line left-handed lens;

FIG. **40** shows the measured vertical electric field detected 0.8 mm above the surface of the lens of FIG. **39** at 1.057 GHz;

FIG. **41** shows the measured vertical electric field above row 0 of the lens of FIG. **39** at 1.057 GHz;

FIG. **42** shows the measured vertical electric field at the source (dashed curve) and image (solid curve) planes along with the diffraction-limited image (solid curve with circles);

FIG. **43** shows an antenna formed of 6 macrocells of resonance cone metamaterial; and

FIGS. **44** and **45** show the grid-to-ground voltage of a six cell antenna operating at 1 GH_z and the resulting radiation pattern.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

The present invention relates generally to a metamaterial that supports propagating backward waves and thus exhibits left-handedness. Such metamaterials inherently support 2-D wave propagation, which is desirable for antennas, antenna beam formers, planar spectrum analyzers, compact RF/microwave lenses and antennas, phase compensators, antenna-integrated multiplexers and other microwave circuit applications.

To illustrate the concept of negative refraction, consider a phase-matching argument at the interface between a right-handed medium **M1** and another generic medium **M2**, as shown in FIG. **1**. The sign of the index of refraction of medium **M2** is not a concern. Consider an incident plane wave in medium **M1** with a wave vector k_1 (i.e. such that the x-component of k_1 is positive). A refracted wave with a wave vector k_2 is then established in medium **M2** such that the tangential wave vector components k_{1t} and k_{2t} are equal across the interface. This is the basis for Snell's Law, and it permits two scenarios for the orientation of k_2, represented as Case **1** and Case **2** in FIG. **1**. The conservation of energy also insists that the normal components of the Poynting vectors S_1 and S_2 remain in the positive-x direction through both media. If the medium **M2** is a conventional RHM, then refraction occurs as illustrated by Case **1**. However, if medium **M2** is a medium supporting propagating backward waves (i.e. a LHM), it is implied that power is propagated along the direction of phase advance, which requires in FIG. **1** that k_2 and S_2 be antiparallel. Consequently, the direction of k_2 is specified uniquely for backward-wave structures as illustrated by Case **2**. Under such conditions, power is refracted through an effectively negative angle, which implies a negative index of refraction.

Metamaterials exhibiting negative indices of refractions and applications therefor that enable electromagnetic radiation to be controlled and guided will now be described.

Planar Metamaterials

Turning now to FIG. **2**, a shunt-centered unit cell for a metamaterial or left-handed medium (LHM) that synthezises a negative refractive index is shown. In this particular example, the metamaterial is in the form of a two-dimensional (2-D), L-C loaded substantially orthogonal, coplanar transmission line network. In the unit cell, $Z_C=(j\omega C)^{-1}$ and $Y_L=(j\omega L)^{-1}$ represent the per-unit-length capacitor impedance and inductor admittance, respectively.

The unit cell dimensionality represented by Δd is provided by the host transmission line medium. At the continuous medium limit, Δd<<λ, the 2-D telegrapher's equations representing the structure of the unit cell can be expressed as:

$$\frac{\partial v_y}{\partial z} = -i_z\left(\frac{1}{j\omega C\Delta d}\right), \frac{\partial v_y}{\partial x} = -i_x\left(\frac{1}{j\omega C\Delta d}\right) \tag{1}$$

and

$$\frac{\partial i_z}{\partial z} + \frac{\partial i_x}{\partial z} = -v_y\left(\frac{1}{j\omega L\Delta d}\right). \tag{2}$$

Combining equations (1) and (2) yields:

$$\frac{\partial^2 v_y}{\partial x^2} + \frac{\partial^2 v_y}{\partial z^2} + \beta^2 v_y = 0, \quad \beta = -\frac{1}{\omega\sqrt{LC}\,\Delta d} \tag{3}$$

where β is the propagation constant. The phase and group velocities are antiparallel and are given by:

$$v_\phi = \frac{\omega}{\beta} = -\omega^2\sqrt{LC}\,\Delta d, \; v_g = \left(\frac{\partial\beta}{\partial\omega}\right)^{-1} = +\omega^2\sqrt{LC}\,\Delta d. \tag{4}$$

Subsequently, a negative refractive index can be defined as:

$$n = \frac{c}{v_\phi} = -\frac{1}{\omega^2\sqrt{LC}\sqrt{\mu_0\varepsilon_0}\,\Delta d}. \tag{5}$$

It is interesting to note that it is possible to achieve the same result for the phase velocity and index of refraction if an equivalent negative permittivity and permeability are defined as:

$$\mu_{eq} = -\frac{1}{\omega^2 C\Delta d}, \; \varepsilon_{eq} = -\frac{1}{\omega^2 L\Delta d}, \tag{6}$$

so that the total stored time-averaged energy, expressed by:

$$W = \frac{\partial(\mu_{eq}\omega)}{\partial\omega}|E|^2 + \frac{\partial(\varepsilon_{eq}\omega)}{\partial\omega}|H|^2, \tag{7}$$

remains positive.

In order to model the 2-D wave equation represented by equation (3), metamaterial including an array of unit cells, each as depicted in FIG. **2**, was implemented in a microwave-circuit simulator simulator. To simulate the incidence of waves on this LHM in a circuit environment, a right-handed medium (RHM) was also designed. The topology of the unit cells in the RHM were identical to those of FIG. **2**, except that the roles of C and L were interchanged, giving rise to the well-known LC low-pass network representation of free-space propagation.

The specification of the unit cell parameters in both media provides information about the permissible operating frequencies, the relative refractive indices, and also the required inductance and capacitance values. In both media, the wave impedance is given by:

$$Z_M = \sqrt{\frac{L}{C}}. \tag{8}$$

It is therefore reasonable to begin with the simple constraint that the two media be matched, and moreover, matched to free space (Z_M=377Ω).

In the limit Δd<<λ in equation (5), it is not possible to specify directly indices of refraction in the individual media, but it is possible to specify a relative index of refraction through the ratio of their respective phase shifts per unit cell $\beta_{LHM}\Delta d/\beta_{RHM}\Delta d$. The LHM was designed to be denser than the RHM, arbitrarily by a factor of 2. Specifically, phase shifts per unit cell of $|\beta_{RHM}\Delta d|=0.25$ and $|\beta_{LHM}\Delta d|=0.5$ were chosen in the right-handed and left-handed media, respectively. Choosing an operating frequency of 2 GHz, the LHM and RHM unit cell capacitive and inductive elements were specified as (C_{LHM}=422.5 fF, L_{LHM}=60.0 nH) and (C_{RHM}=52.8 fF, L_{RHM}=7.5 nH), respectively. The corresponding cut-off frequencies are given by:

$$f_{c,LHM} = \frac{1}{4\pi\sqrt{L_{LHM}C_{LHM}}},\ f_{c,RHM} = \frac{1}{\pi\sqrt{L_{RHM}C_{RHM}}}, \tag{9}$$

which were found to be 500 MHz and 16 GHz, respectively. Finally, the designed LHM and RHM arrays were appropriately terminated with matching resistors on all edges and simulated with a microwave-circuit simulator.

To verify the ray picture presented in the phase-matching argument of FIG. **1**, a RHM/LHM interface was constructed using 42×42 RHM and LHM unit cell arrays with $\beta_{RHM}\Delta d=+0.25$ and $\beta_{LHM}\Delta d=-0.5$, yielding a relative refractive index of −2. The RHM unit cell array was excited with a plane wave, which was simulated using sequentially phase-shifted voltage sources along the left boundary of the unit cell array. FIG. **3** illustrates the plane wave illuminating the RHM/LHM interface at 2 GH$_z$ for an incident angle of θ_{RHM}=29° with the axes being labelled according to unit cell number and the right vertical scale designating radians. The steepest phase descent in the LHM is observed along the direction of propagation, which is θ_{LHM}=−14° from the normal, in exact correspondence with Snell's Law for the given design parameters.

Turning now to FIG. **4**, it can be seen that a RHM/LHM planar interface **410** can also be used to focus electromagnetic waves from a point source located inside the RHM, within the LHM. These conditions can be modelled by exciting a single node **400** inside the RHM and observing the magnitude and phase of the voltages to ground at all points in the LHM. The focusing effect manifests itself as a "spot" distribution of voltage **420** at a predictable location in the LHM.

An alternative embodiment of an RHM/LHM interface used to generate the results of FIG. **3** will now be examined. In this embodiment finite length transmission line sections (k, Z_0, finite Δd) are inserted in each LC unit cell. In order that the host transmission-line medium does not significantly alter the propagation constant predicted by equation (5), it is necessary to modify the loading elements C_{LHM} and L_{LHM} to compensate for the presence of the distributed transmission line parameters. In the final design, the lines in each unit cell are designed to be air-filled, with Δd=5 mm. From equation (5), and using the appropriately compensated loading element values, the corresponding equivalent, absolute index of refraction of the LHM is approximately equal to −2.4. To maintain the relative refractive index of −2, the absolute index of refraction of the RHM is made to be +1.2.

In the interest of completeness, cases of both positive and negative refraction are examined, with the host transmission line medium in place. In the first case, a 42×21 RHM unit cell array is interfaced with another 42×63 RHM unit cell array with a relative refractive index of +2. The plane wave source is placed 11 unit cells into the first RHM. Here, focusing is not expected since Snell's Law for positive-index media predicts a continued divergence into the second RHM. FIG. **5** shows a point source illuminating the RHM/LHM interface at 2 GH$_Z$ as well as the corresponding magnitude and phase plots of these results with the axes labelled according to cell number. As can be seen, the results confirm that the cylindrical wave excitation diverges into the second medium.

In the second case, a RHM unit cell array is interfaced with a LHM unit cell array with a relative refractive index of −2. The unit cell array dimensions and source location are as specified above. This arrangement is expected to show focusing inside the LHM, in accordance with FIG. **4**. The paraxial limit dictates a focus in the LHM at twice the distance of the source from the interface, or near unit cell **44** of the array. FIG. **6** shows the point source illuminating the RHM/LHM interface at 2 GH$_Z$, as well as the corresponding magnitude and phase results with the axes labelled according to cell number. As can be seen, the results show focusing in the LHM, manifested in increased voltage amplitudes (nearly 65% of the source amplitude), and also in the reversal of the concavity of the wavefronts at both the RHM/LHM boundary and the expected focal point.

For applications in which waves are propagated only in a single dimension e.g. phase-shifting lines as will be described, the metamaterial above may be simplified to a 1-D array using a single transmission line i.e. a linear LHM metamaterial is a simplified case of the planar metamaterial.

Since the metamaterial exhibits left-handedness and allows electromagnetic radiation to be guided and controlled, the metamaterial is useful in a number of applications. Examples of applications for the present metamaterial will now be described.

Near-Field Focusing Device

Turning now to FIG. **7**, a focusing device is shown that includes a 55 mm×50 mm parallel-plate waveguide serving as a RHM interfaced with a negative refractive index metamaterial including an 11×6 unit cell array around 1.5 GHz. Each unit cell has a dimension of 5 mm. The fabricated 11×6 unit cell areas includes 400 μm wide microstrip lines on a 60 mil Rexolite® dielectric ($\in_r$=2.53) substrate. Shunt chip inductors are embedded into 1 mm holes drilled into the substrate at the appropriate unit cell sites. Chip capacitors are surface-mounted between gaps etched into the grid lines, and additional capacitors are placed at the array edges to maintain unit cell uniformity throughout. The two media meet along a flat border, defining their respective extents. The LHM extent is parallel to and displaced from the nearest microstrip line. The parallel-plate waveguide is excited with a shorted vertical probe connected to a SMA connector. Matching chip resistors of 100Ω are used to terminate the unit cells at the LHM and parallel-plate waveguide boundaries. The focusing device as shown measures approximately 60 mm×95 mm×1.5 mm.

FIG. **8** shows a sample of measured vertical E-field distributions over the 11×6 LHM unit cell array at 1.55 GHz, 1.65 GHz, and 2.55 GHz. The first two frequencies lie in the

LH passband, whereas the last frequency occurs in a second (RH) passband. In accordance with theory, the field distributions at 1.55 GHz and 1.65 GHz exhibit focusing, manifested by a localized region of increased transmission through the focusing device. The maximum focal amplitude obtained was observed at a frequency of 1.65 GHz (the central plot of FIG. **8**), where the distinction between the peak and the two edges of the spot was noted to be approximately 15 dB. Furthermore, the concavities of the wavefronts of FIG. **8** also indicate the convergent progression of phase associated with focusing. As expected, neither phenomenon is evident at 2.55 GHz, since the second passband does not possess left-handed properties. As will be appreciated, the results demonstrate focusing of an incident cylindrical wave over an electrically short area, i.e. near-field focusing.

Planar Resonance Cone Metamaterial

Turning now to FIGS. **9** to **11**, a planar resonance cone metamaterial is illustrated. In this embodiment, the metamaterial includes a substantially orthogonal, coplanar, periodic square-celled transmission line network that is analogous to a sheet of uniaxial plasma with permittivities of opposite signs in two orthogonal, in-plane directions. As can be seen, the transmission line network is disposed over a ground plate and parallel to it. Electromagnetic radiation is fed to the transmission line network at one corner with respect to the ground plate. The transmission line network is connected to instruments through coaxial connectors as shown in FIG. **10** and includes chip capacitors and meander-line inductors as shown in FIG. **11**. Resonance cone angle scans with frequency and with peak frequencies detected at the midpoints of the transmission line network sides, yielded an end-to-end frequency ratio of 2:1 with a transmission line network of only 4 cells by 4 cells. A center frequency of 1.4 GHz was used. The commercial chip capacitive and inductive elements used to construct the transmission line network yielded a compact array. A larger transmission line network having 24 cells by 24 cells was also modelled computationally. This transmission line network displayed resonance cones that showed little or no near-field beam spreading with increasing distance from the source. When a cone beam encountered an edge of the transmission line network with insufficient resistive absorption, specular reflection of the cone beam was observed.

Changing the reactive loads creates a different transmission line network. For example, a "transpose" transmission line network can be created by interchanging the inductive and capacitive elements.

Phase-Shifting Line Using a Linear Metamaterial

The metamaterial in accordance with the present invention is also suitable for use in a compact 1-D phase-shifting device that can be used to synthesize arbitrary transmission phases. Such as shifting device includes sections of LHM metamaterial lines cascaded with sections of conventional RHM transmission lines. Several embodiments of such a phase-shifting device, having a 1, 2, 4, and 8 stages can be seen in FIG. **12**. The phase-shifting device offers significant advantages when compared to standard delay transmission lines. The phase-shifting device is more compact in size and can achieve a positive, a zero, or a negative phase shift while occupying the same or shorter physical length. The phase-shifting device also exhibits a linear, flatter phase response with frequency, leading to shorter group delays.

In a LHM, the phase leads in the direction of group velocity, therefore incurring a positive phase shift with propagation away from the source. In addition, it is well known that in conventional RHM transmission lines, the phase lags in the direction of positive group velocity, thus incurring a negative phase shift with propagation away from the source. It therefore follows that phase compensation can be achieved at a given frequency by cascading a section of a LHM with a section of a RHM to form a unit cell with a given phase shift.

The unit cell of the phase-shifting device is shown in FIG. **13** and has total dimension d_o. The unit cell includes a host transmission line medium TL periodically loaded with discrete lumped element components, L_o and C_o.

The dispersion characteristics of the unit cell can be determined by the following equations:

$$\cos(\beta_{Bloch}d) = \cos(\beta_{TL}d)\left(1 - \frac{1}{4\omega^2 L_o C_o}\right) + \sin(\beta_{TL}d)\left(\frac{1}{\omega C_o Z_o} + \frac{Z_o}{\omega L_o}\right) - \frac{1}{4\omega^2 L_o C_o} \tag{10}$$

where:

β_{Bloch} is the Bloch propagation constant; and

$\beta_{TL}=\omega\sqrt{LC}$ is the propagation constant of the host transmission line.

In order to consider a series of cascaded unit cells as an effective periodic medium, the physical length of the unit cell must be much smaller than a wavelength, therefore restricting the phase shift per unit cell and the length of the transmission lines to small values (βBlochd<<1 and βTLd<<1). Thus, an effective propagation constant, βeff, can be defined for the medium by the following equation:

$$\beta_{eff} = \pm\sqrt{\left(L - \frac{1}{\omega^2 C_o d}\right)\left(C - \frac{1}{\omega^2 L_o d}\right)} \tag{11}$$

FIG. **14** shows the dispersion relation for a unit cell with typical parameters C_o=15 pF, L_o=20 nH, Z_o=50Ω and $\beta_{TL}d$=0.28 rad. It can be observed that the corresponding dispersion diagram exhibits a band structure with two distinct passbands and stopbands. Expressions for the pertinent cut-off frequencies as indicated in FIG. **14** are as follows:

$$f_b = \frac{1}{4\pi\sqrt{L_o C_o}},\ f_{c1} = \frac{1}{2\pi\sqrt{L C_o}},\ f_{c2} = \frac{1}{2\pi\sqrt{L_o C}} \tag{12}$$

Equating f_{c1} and f_{c2} causes the stopband between these two cut-off frequencies to close and the band becomes continuous. This corresponds to the following matching condition for the LHM and RHM sections:

$$Z_o=\sqrt{L_o/C_o}=\sqrt{L/C} \tag{13}$$

Under this condition, it can be shown that the effective propagation constant of equation (11) simplifies to the expression:

$$\beta_{eff} \approx \omega\sqrt{LC} + \frac{-1}{\omega\sqrt{L_o C_o}} \tag{14}$$

Expression (14) can be interpreted as the sum of the propagation constants of the host transmission line and a uniform LHM line. For a transmission line medium with periodicity d and phase shift $\phi_{TL}=\beta_{TL}d$, the total phase shift per unit cell, $|\phi_o|$, given that the matching condition of equation (13) is satisfied, can be written as:

$$|\phi_o| = \beta_{eff} d = \phi_{TL} + \frac{-1}{\omega\sqrt{L_o C_o}} \tag{15}$$

Thus equations (13) and (15) can be used to determine unique values for L_o and C_o for any phase shift, ϕ_o, given a transmission line section with intrinsic phase shift β_{TL} and characteristic impedance Z_o.

The unit cell of FIG. **13** was implemented in coplanar-waveguide (CPW) technology at a design frequency of f_o=0.9 GHz using microwave-circuit simulator. The lumped element components and the transmission lines were assumed to be ideal. The transmission lines were designed with Z_o=50Ω, $\in_r$=2.2, dielectric height, h=20 mils and length d=7.4 mm. The dispersion relation for the unit cell with ϕ_o=0° is shown in FIG. **15**. The impedance matching condition of equation (13) has been satisfied and therefore, the stopband has been closed. It can also be observed that at f_o=0.9 GHz, the phase shift is 0°.

Based on the above parameters a +10-degree phase-shifting device was designed including 4 unit cells of total physical length 0.11λCPW=32 mm, with loading element values of C_o=21.66 pF and L_o=54.15 nH. The resulting phase characteristic of the phase-shifting device is shown in FIG. **16**. It can be observed that the phase shift is +10 degrees at fo=0.9 GHz with a phase slope of −95.7-degrees/GHz. In addition, the phase response around fo is linear with respect to frequency, implying a constant group delay for the phase-shifting device. Also shown in FIG. **16** is the phase characteristic of a conventional 50Ω transmission line of length 35/36 λCPW=275.7 mm for comparison. The transmission line exhibits as expected a −350-degree phase shift at fo, which is equivalent to +10 degrees, with a phase slope of −389-degrees/GHz. In addition, its physical length is approximately 9 times longer than the 4 unit cell phase-shifting line.

Referring back to FIG. **12**, an impression of the relative sizes of the two structures can be obtained. The proposed +10-degree phase-shifting device offers two main advantages over its equivalent transmission line implementation, namely a +10-degree phase shift while occupying significantly less physical space than a conventional transmission line, and a shorter group delay which is desirable for applications that require broadband operation.

Also shown in FIG. **16** is the phase characteristic of a 4-stage −10° phase-shifting device with loading element values of C_o=29.46 pF and L_o=73.65 nH. It can be observed that the −10° phase characteristic is similar to the +10° phase characteristic, with a phase slope of −72.9°/GHz. The −10° phase-shifting device occupies the same physical length as the +10° phase-shifting device and has loading element values that are at a ratio of approximately 1.4:1 compared to the ones used for the +10° phase shifting device. This implies that a reasonable variation of the loading element values using tuneable components can produce either a positive or a negative phase shift.

FIG. **16** also shows the phase characteristic of a 4-stage +10° uniform backward wave L-C line with loading element values of C_o=81.06 pF and L_o=202.64 nH. This corresponds to the unit cell of FIG. **13** with the transmission line sections removed. Setting therefore ϕTL to zero in equation (15), implies that ϕ_o will always remain negative, corresponding to a phase advance for a positively traveling plane wave of the form exp(−jβeffd). The absence of transmission lines implies that any combination of C_o and L_o values will produce a phase shift that will always be greater than 0 degrees for the unit cell. This is verified by the phase characteristic of the L-C line in FIG. **16** that stays well above 0 degrees at all times. Therefore, although the backward wave L-C line and the proposed unit cell of FIG. **13** can both provide positive phase shifts, the latter has the additional advantage of being able to provide a negative phase shift by simply varying the loading element values. More importantly, short, broadband 0-degree phase shift lines can be realized which can be used in numerous applications.

The 1-D phase-shifting structures were constructed using CPW technology on a Rogers™ RT5880 substrate with ∈r=2.2, and a dielectric height, h=20 mils. Standard size 0402 Panasonic ECJ-0EC capacitors were used for C_o with dimensions L=1 mm, W=0.5 mm, and H=0.5 mm, and standard size 0603 Panasonic ELJ-RE/FJ inductors were used for L_o with dimensions L=1.6 mm, W=0.8 mm, and H=0.8 mm. The 50Ω transmission lines were designed to have a length of d=7.4 mm, and a gap of s=0.6 mm was created to accommodate the series capacitors, resulting in a unit cell of total length d_o=8 mm. At 0.9 GHz the transmission lines were designed with a center conductor width of w=4 mm and a gap between the center conductor and the ground plane of g=0.106 mm. In addition, two 5 mm transmission lines were added to each end of the phase-shifting devices in order to accommodate SMA connectors. A Thru-Reflect-Line (TRL) calibration was carried out in order to remove the effects of the connectors and establish the reference planes at the input and output ports of the phase-shifting devices. All measurements were carried out on a HP8753C series vector network analyzer. The simulated results were obtained by replacing the ideal models for the capacitors and inductors with their corresponding S-parameter files provided by the vendors. Since the S-parameter files were extracted directly from device measurements, they therefore contain all the parasitic values associated with each component.

FIG. **17** shows the simulated (- - -) and measured (-) phase responses of 1-stage, 4-stage and 8-stage 0° phase-shifting devices with loading element values of C_o=12 pF and L_o=100 nH. It can be observed that the experimental results match very closely the simulated results, with phase slopes of −30.2°/GHz, −122.1°/GHz and −237.5°/GHz for the phase-shifting devices respectively. The measured insertion losses are 0.1 dB, 0.7 dB and 1.6 dB respectively at f_o=0.9 GHz. It is therefore evident that any number of stages can be used in order to produce the desired phase shift, however as the number of stages increases, so does the slope of the phase characteristic. For broadband applications therefore, it is desirable to keep the number of stages to a minimum.

FIG. **18** shows the simulated (- - -) and measured (-) phase responses of a 4-stage +10° phase-shifting device with loading element values of C_o=12 pF and L_o=68 nH and a 4-stage −10° phase-shifting device with loading element values of C_o=15 pF and L_o=120 nH. It can be observed that the experimental results correspond very closely to the simulated results with phase slopes of −136.6°/GHz and −108.4°/GHz for the +10° and −10° phase-shifting devices respectively. Also shown in FIG. **18** is the magnitude response of the −10° 4-stage phase-shifting device. The simulated (- - -) and measured (-) results correspond closely, however as the number of stages is increased the phase-shifting device begins to radiate, and resembles a leaky-wave structure. Therefore the phase-shifting devices should be kept short in length to avoid unnecessary energy leakage. The measured insertion losses at f_o=0.9 GHz are 0.4 dB and 0.5 dB respectively for the +10° and −10° phase-shifting devices.

The phase-shifting devices described above use cascaded sections of LHM lines and conventional transmission lines and offer significant advantages over conventional delay lines and uniform backward-wave L-C lines. The phase-shifting devices are compact in size, can be easily fabricated using standard etching techniques and exhibit a linear phase response around the design frequency. The phase-shifting devices can incur a negative or a positive phase, as well as a 0° phase depending on the values of the loading elements, while maintaining a short physical length. In addition, the phase incurred is independent of the length of the phase-shifting devices. Due to the compact, planar design, the phase-shifting devices are easily integrated with other microwave components and devices making them ideal for broadband applications requiring small, versatile, linear phase shifters.

Spectrum Analyser Using a Resonance Cone Metamaterial

The resonance cone metamaterial is useful in spectrum analysis. To illustrate this, a spectrum analyser incorporating resonance cone metamaterial was simulated. For the representation of metamaterial, analyser simulations employed a full-electromagnetic, thin-wire moment-method program, permitting the insertion of lumped circuit elements in finite-length wire segments. The basic network simulated is shown in FIG. **21**, and includes a 12×12 unit cell array, each unit cell being a 2.5 mm square, yielding a total grid size of 30 mm×30 mm. The grid is disposed above the ground plane a distance of 2.5 mm. The capacitance was 2 pF per segment and the inductance was 5.6 nH per segment. The chosen capacitance and inductance values were selected for availability as well as to achieve the desired resonance cone effects using existing X-Y scanning and network analysis equipment. The inductors used in the experiment had a manufacturer nominal quality factor Q of around 27. This was achieved in the simulation by adding a 1.6Ω resistor in series with each inductor. A resistor of the same value was added in series with each capacitor as well. Also shown in FIG. **21** is a 100 kΩ resistor from each grid intersection to ground to enable deduction of the grid-to-ground voltage from the computed resistor current. Along the edges, 50Ω resistors were connected to ground in place of the 100 kΩ resistors. For this value of edge resistance, resonance cone specular reflection from the edges is not significant.

Contour plots of grid-to-ground voltage magnitude and the Poynting vector real parts evaluated from the electric and magnetic fields on the ground-plane level at the center of each unit cell for a corner feed of 1 volt are shown in FIG. **22**. The simulated resonance cones and the way the cone orientation scans with frequency over the eight frequencies employed are illustrated. The arrows depict the Poynting vector real parts calculated on the ground plane. From the Poynting vector plot it can be seen that power flow is directed along the resonance cones. Apparent specular reflection from the grid edges is sometimes visible (for example at 0.7, 0.9, 1.9 and 2.3 GHz) but generally it is weak. As well, very weak parasitic resonance cones can be seen in FIG. **22** (for example at 0.9 and 2.3 GHz), probably caused by scattering from the inhomogeneities inherent in the grid structure. FIG. **23** shows the frequency response for the voltages across the 50Ω resistors to ground at all points along two edges of the grid.

Focusing Device Using Two Resonance Cone Metamaterials

Another focusing device making use of resonance cone metamaterial was created using a two media plane including metamaterial similar to that shown in FIG. **11**. By interchanging (transposing) the inductors and capacitors in the grid in part of the media, an interface is formed, separating two media. If the plasma negative and positive permittivities are interpreted by representing the media in terms of arrays of inductors and capacitors respectively, then interchanging the inductors and capacitors corresponds to moving the operating point from one hyperbolic region to the other in the parameter space as shown in FIG. **20**. The hyperbolic regions characterize the relevant partial differential equation. The vertical axis involves the electron cyclotron frequency ω_c and is proportional to the square of the ambient magnetic field, while the horizontal axis involves the plasma frequency ω_p and is proportional to the ambient electron density. The capacitor and inductor symbols characterize the impedance properties of the plasma medium as they effect the input of impedance of a small, spherical RF probe immersed in the plasma medium. These two hyperbolic regions suggest two quite different periodic physical media that, when interfaced, display unusual refraction phenomena. If the inductors and capacitors are regarded as physical entities and not just as aids to interpretation, a physical inductor-capacitor (L-C) network becomes a metamaterial that exhibits a resonance cone phenomena. This enables a two-medium configuration with a linear interface between the original medium and the transpose medium.

The component layout of a focusing device including multi-resonance cone materials is shown in FIG. **24**, and its physical grid realization is shown in FIG. **25** in which the grid elements are chip-type surface-mount inductors and capacitors soldered together. The grid has 12 by 12 unit cells. Medium **1** is constituted by the lower 5 rows of the grid and includes inductors on the horizontal segments and capacitors on the vertical segments. Medium **2** is constituted by the upper 6 rows of the grid and includes capacitors on the horizontal segments and inductors on the vertical segments. The sixth row of cells is the transition region, or interface, where the lower edges of the unit cell carry inductive loads, the upper edges carry capacitive loads, and the vertical segments carry a capacitor on the lower half and an inductor on the upper half. Therefore the boundary between the two media lies in the middle of the transition region.

To accommodate the physical size of the chip-type inductors and capacitors, the unit cells in the transition region are elongated i.e. the vertical dimension is doubled compared to unit cells elsewhere in the grid. The overall size of the grid is 30 mm×32.5 mm and the boundary is a horizontal line 15 mm from the bottom of the grid. The grid is aligned so that individual vertical transmission lines run directly through both media and the interface. In the refraction experiments, the vertical E-field is picked up by an open-ended coaxial probe positioned sequentially just above each conductor intersection, and the probe signal is fed to a network analyzer with output **S21** which, when plotted on a linear scale, is approximately proportional to the grid-to-ground voltage.

The two-medium result for corner feed with the feed point being below point A in FIG. **24**, is shown in FIG. **26**, which displays clearly the negative refraction of the resonance cone as it traverses the transposition interface. Experimental results at the top exhibit contours of normalized /**S21**/, and the simulation at the bottom exhibits contours of grid-to-ground voltage magnitude with the arrows depicting the Poynting vector real parts on the ground plane. The counter lines in the bottom plot are at the same levels as the three lowest contour lines in the top plot. Notice that specular reflection from the interface is negligible and there is no visible transmission into the second medium in the same direction as the incident cone. This can also be seen from the

Poynting vectors in the bottom plot of FIG. **26**, which displays the simulation results, where the power flow associated with specular reflection from the interface is negligible and no power along the original resonance cone is transmitted into the second medium. In order to extend the refraction results to include focusing, the physical set-up of FIG. **25** was used with coaxial feed from beneath the ground plane to point B on the grid in FIG. **24**, near the middle of one of the two planar metamaterials.

Simulation and experimental results are shown in FIGS. **27** and **28** at 1.3 GH_Z. The arrows display the Poynting vector real ports calculated on the ground plane. Heavy contour is at 0.707 of focal maximum of 0.867 units of normalized /**S21**/. Simulation and experimental results are also shown in FIGS. **29** and **30** at 1.7 GH_Z. In FIG. **29** heavy contour is at 0.707 of focal maximum of 0.708 and in FIG. **30** heavy contour is at 0.707 of focal maximum of 0.764. In all cases, one can see the cones emanating from the feed point (the "source"), the backward refraction at the y=15 mm interface, and the cones merging at the "focus". Note that in FIGS. **27** and **29** the power flow closely follows the directions of the resonance cones. Furthermore, FIG. **29** shows the power flow emanating from the source and following the resonance cones to converge at the focus, from where it diverges again into a new set of resonance cones. In FIGS. **29** and **30**, the focal region is taken to be bounded by the contour that is at 0.707 of the focal region maximum, so this contour may be termed the "half-power" contour. It is worth noting, that at 1.7 GHz, the experimental focal region boundary lies within a square measuring 1/25th free-space wavelength on a side, so the phenomenon properly may be termed "sub-wavelength focusing". In contrast, at 1.3 GHz the focal point is too close to the upper edge of the material to exhibit an equally well localized focal region, and thus this represents a useful low-frequency limiting case for the particular overall grid size in use. As well, with increasing frequency, it should be noted that the focal region moves gradually toward the boundary between the two media.

Couplers Using Linear Metamaterials

The present metamaterial is also useful in couplers by combining the metamaterial with conventional microchip (MS) transmission lines. In particular, it has been found that the metamaterial is useful in both a coupled-line coupler and a branch-line coupler. The MS/LHM coupled-line coupler is realized by means of one regular microstrip line that is edge-coupled to a LHM line. Such a coupler excites modes on the two lines whose propagation constants are co-directional but whose corresponding Poynting vectors are contra-directional, leading to backward power coupling. Moreover, by comparison to a conventional coupled-line microstrip coupler of the same length and line spacing, the present MS/LHM coupled-line coupler offers better performance in terms of coupled power, return loss and isolation without any bandwidth degradation. The MS/LHM coupled-line coupler can also be designed for arbitrary backward coupling.

The branch-line coupler uses LHM lines to split power equally between the output ports with interesting phase compensation characteristics. In conventional branch-line couplers, the through and coupled ports are −90° and −180° out of phase respectively with reference to the input port. The present branch-line coupler using an LHM line, results in the power emerging from the coupled port to be in phase with the input port and permits a choice of either positive or negative phase-quadrature (±90°) at the through port.

For ease of understanding, the theory behind the coupled-line coupler will be described. A MS/LHM coupled-line coupler can be realized by means of one regular microstrip line that is edge-coupled to a LHM line as shown in FIG. **31**. The LHM is synthesized by periodically loading a host microstrip transmission-line (TL) medium with series capacitors and shunt inductors. In such a backward-wave transmission line, the phase velocity and power flow are anti-parallel.

Coupled-line couplers rely on proximity interaction of fields between transmission lines to transfer power between them. In co-directional coupled-line couplers, the direction of the propagation vectors on the two lines is the same. When such couplers are constructed using either two regular or two LHM lines, the underlying propagation phenomenon is fundamentally similar to that on a corresponding isolated line of the same type. Indeed in such co-directional couplers including two lines of the same type, the power also couples co-directionally and appears at the far end of the coupler (i.e. away from the source). Peculiar features arise when two different types of lines are used. Herein it is shown that a MS/LHM coupler excites co-directional forward traveling waves but delivers power backwards as a result of the power flow being contra-directional.

The analysis presented herein assumes that port **1** in FIG. **31**(*a*) is the excited port. The operation of coupled line couplers can be understood in terms of constructive and destructive interference of the two modes that are allowed to propagate. Using a coupled-mode differential-equation formulation, it is possible to show that the general expressions for voltages and currents on the two lines take the form:

$$V_1=(V_c{}^+e^{-j\beta_c z}+V_c{}^-e^{j\beta_c z})+(V_\pi{}^+e^{-j\beta_\pi z}+V_\pi{}^-e^{j\beta_\pi z}) \tag{16}$$

$$V_2=R_c(V_c{}^+e^{-j\beta_c z}+V_c{}^-e^{j\beta_c z})+R_\pi(V_\pi{}^+e^{-j\beta_\pi z}+V_\pi{}^-e^{j\beta_\pi z}) \tag{17}$$

$$I_1=\frac{1}{Z_{c1}}(V_c^+e^{-j\beta_c z}-V_c^-e^{j\beta_c z})+\frac{1}{Z_{\pi 1}}(V_\pi^+e^{-j\beta_\pi z}-V_\pi^-e^{j\beta_\pi z}) \tag{18}$$

$$I_2=\frac{R_c}{Z_{c2}}(V_c^+e^{-j\beta_c z}-V_c^-e^{j\beta_c z})+\frac{R_\pi}{Z_{\pi 2}}(V_\pi^+e^{-j\beta_\pi z}-V_\pi^-e^{j\beta_\pi z}) \tag{19}$$

Subscripts **1** and **2** refer to line **1** (microstrip) and line **2** (LHM) of the coupler respectively; c and π are the two possible modes and the coefficients R_c and R_π are the ratios of the voltages on line **2** to line **1** for each mode.

To analyze the MS/LHM coupler of FIG. **31**, some simplifying assumptions are made. First, the lines of the coupler are assumed to the far removed from each other so that the coupled-mode propagation constants β_c and β_π correspond to the isolated propagation constants β_1 and β_2 respectively of each line. This implies that β_2 (LHM line) has a negative value. Hence all occurrences of β_c and β_π in equations (16) to (19) can be replaced by β_1 and β_2 respectively. Furthermore line **1** is assumed to be the excited line and therefore, it is anticipated that mode **1** will be the dominant mode for determining the voltage on line **1**. Second, to minimize reflections, only the case of properly terminated lines is considered. Thus each mode travels in one direction only. Mode **1**, being dominant on line **1**, has a forward phase velocity and carries power away from the source. The dilemma lies in the choice of the direction of the phase velocity for mode **2**. To resolve this issue, one can consider the limiting case when the magnitudes of the isolated propagation constants of the modes are close to each other. As mode **1** travels forward, due to phase matching constraints, it is expected that the coupled mode (mode **2** in this case) should also travel forward. The present situation is the reciprocal case and therefore, power from the excited regular MS line will couple backwards into port **2** of the LHM line (see FIG. **31**(*a*)). In the general case when the two mode propagation constants are not close to each other, maximum power can be coupled backwards into port **2** (see FIG. **32**(*a*)) only when the excited modes are co-directional. Hence in the following discussion, only the case of co-directional (phase-wise) coupled modes will be considered.

Lastly, it is assumed that the magnitudes of the impedances for each mode on line **1** are the same and are denoted by Z_1; similarly for line **2** they are denoted by Z_2. Caution must be exercised in choosing the signs of the impedances in the current equations 3 and 4. The impedance term in front of V_c^+ and V_c^- (equation 3) will be positive as usual. Since V_π^+ and V_π^- (equation 3) actually correspond to backward and forward traveling waves respectively on line **1** (due to the negative sign of β_2), and to ensure that the power carried by a forward traveling wave in a regular medium is also forward, $Z_{\pi 1}$ should be negative. Similar arguments applied to line **2** (LHM line) require that the sign of Z_{c2} be negative and that of $Z_{\pi 2}$ be positive to ensure that power flow and phase flow occur in opposite directions.

With these assumptions, equations (16) to (19) can be simplified to:

$$V_1=V_c^+e^{-j\beta_1 z}+V_\pi^-e^{j\beta_2 z} \tag{20}$$

$$V_2=R_cV_c^+e^{-j\beta_1 z}+R_\pi V_\pi^-e^{j\beta_2 z} \tag{21}$$

$$I_1=\frac{V_c^+}{Z_1}e^{-j\beta_1 z}+\frac{V_\pi^-}{Z_1}e^{j\beta_2 z} \tag{22}$$

$$I_2=-\frac{R_c}{Z_2}V_c^+e^{-j\beta_1 z}-\frac{R_\pi}{Z_2}V_\pi^-e^{j\beta_2 z} \tag{23}$$

Applying boundary conditions at port **1** (presence of source V_s and matching source impedance Z_1) and port **4** (termination to Z_2) respectively yields:

$$V_c^+e^{j\beta_1 d}+V_\pi^-e^{-j\beta_2 d}=\frac{V_s}{2} \tag{24}$$

$$R_cV_c^++R_\pi V_\pi^-=0 \tag{25}$$

Solving for V_c^+ and V_π^-, and plugging back into equations (20) and (21), the following expressions for the line voltages along the coupler can be obtained:

$$V_1(z)=\frac{V_s}{2}\frac{R_\pi e^{-j\beta_1 z}-R_ce^{j\beta_2 z}}{R_\pi e^{j\beta_1 d}-R_ce^{-j\beta_2 d}} \tag{26}$$

$$V_2(z)=\frac{V_s}{2}\frac{R_\pi R_c(e^{-j\beta_1 z}-e^{j\beta_2 z})}{R_\pi e^{j\beta_1 d}-R_ce^{-j\beta_2 d}} \tag{27}$$

Equations (26) and (27) confirm that port **4** (z=0) is the isolated port and port **2** (z=−d) is the coupled port. Expressions for power delivered to the through port (port **3**) and coupled port (port **2**) can be derived from equations (26) and (27):

$$P_2=\frac{1}{Z_2}\left(\frac{V_s}{2}\right)^2\frac{(R_CR_\pi)^2(1-\cos((\beta_1+\beta_2)d))}{(R_c^2+R_\pi^2-2R_cR_\pi\cos((\beta_1+\beta_2)d))} \tag{28}$$

-continued

$$P_3=\frac{1}{2Z_1}\left(\frac{V_s}{2}\right)^2\frac{(R_C-R_\pi)^2}{(R_c^2+R_\pi^2-2R_cR_\pi\cos((\beta_1+\beta_2)d))} \tag{29}$$

From equation (29) it can be seen that the power delivered to the through port (port **3**) is minimized (i.e. the power to the coupled port is maximized) when the argument of the cosine function in the denominator takes values which are odd integer multiples of π. This allows the definition of the coherence length of the coupler, which is the optimal length for maximum coupling, as:

$$d_{coherence}=\pi/|\beta_1+\beta_2| \tag{30}$$

Note that in the above equation (30), β_2 is negative. An interesting feature of such a coupler is that it is possible to achieve arbitrary backward coupling by making the magnitudes of the propagation constants of the two modes close to each other.

Two coupled-line couplers were constructed, namely a short MS/LHM coupled-line coupler and a long MS/LHM coupled-line coupler with arbitrary coupling. The substrate used to construct the couplers was a low-loss Rogers™ TMM4® having a relative dielectric constant $\in_r=4.6$ and 50 mils thickness (loss tangent=0.002). The regular MS lines were designed using a microwave-circuit simulator, whereas Matlab® simulations of the dispersion relation of the periodic LHM line were performed to estimate the corresponding propagation constant at the design frequency. Moreover, microwave circuit simulations of the couplers were performed using a microwave-circuit simulator.

The short MS/LHM coupled-line coupler was designed with a finite coherence length to demonstrate the validity of the theory. The long MS/LHM coupled-line coupler has magnitudes of the two modal propagation-constants close to each other. By taking a finite number of cells (the optimal length infinite as defined by equation 15), a comparison with a conventional (MS/MS) coupled-line microstrip coupler of the same length, line spacing, and propagation constant is permitted.

Using a microwave circuit simulator the widths of the lines of the short MS/LHM coupled-line coupler are designed so that both the MS and LHM lines have an impedance of 50Ω when placed 0.4 mm apart. The width of the MS and LHM lines used was 2.383 mm. Using a unit cell size of 5 mm for the LHM line, the choice of the loading elements are 2.7 nH shunt inductors and 0.9 pF series capacitors. Again, the microwave circuit simulator is used to determine the effective dielectric constant for the line segments. This is used in Matlab simulations of the periodically loaded transmission-line based LHM line to extract its dispersion characteristics (see FIG. **32**(*a*)). A design frequency of 2.2 GHz is selected for this configuration so that the magnitude of the isolated propagation constants differ enough (see FIG. **32**(*a*)) to give a short coherence length (see equation 15).

A spatial Fourier transform of the line voltages, extracted by exciting port **1** in ADS simulations, is shown for both lines of the coupled-line coupler at 2.2 GHz using 400 sample points (see FIGS. **33**(*a*) and (*b*)). These plots demonstrate the validity of the assumption that the propagation constants of the coupled modes ($|\beta_1|=85.3\ \text{m}^{-1}$ and $|\beta_2|=195\ \text{m}^{-1}$) are indeed close to the isolated propagation constants of the individual lines (compare to FIG. **32**(*a*)). Moreover the Fourier spectrum demonstrates that both modes propagate forward (co-directional) and that β_1 is dominant on line **1** (MS). Furthermore, the assumption of minimal reflections is evident from the small peaks in the negative region of the spectrum in FIGS. **33**(*a*) and **33**(*b*). In addition, using equation (30), the coherence length is calculated to be 28.6 mm and can be approximated by 6 unit cells of the MS/LHM coupled-line coupler. By comparing the coupled power as a function of frequency for various coupler sizes, this is verified to be true as shown in FIG. **34**. Moreover, the input power at port **1** is $V_s^2/8Z_0$ and the output power at the coupled port is given by equation (28). The implicated voltage ratios R_c and R_π can be estimated from FIGS. **33**(*a*) and **33**(*b*) and the corresponding theoretical value for the coupled power (S_{21}) amounts to −7.46 dB at the coherence length, which is close to the simulation results for a 6 unit cell long coupler (see FIG. **34**).

Fair comparison between a conventional coupled-line backward coupler (MS/MS) and a metamaterial long MS/LHM coupled-line coupler (see FIG. **32**(*b*)) can be made if their propagation constants and line impedances are similar. This is because, it is always possible to slow down the coupled waves and improve coupling in conventional couplers by loading them. For this purpose, a design frequency of 2.8 GHz (FIG. **32**(*a*)) is selected. The widths of the MS and LHM strips of the MS/LHM coupled-line coupler are taken to be 2.45 mm and 2.0 mm respectively so that at a line separation of 0.4 mm at the design frequency, the impedances of each line are close to 50Ω. The loading elements are the same as above with reference to the short MS/LHM coupled-line coupler.

A regular MS/MS backward coupler was also designed at the same frequency with a propagation constant of 108.2 m^{-1} and impedance close to 50Ω. The widths of the strips were taken to be 2.122 mm in this case and the length of the coupler was optimized to 14.5 mm (λ/4).

From MATLAB® simulations of the periodic LHM lines (see FIG. **32**(*a*)) it is found that at 2.8 GHz, the propagation constants for both lines of the MS/LHM coupled-line coupler are similar to those of the MS/MS coupler lines (MS and LHM propagation constants are 108.9 m^{-1} and 105 m^{-1} respectively). This makes the coherence length for the MS/LHM coupled-line coupler very long (equation 15). For comparison with the designed conventional MS/MS coupler, the former is constructed out of 3 unit cells corresponding to a total length of 15 mm (see FIG. **32**(*b*)).

From theory (equation (15)) it is anticipated that this MS/LHM coupled-line coupler will have a long coherence length if the propagation constants of its two modes are close to each other. This is true at 2.8 GHz as shown in the dispersion diagram for the LHM-line (see FIG. **31**(*a*)).

For comparison with a conventional MS/MS backward coupler, simulation and experimental results are presented in FIGS. **35**(*a*) to **35**(*c*), involving a λ/4 MS/MS coupler and a 3 unit cell long MS/LHM coupled-line coupler, both of approximately equal lengths, equal spacing and propagation constants (see FIG. **32**(*b*)). The return loss (S_{11}), isolation (S_{41}) and coupled power (S_{21}) for each coupler were measured using a HP8753D network analyzer and values obtained were compared to microwave-circuit simulation results. As shown in FIG. **35**(*a*), the coupled power of the MS/LHM coupled-line coupler is better than that of the MS/MS coupler. Furthermore, from FIG. **35**(*b*), it is seen that the amount of power leaking into the isolated port of the MS/LHM coupled-line coupler is lower than that of the corresponding MS/MS coupler. In addition, at the design frequency, the return loss of the MS/LHM coupled-line coupler is lower than its conventional counterpart (see FIG. **35**(*c*)). Hence, the metamaterial MS/LHM coupled-line coupler exhibits superior performance in terms of the coupled power, isolation and return loss when compared to a conventional MS/MS coupler of the same length, line separation and propagation constant.

As expected from the dispersion analysis and the theory presented earlier, the MS/LHM coupled-line coupler has a very large coherence length. Under such conditions, arbitrary coupling can be achieved as demonstrated in FIG. **35**(*d*). As the number of unit cells is increased, the coupled power improves and it is possible to achieve close to 0 dB coupled power.

Overall, there is good agreement between theory, simulation and experiment. The predictions of the coherence length as well as the level of the coupled power agree well with the experimentally observed results. The coupled-line coupler demonstrates better performance in terms of coupling, isolation and reflection when compared to a conventional microstrip coupler of the same length, line spacing and propagation constant.

Small discrepancies between simulation and experimental results can be attributed to a number of factors. The absence of accurate models for the inductors used and their self-resonance characteristics affect the design. Moreover chip components with finite dimensions add to the overall electrical length of the MS/LHM coupler which needs to be properly accounted for.

In conventional microstrip branch-line couplers, power splits equally between the through and coupled ports and the ports are −90° and −180° out of phase respectively with reference to the input port. Interesting phase compensation effects can be achieved when some of the branches of the branch-line couplers are replaced by LHM lines.

Two different branch-line coupler designs are presented below denoted as type **1** and type **2**. The type **1** branch-line coupler uses regular microstrip lines for the low-impedance branches and LHM lines for the high-impedance branches (see FIG. **36**(*a*)). The type **2** branch-line coupler is the dual of the type **1** branch-line coupler and utilizes LHM lines for the low-impedance branches and microstrip lines for the high-impedance branches (see FIG. **36**(*b*)). For both branch-line couplers, power splits equally between the two output ports with a 0°-phase shift with respect to the input at the coupled port. Furthermore, the type **1** branch-line coupler offers a negative phase quadrature (−90°) while the type **2** branch-line coupler provides a positive phase quadrature (+90°) at the through port with respect to the input port.

FIG. **36**(*a*) shows the structure of the type **1** branch-line coupler made of alternating MS and LHM lines. The scattering parameters of the coupler can be determined using even-odd mode analysis. It can be easily shown that the impedance looking into a segment of LHM transmission line of length d is given by:

$$Z_{in} = Z_0 \frac{Z_L + jZ_0 \tan\beta d}{Z_0 + jZ_L \tan\beta d} \tag{31}$$

where:

Z_L is the load impedance at the end of the line;

Z_0 is its characteristic impedance; and

β is a negative number corresponding to the propagation constant.

For the purpose of analysis, port **1** is excited by a source V_s of internal impedance Z_0 and all other ports are terminated at Z_0. In the even mode analysis, both port **1** and port **2** are excited by $V_s/2$ sources. In the odd mode, the source at port **1** is $V_s/2$ and the source at port **2** is $-V_s/2$ (see FIG. **37**).

In the even mode, looking down the LHM lines at port **1** and port **3** (see FIG. **36**(*a*)), one sees open λ/8 lines and hence βd is −π/4. From equation (31), this corresponds to shunt loading of the λ/4 MS line at its ends by a susceptance $-jY_0$ (see FIG. **37**). In the odd mode, one can observe shorted λ/8 segments of LHM lines instead, corresponding to shunt loading of the MS line by a susceptance jY_0.

By analyzing the equivalent circuits in FIG. **37**, it is seen that the impedance looking into each port is Z_0. Since the ports are always matched, S_{11}, S_{22}, S_{33} and S_{44} are zero. As the waves in each port travel in only one direction, by superposition of the even and odd modes, S_{21} is zero. In the even mode, the signal at port **1** can be related to the signal at port **3** by the following transfer matrices:

$$\begin{bmatrix} V_s/4 \\ I_1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ -jY_0 & 1 \end{bmatrix} \begin{bmatrix} 0 & j\frac{Z_0}{\sqrt{2}} \\ jY_0\sqrt{2} & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -jY_0 & 1 \end{bmatrix} \begin{bmatrix} V_3 \\ V_3 Y_0 \end{bmatrix} \tag{32}$$

$$\Longleftrightarrow V_3^{even} = \frac{1}{\sqrt{2}}\frac{V_s}{4}(1-j) = V_4^{even} \tag{33}$$

In the even mode, the voltage at port **3** and port **4** are identical (see FIG. **37**). In the odd mode, the transfer matrices are:

$$\begin{bmatrix} V_s/4 \\ I_1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ jY_0 & 1 \end{bmatrix} \begin{bmatrix} 0 & j\frac{Z_0}{\sqrt{2}} \\ jY_0\sqrt{2} & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ jY_0 & 1 \end{bmatrix} \begin{bmatrix} V_3 \\ V_3 Y_0 \end{bmatrix} \tag{34}$$

$$\begin{bmatrix} -V_s/4 \\ I_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ jY_0 & 1 \end{bmatrix} \begin{bmatrix} 0 & j\frac{Z_0}{\sqrt{2}} \\ jY_0\sqrt{2} & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ jY_0 & 1 \end{bmatrix} \begin{bmatrix} V_4 \\ V_4 Y_0 \end{bmatrix} \tag{35}$$

$$\Leftrightarrow V_3^{odd} = -\frac{1}{\sqrt{2}}\frac{V_s}{4}(1+j);\ V_4^{odd} = \frac{1}{\sqrt{2}}\frac{V_s}{4}(1+j) \tag{36}$$

where equation (34) is the transfer matrix from port **1** to port **3** and equation (35) is the transfer matrix from port **2** to port **4** (see FIG. **37**). The amplitude of the total incident voltage (odd and even) at port **1** is $V_s/2$. Hence from superposition of the modes, S_{31} and S_{41} are equal to −j/√2 and 1/√2 respectively. The scattering matrix for the MS/LHM branch-line coupler is:

$$\begin{bmatrix} V_1^- \\ V_2^- \\ V_3^- \\ V_4^- \end{bmatrix} = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & -j & 1 \\ 0 & 0 & 1 & -j \\ -j & 1 & 0 & 0 \\ 1 & -j & 0 & 0 \end{bmatrix} \begin{bmatrix} V_1^+ \\ V_2^+ \\ V_3^+ \\ V_4^+ \end{bmatrix} \tag{37}$$

From equation (37), it is seen that in the MS/LHM branch-line coupler, the power divides equally between the through port (port **3**) and coupled port (port **4**) and they are 90° and 0° out of phase respectively with reference to the input (port **1**).

To construct the type **1** branch-line coupler a substrate similar to that of the coupled-line couplers was used. In the type **1** branch-line coupler, the MS strips have an impedance of 50/√2Ω whereas LHM strips have an impedance of 50Ω (using a microwave-circuit simulator). The design frequency is chosen to be 1.9 GHz so that each side of the coupler is λ/4 long (from Matlab® simulations of the dispersion characteristics of the line). The MS line used is 4.018 mm wide and 20.603 mm long. The LHM-line strip comprises 3 unit cells of width 2.343 mm and length 5.2 mm each. The latter is loaded with 3.3 nH shunt inductors and 1.6 pF series capacitors. The end capacitors of each LHM line segment are 2.4 pF. The terminating capacitors are chosen to be almost twice the value of the interior ones to preserve the symmetry of the unit cells making up the LHM lines (see FIG. **31**(*b*)).

During simulation, port **1** of the branch-line coupler shown in FIG. **36**(*a*) is excited in a microwave-circuit simulation and all other ports are terminated with 50Ω loads. The reflected power (S_{11}), isolation (S_{21}), through power (S_{31}) and coupled power (S_{41}) are recorded and compared to theoretical estimates from even-odd mode analysis. To apply the previously presented even-odd mode analysis, Matlab® simulations are performed for both lines to determine their dispersion characteristic. Subsequently, the corresponding phase shifts are used in the even-odd mode analysis. These theoretical results are compared with a microwave-circuit simulation and are presented in FIGS. **38**(*a*) to **38**(*c*).

In this branch-line coupler, the input power splits in half between the through port (port**3**) and coupled port (port **4**) as expected (see equation (22)). This is demonstrated in FIGS. **38**(*a*) and **38**(*b*). FIGS. **38***a* and **38***b* also show that at the design frequency, the through and coupled ports are matched (see S_{11} in FIG. **38**(*a*)) and port **2** is isolated (see FIG. **38**(*b*)). In FIGS. **38**(*a*) and **38**(*b*) the response of a commensurate, conventional, branch-line coupler is also included for comparison purposes. As shown, there is no degradation of the useful bandwidth between the conventional and the type **1** branch-line coupler. However, from theory the through port (port **3**) undergoes a phase shift of −90° and the coupled port (port **4**) undergoes a phase shift of 0° with respect to the input. This is clearly demonstrated from the simulation results in FIG. **38**(*c*).

The schematic for the type **2** MS/LHM branch-line coupler is shown in FIG. **36**(*b*). The scattering parameters for this branch-line coupler can be determined in the same way followed for the type **1** case. Since in this branch-line coupler, the MS and LHM lines are switched, every occurrence of j in equations (32) to (37) is replaced by −j. Hence the scattering matrix for the type **2** MS/LHM branch-line coupler is:

$$\begin{bmatrix} V_1^- \\ V_2^- \\ V_3^- \\ V_4^- \end{bmatrix} = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & j & 1 \\ 0 & 0 & 1 & j \\ j & 1 & 0 & 0 \\ 1 & j & 0 & 0 \end{bmatrix} \begin{bmatrix} V_1^+ \\ V_2^+ \\ V_3^+ \\ V_4^+ \end{bmatrix} \tag{38}$$

From equation (38), it is seen that in the type **2** MS/LHM branch-line coupler, the power divides equally between the through port (port **3**) and coupled port (port **4**) and the parts are +90° and 0° out of phase respectively with reference to the input (port **1**).

For the type **2** branch-line coupler, the LHM strips are designed with 50/√2Ω impedance and the MS strips with 50Ω impedance. The design frequency is chosen at 1.7 GHz so that again all sides are λ/4 long. In this case, the MS lines used are 2.342 mm wide and 23.645 mm long. The LHM-line strip comprises 3 unit cells of width 4.017 mm and length 5 mm each. The latter is loaded with 2.7 nH shunt inductors and 2.4 pF series capacitors, with terminating 4 pF capacitors for the LHM lines.

The type **2** branch-line coupler splits the input power equally between the two forward ports (through and coupled) and the backward port is isolated. As will be appreciated, the magnitude response is very similar to that of the type **1** branch-line coupler. From theory (equation (23)) and verified from the simulation results in FIG. **38**(*d*), the through port (port **3**) undergoes a phase shift of 90° and the coupled port (port **4**) undergoes a phase shift of 0° with respect to the input.

A conventional branch-line coupler allows for equal power split between the output ports but with −90° and −180° phase shifts with respect to the input (see FIGS. **38**(*a*) to **38**(*c*)). As will be appreciated, the present branch-line couplers offer more options in the design of circuits involving branch-line couplers. than available with conventional branch-line couplers. Specifically either a positive or a negative phase quadrature at the through port can be achieved, associated with a phase compensation at the coupled port.

The present coupled-line coupler demonstrates superior performance in terms of coupling, isolation and return loss when compared to a conventional microstrip coupled-line coupler of the same length, line spacing and propagation constant. Moreover, it is possible to realize such MS/LHM coupled-line couplers to achieve an arbitrary coupling coefficient. Furthermore, MS/LHM branch-line couplers possess similar functionality to their conventional counterparts when considering the magnitude of the power transfer between the ports. However, new functionality is added by the ability to obtain phase compensation at the coupled port (0° phase shift with respect to the input) along with a choice of either a positive or a negative phase quadrature (±90° phase shift) at the through port. On the other hand, the corresponding bandwidth remains comparable to that of conventional, commensurate, microstrip branch-line couplers.

Backward Leaky-Wave Antenna Using Metamaterial

Charged particles traveling at speeds greater than the phase velocity of light in a medium emit coherent radiation better known as Cherenkov radiation. The angle of the radiated conical wave front is given by the velocity of the particle (V) with respect to the phase velocity of EM waves (v) within the medium in the following manner:

$$\mathrm{Cos}(\theta) = v/V = \frac{c/n_0}{V} \tag{39}$$

where:

n_0 is the refractive index of the surrounding medium;

c is the speed of light in a vacuum; and

θ is the angle between the particle velocity and the radiated EM wave front.

This expression suggests that in a medium with negative no, the angle θ becomes obtuse. This implies that radiation is directed backward rather than forward, as is the case in a RHM.

Similarly, if a periodic guiding structure supports Bloch currents (moving charge) or equivalently EM waves with phase velocities greater than the speed of light, the angle of the radiated wave front is derived from equation (39) by letting V be the phase velocity of the EM wave along the guiding interface. This is due to the phase matching condition along the interface of the guide and surrounding medium. If the guiding structure is a medium with an effective refractive index n_1, and the surrounding medium has a refractive index n_0, then the angle of the radiated wave front is given by the following expression:

$$\mathrm{Cos}(\theta) = \frac{c/n_0}{c/n_1} = \frac{n_1}{n_0} \tag{40}$$

The above equation indicates that if the refractive index of the guiding medium (n_1) is negative, the radiation emitted into a RHM will be directed backward. It is in fact the phase advancement (backward-wave propagation) that causes backward radiation into the surrounding medium.

In order to excite backward-wave radiation from a dual transmission line LHM into free space, the L, C parameters need to be chosen such that the effective refractive index of the LHM, (n_1), is negative and smaller in magnitude than one, as indicated by equation (40). Equivalently, the magnitude of the propagation constant along the guiding LHM needs to be designed to be smaller in magnitude than the propagation constant in free-space k_0.

A radiating LHM antenna at 15 GHz based on dual transmission lines of the type shown in FIG. **13** was created. The LHM antenna includes 16 unit cells, with each unit cell having a dimension of 4.268 mm, approximately a factor of 5 smaller than the free-space wavelength of 2 cm at 15 GHz. Thus, the antenna can be treated as an effective medium. Commercial method of moments software was used to design the layout of the antenna. The LHM was fabricated by a mask/photo-etching technique on a 20-mil thick Rogers™ RO3203 circuit board with a relative permittivity of 3. The interconnecting transmission line sections were implemented in coplanar waveguide (CPW) technology. The transmission lines include a planar center conductor with two adjacent ground planes on either side. In the coplanar waveguide configuration, both ground planes and the center conductor lie in the same plane, which allows the simple integration of shunt inductors and series capacitors. The gaps in the CPW center conductor serve as the series capacitors and the narrow lines connecting the center conductor to the coplanar ground planes act as the shunt inductors. It is in fact these capacitive gaps that radiate in the structure and cause a backward emerging transverse magnetic wavefront. On the contrary, the inductive lines are non-radiating due to the antiparallel currents flowing on each pair of inductive lines. This odd symmetry causes cancellation in the far field and leads to low cross-polarization levels.

Although there are various radiating structures that exhibit phase and group velocities of opposite sign, the proposed structure, unlike conventional structures operates in the long wavelength regime and demonstrates backward-wave radiation in its lowest passband of operation. The proposed structure supports a backward-wave fundamental spatial harmonic that radiates. Early examples of backward-wave radiating structures include the helix antenna, corrugated dielectric, or metallic surfaces, and periodic arrays of radiating elements fed by slow wave transmission line sections of large periodic spacing (d>λ/2). These structures, however, radiate in higher-order passbands (exhibit higher-order radiating spatial harmonics) and therefore, effective material constants such as a refractive index cannot in general be defined. On the other hand, log-periodic dipole arrays and related uniform dipole arrays with a transposed feed have shown to produce backward waves even for small longitudinal periodic spacings. Nevertheless, the dipoles are resonant so element dimensions still remain electrically large (~λ/2) and therefore effective material parameters, e and m cannot be defined.

Super-Lens Formed From Metamaterials and RHM

The present metamaterial is also suitable for use in a focusing device that overcomes diffraction limits, hereinafter referred to as a "super-lens". The super-lens includes two-field focusing devices of the type previously discussed and is formed by sandwiching the LHM between the two RHM at two parallel interfaces. The LHM is a planar slab having a grid of printed metallic strips over a ground plane, loaded with series capacitors C and shunt inductors L. The two RHMs are two unloaded printed grids which act as homogeneous and isotropic media with positive indices of refraction.

FIG. **39** illustrates the planar transmission line left-handed super-lens. The unit cell of the left-handed grid is shown in the top insert while the unit cell of the positive refractive index grid is shown in the bottom insert. The super-lens is fabricated on a grounded microwave substrate (Rogers™ RO3003) of thickness 60 mil (1.52 mm) and dielectric constant $\in_r$=3.00. The left-handed slab has a 5×19 grid of printed metallic strips (microstrip lines) loaded with series chip capacitors C and shunt chip inductors L to the ground. Each unit cell has dimensions 8.40 mm×8.40 mm and therefore is much smaller than the nominal operating wavelength of 15.59 cm at 1 GHz. Hence, the loaded periodic grid acts as an effective medium exhibiting a negative index of refraction. The left-handed planar slab is sandwiched between two commensurate unloaded printed grids that act as effective homogenous media with positive indices of refraction. The unloaded grid and ground plane behave like a dielectrically loaded parallel-plate waveguide, but in addition allow simple measurement of the guided fields through proximity coupling. The left-handed grid is designed so that it is impedance matched and exhibits a refractive index of −1 relative to the unloaded grids at the design frequency of 1.00 GHz.

The first unloaded grid is excited at a point which is imaged by the left-handed slab to the second unloaded grid, with a vertical monopole fed by a coaxial cable through the ground plane. The monopole attaches the center conductor of the coaxial cable to a point on the unloaded grid, while the outer conductor of the coaxial cable attaches to the ground plane. The vertical monopole lies along the center row (row **0**), located 2.5 unit cells away from the first interface of the left-handed slab. According to geometrical optics, the source and image should be symmetrically positioned with respect to the left-handed slab. This is due to the fact that the distance from the source to the first interface (2.5 unit cells) is half the left-handed slab thickness (5 cells). The set-up shown in FIG. **39** is a practical implementation for imaging a point source from one homogeneous dielectric to another using a left-handed slab.

The vertical electric field over the entire structure is measured using a detecting probe. The field is detected 0.8 mm above the entire surface of the structure, using a short vertical probe connected to a Hewlett-Packard Vector Network Analyzer model 8753D. Port **1** of the network analyzer is connected to the coaxial cable that feeds the exciting monopole. Port **2** is connected by a separate coaxial cable to the detecting probe that is scanned above the surface of the structure using a computer-controlled stepper motor. The measured transmission coefficient is proportional to the voltage of the grid nodes with respect to the ground plane. The best focusing results were observed at 1.057 GHz, a frequency slightly higher than the design frequency of 1.00 GHz. This is primarily due to the variation of chip inductors and capacitors from their nominal values, as well as fabrication tolerances in printing the grid lines. The measured vertical electric field above each unit cell for the entire structure is shown in FIG. **40**, at a frequency of 1.057 GHz. The plot is normalized with respect to the source amplitude. The source is located at (column, row)=**(0,0)** and the image at **(10,0)**, whereas the first and second interfaces are located between columns **2** & **3** and **7** & **8**, respectively. As shown, the enhancement of evanescent waves is quite evident at the second interface of the left-handed slab near the center row (row **0**) and the results agree well with microwave-circuit simulations. FIG. **41** explicitly shows the measured electric field along row **0** to emphasize the growing evanescent fields within the left-handed lens. The vertical dashed lines identify the source at column **0** and the image at column **10** while the vertical solid lines identify the interfaces of the left-handed slab.

Geometrical optics establish that the source and its image should be separated by twice the thickness of the slab (2×5=10 unit cells). Thus, the measured vertical electric field along the image column (column **10**) is shown in FIG. **42**. Plotted in the same Figure are the measured transverse patterns at the source column (column **0**), as well as the theoretical diffraction-limited pattern. All patterns in FIG. **42** are normalized to unity for comparison purposes. Nevertheless, the measured source and image peaks lie within 7% of each other. In addition, it is important to explain how the theoretical diffraction-limited pattern was computed. Due to the close proximity (0.54 effective wavelengths) of the source and its image, evanescent waves that reach the image should be accounted for. For this reason, the diffraction-limited pattern assumes that the propagating components are focused whereas the evanescent components are not neglected, but rather assumed to exponentially decay from the source to the image, with attenuation factors corresponding to a refractive index of n=+1. Expressions for the voltage (V) at the image plane (column **10**) are given by the integral in equation 41 below:

$$V(x) = C\int_{-\infty}^{\infty} \frac{e^{ik_{z1}D} e^{ik_{z2}D} e^{ik_x x}}{k_{z1}} \, dk_x \tag{41}$$

$k_{z1}=-k_{z2}=\sqrt{k_o^2-k_x^2}$ *for* $k_{.x.}<k_o$ (propagating waves)

$k_{z1}=k_{z2}=i\sqrt{k_x^2-k_o^2}$ *for* $k_{.x.}>k_o$ (evanescent waves)

where:

C is a constant that normalizes V(0)=1;

D is the width of the lens; and

k_o is the intrinsic wavenumber in all grid media.

The half-power beamwidth of the diffraction-limited image shown in FIG. **42** is 129 degrees. It was found that the diffraction-limited image including attenuating evanescent waves and the image neglecting them altogether are almost identical.

With this clarification in mind, a comparison of the images shown in FIG. **42** can be made. Clearly, the measured image pattern is narrower than the theoretical diffraction-limited one. The measured half-power beamwidth is 75 degrees. This is significantly narrower than the 129 degrees for the diffraction-limited image. This establishes that it is possible to overcome the diffraction limit when imaging from one homogeneous dielectric to another through a left-handed isotropic lens. This narrowing of the beamwidth beyond the diffraction limit can be ascribed to the enhancement of the evanescent waves evident in FIGS. **39** and **40**. Nevertheless, the image is still imperfect since the source beamwidth is narrower than that of the image. This is not surprising considering that slight material losses and mismatches at the lens interfaces lead to departures from the n=−1 condition and thus, degrade the ability of a left-handed lens to achieve perfect imaging.

Resonance Cone Antenna

Resonance cone metamaterial may also be used in an antenna, by shunting the metamaterial with inductors, at the transmission line intersections. FIG. **43** shows a resonance cone antenna **4300** constructed using metamaterial. The antenna includes a 2×3 array of macrocells. Each macrocell includes a plurality of microcells of orthogonal pairs of transmission line segments joined in a substantially rectangular fashion. The segments are loaded periodically with lumped capacitors in one direction and lumped inductors in a perpendicular direction. The microcells of the macrocells have a shared orientation that is different from the orientation of microcells in adjacent macrocells by 90 degrees. Macrocells are joined by transition regions similar to those described previously with reference to the focusing device. The transmission line segments of the transition regions include both lumped capacitors and inductors arranged in a manner consistent with FIG. **24**. The device input, or feed point, is located at the transition region adjacent the center of the macrocell array.

This arrangement of metamaterials, and input location allows input waves of compatible wavelength, to form a resonance cone patern of two squares that are multi-refracted within the macrocell array. This gives radiation patterns that can be close to the ground plane or elevated, but do not suffer from unwanted edge interactions as shown in FIGS. **44** and **45**. Moreover, as the frequency departs from the design value, the resonance cone squares turn into expanding or contracting square spirals that become weak before reaching the grid edges due to radiation or ohmic losses. This phenomenon is inherently non-resonant which leads to broadened operating bandwidths as compares to patch antennas over ground.

As will be appreciated it has been shown that negative refraction and focusing of electromagnetic waves can be achieved in metamaterials that support backward waves without employing resonances or directly synthesizing the permittivity and permeability. Schemes for fabricating such media by appropriately loading a host transmission line medium have also been described. The resulting planar topology permits LHM structures to be readily integrated with conventional planar microwave circuits and devices and used in a variety of applications to guide and control electromagnetic radiation.

Although preferred embodiments of the present invention have been described, those of skill in the art will appreciate that variations and modifications may be made without departing from the spirit and scope thereof as defined by the appended claims.

What is claimed is:

1. A planar metamaterial comprising:

two substantially orthogonal, coplanar sets of transmission lines, said transmission lines being spaced with a periodicity, loaded with capacitors with said periodicity, and shunted with inductors with said periodicity such that for an electromagnetic wave having a wavelength greater than said periodicity and traveling along the plane of said transmission lines, an effective permeability and permittivity of said metamaterial are simultaneously negative.

2. A planar metamaterial according to claim **1** wherein the wavelength of said electromagnetic wave is greater than said periodicity by an order of magnitude.

3. A linear metamaterial comprising:

a transmission line, having a linear dimension, and being loaded with capacitors, and shunted with an inductor such that for an electromagnetic wave having a wavelength greater than said linear dimension and traveling along the axis of said transmission line, an effective permeability and permittivity of said metamaterial are simultaneously negative.

4. A planar metamaterial according to claim **3** wherein the wavelength of said electromagnetic wave is greater than said periodicity by an order of magnitude.

5. A metamaterial according to claim **4** wherein the values of said capacitors and inductor are proportioned to provide a continuous passband for said electromagnetic wave.

6. A metamaterial according to claim **4** wherein said transmission line includes two substantially identical capacitors on either side of said inductor.

7. A metamaterial according to claim **4** further comprising a plurality of substantially identical transmission lines arranged in series.

8. A metamaterial according to claim **7** wherein each transmission line includes two substantially identical capacitors on either side of said inductor.

9. A metamaterial according to claim **8** wherein the values of said capacitors and inductor are proportioned to provide a continuous passband for said electromagnetic wave.

10. A planar resonance cone metamaterial comprising:

a first set of transmission lines, spaced with a periodicity, and loaded with capacitors with said periodicity;

a second set of transmission lines, substantially orthogonal and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said periodicity, and loaded with inductors with said periodicity, said first and second sets of transmission lines exhibiting characteristics such that for an electromagnetic wave having a wavelength greater than said periodicity by an order of magnitude, and traveling along the linear axis of said first set of transmission lines, an effective permittivity of said metamaterial is positive such that for an electromagnetic wave having a wavelength greater than said periodicity by an order of magnitude and traveling along the linear axis of said second set of transmission lines, the effective permittivity of said metamaterial is negative.

11. A metamaterial according to claim **10** further comprising an input on the perimeter of said metamaterial coincident with an intersection of one transmission line of said first set and one transmission line of said second set and a plurality of outputs on the perimeter of said metamaterial coincident with intersections of transmission lines of said first and second sets.

12. A planar resonance cone metamaterial comprising:

a first set of transmission lines, spaced with a first periodicity, and loaded with capacitors with a second periodicity;

a second set of transmission lines, substantially orthogonal and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said second periodicity, and being loaded with inductors with said first periodicity whereby for an electromagnetic wave having a wavelength greater than said first and second periodicities by an order of magnitude and traveling along the longitudinal axis of said first set of transmission lines, an effective permittivity of said metamaterial is positive and for an electromagnetic wave having a wavelength greater than said first and second priodocities and traveling along the longitudinal axis of said second set of transmission lines, the effective permittivity of said metamaterial is negative.

13. A near field focusing device comprising:

a first set of transmission lines, said first set of transmission lines being spaced with a first periodicity and loaded with capacitors with a second periodicity;

a second set of transmission lines, substantially orthogonal to, and coplanar with said first set of transmission lines, said second set of transmission lines being spaced with said second periodicity, loaded with capacitors with said first periodicity, and shunted with inductors, said first set of transmission lines intersecting said second set of transmission lines such that for an electromagnetic wave having a wavelength greater than said first or second periodicity by an order of magnitude, and traveling along the plane of said transmission lines, an effective permeability and permittivity of said metamaterial are simultaneously negative; and

a planar waveguide having a flat extent, coupled to said transmission lines, such that said flat extent is parallel to one set of transmission lines.

14. A phase-shifting device comprising:

a transmission line, having a linear dimension and characteristic impedance;

capacitors loaded on said transmission line; and

an inductor shunting said transmission line, said transmission line exhibiting characteristics such that for an electromagnetic wave having a wavelength greater than said linear dimension by an order of magnitude and traveling along the axis of said transmission line, an

effective permeability and permittivity of transmission are simultaneously negative and such that said transmission line provides a continuous passband for said electromagnetic wave along said transmission line.

15. A phase-shifting device according to claim **14** further comprising a plurality of transmission lines coupled in series.

16. A phase-shifting-device according to claim **15** wherein each transmission line includes a pair of identical capacitors on either side of said inductor.

17. A near field focussing device comprising:

a parallel-plate waveguide; and

a negative refractive index metamaterial in line with said waveguide and forming an interface therewith.

18. A focussing device according to claim **17** wherein said waveguide serves as a right-handed medium, electromagnetic radiation passing through said interface from said waveguide being focussed in said metamaterial.

(57) **ABSTRACT**

Arrangement of resonators in an aperiodic configurations are described, which can be used for electromagnetic cloaking of objects. The overall assembly of resonators, as structures, do not all repeat periodically and at least some of the resonators are spaced such that their phase centers are separated by more than a wavelength. The arrangements can include resonators of several different sizes and/or geometries arranged so that each size or geometry corresponds to a moderate or high "Q" response that resonates within a specific frequency range, and that arrangement within that specific grouping of akin elements is periodic in the overall structure. The relative spacing and arrangement of groupings can be defined by self similarity and origin symmetry.

RELATED APPLICATION

This application claims priority to U.S. Provisional Patent Application No. 61/189,966, filed 25 Aug. 2008 and entitled "Method and Apparatus for Wideband Electromagnetic Cloaking, Negative Refractive Index Lensing and Metamaterial Applications," the entire contents of which are incorporated herein by reference.

BACKGROUND

Much time and effort has been devoted to the quest for so-called invisibility machines. Beyond science fiction, however, there has been little if any real progress toward this goal.

Materials with negative permittivity and permeability leading to negative index of refraction were theorized by Russian noted physicist Victor Veselago in his seminal paper in *Soviet Physics* USPEKHI, 10, 509 (1968). Since that time, metamaterials have been developed that produce negative index of refraction, subject to various constraints. Such materials are artificially engineered micro/nanostructures that, at given frequencies, show negative permeability and permittivity. Metamaterials have been shown to produce narrow band, e.g., typically less than 5%, response such as bent-back lensing. Such metamaterials produce such a negative-index effect by utilizing a closely-spaced periodic lattice of resonators, such as split-ring resonators, that all resonate. Previous metamaterials provide a negative index of refraction when a sub-wavelength spacing is used for the resonators.

In the microwave regime, certain techniques have been developed to utilize radiation-absorbing materials or coatings to reduce the radar cross section of airborne missiles and vehicles. While such absorbing materials can provide an effective reduction in radar cross section, these results are largely limited to small ranges of electromagnetic radiation.

SUMMARY

Embodiments of the present disclosure can provide techniques, including systems and/or methods, for cloaking objects at certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands). Such techniques can provide an effective electromagnetic lens and/or lensing effect for certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands).

The effects produced by such techniques can include cloaking or so-called invisibility of the object(s) at the noted wavelengths or bands. Representative frequencies of operation can include, but are not limited to, those over a range of 500 MHz to 1.3 GHz, though others may of course be realized. Operation at other frequencies, including for example those of visible light, infrared, ultraviolet, and as well as microwave EM radiation, e.g., K, Ka, X-bands, etc. may be realized, e.g., by appropriate scaling of dimensions and selection of shape of the resonator elements.

Exemplary embodiments of the present disclosure can include a novel arrangement of resonators in an aperiodic configuration or lattice. The overall assembly of resonators, as structures, do not all repeat periodically and at least some of the resonators are spaced such that their phase centers are separated by more than a wavelength. The arrangements can include resonators of several different sizes and/or geometries arranged so that each size or geometry ("grouping") corresponds to a moderate or high "Q" (that is moderate or low bandwidth) response that resonates within a specific frequency range, and that arrangement within that specific grouping of akin elements is periodic in the overall structure—even though the structure as a whole is not an entirely periodic arrangement of resonators. The relative spacing and arrangement of groupings (at least one for each specific frequency range) can be defined by self similarity and origin symmetry, where the "origin" arises at the center of a structure (or part of the structure) individually designed to have the wideband metamaterial property.

For exemplary embodiments, fractal resonators can be used for the resonators in such structures because of their control of passbands, and smaller sizes compared to non-fractal based resonators. Their benefit arises from a size standpoint because they can be used to shrink the resonator (s), while control of passbands can reduce or eliminates issues of harmonic passbands that would resonate at frequencies not desired.

It should be understood that other embodiments of wideband electromagnetic resonator or cloaking systems and methods according to the present disclosure will become readily apparent to those skilled in the art from the following detailed description, wherein exemplary embodiments are shown and described by way of illustration. The systems and methods of the present disclosure are capable of other and different embodiments, and details of such are capable of modification in various other respects. Accordingly, the drawings and detailed description are to be regarded as illustrative in nature and not as restrictive.

BRIEF DESCRIPTION OF THE DRAWINGS

Aspects of the disclosure may be more fully understood from the following description when read together with the accompanying drawings, which are to be regarded as illustrative in nature, and not as limiting. The drawings are not necessarily to scale, emphasis instead being placed on the principles of the disclosure. In the drawings:

FIG. **1** depicts a diagrammatic plan view of a resonator cloaking system utilizing a number of cylindrical shells, in accordance with exemplary embodiments of the present disclosure;

FIG. **2** depicts a diagrammatic plan view of a resonator cloaking system utilizing a number of shells having an elliptical cross-section, in accordance with an alternate embodiment of the present disclosure;

FIG. **3** depicts an exemplary embodiment of a portion of shell that includes repeated conductive traces that are configured in a fractal-like shape; and

FIG. **4** depicts a perspective view (photograph) of an exemplary embodiment of the present disclosure.

While certain embodiments depicted in the drawings, one skilled in the art will appreciate that the embodiments depicted are illustrative and that variations of those shown, as well as other embodiments described herein, may be envisioned and practiced within the scope of the present disclosure.

DETAILED DESCRIPTION

The present disclosure is directed to novel arrangements of resonators useful for obscuring or hiding objects at given bands of electromagnetic radiation. Embodiments of the present disclosure can provide techniques, including systems and/or methods, for hiding or obscuring objects at certain wavelengths/frequencies or over certain wavelength/frequency ranges or bands. Such techniques can provide an

effective electromagnetic lens and/or lensing effect for certain wavelengths/frequencies or over certain wavelength/frequency ranges or bands. The effects produced by such techniques can include cloaking or so-called invisibility of the object(s) at the noted wavelengths or bands.

Representative frequencies of operation can include, but are not limited to, those over a range of about 500 MHz to about 1.3 GHz, though others may of course be realized. Operation at other frequencies, including for example those of visible light, infrared, ultraviolet, and as well as microwave EM radiation, e.g., K, Ka, X-bands, etc. may be realized, e.g., by appropriate scaling of dimensions and selection of shape of the resonator elements.

Embodiments of the present disclosure include arrangement of resonators or resonant structures in aperiodic configurations or lattices. The overall assembly of resonator structures can include nested or concentric shells, that each include repeated patterns of resonant structures. The resonant structures can be configured as a close-packed arrangement of electrically conductive material. The resonant structures can be located on the surface of a circuit board.

The overall assemblies, as structures, do not all repeat periodically and at least some of the resonators are spaced such that their phase centers are separated by more than a wavelength. The arrangements can include resonators of several different sizes and/or geometries arranged so that each size or geometry ("grouping") corresponds to a moderate or high quality-factor "Q" response (that is, one allowing for a moderate or low bandwidth) that resonates within a specific frequency range, and that arrangement within that specific grouping of like elements is periodic in the overall structure—even though the structure as a whole is not an entirely periodic arrangement of resonators. The relative spacing and arrangement of groupings (at least one for each specific frequency range) can be defined by self similarity and origin symmetry, where the "origin" arises at the center of a structure (or part of the structure) individually designed to have the wideband metamaterial property.

For exemplary embodiments, fractal resonators can be used for the resonators because of their control of passbands, and smaller sizes. A main benefit of such resonators arises from a size standpoint because they can be used to shrink the resonator(s), while control of passbands can reduce/mitigate or eliminate issues of harmonic passbands that would resonate at frequencies not desired.

Exemplary embodiments of a resonator system for use at microwave (or nearby) frequencies can be built from belts of circuit boards festooned with resonators. These belts can function to slip the microwaves around an object located within the belts, so the object is effectively invisible and "see thru" at the microwave frequencies. Belts, or shells, having similar closed-packed arrangements for operation at a first passband can be positioned within a wavelength of one another, e.g., $\frac{1}{10}\lambda$, $\frac{1}{8}\lambda$, $\frac{1}{4}\lambda$, $\frac{1}{2}\lambda$, etc.

An observer can observe an original image or signal, without it being blocked by the cloaked object. Using no power, the fractal cloak can replicates the original signal (that is, the signal before blocking) with great fidelity. Exemplary embodiments can function over a bandwidth from about 500 MHz to approximately 1500 MHz (1.5 GHz), providing 3:1 bandwidth; operation within or near such can frequencies can provide other bandwidths as well, such as 1:1 up to 2:1 and up to about 3:1.

FIG. **1** depicts a diagrammatic plan view of a cloaking system **100** and RF testing set up in accordance with exemplary embodiments of the present disclosure. As shown in FIG. **1**, a number of concentric shells (or bands) **102** are placed on a platform (parallel to the plane of the drawing). The shells include a flexible substrate (e.g., polyimide with or without composite reinforcement) with conductive traces (e.g., copper, silver, etc.) in fractal shapes or outlines. The shells **102** surround an object to be cloaked (shown as **104** in FIG. **1**). A transmitting antenna **1** and a receiving antenna **2** are configured at different sides of the system **100**, for verifying efficacy of the cloaking system **100** and recording results. The shells **102** can be held in place by radial supports **106** (while only four are shown, **12** were used in the exemplary embodiment indicated).

The shells indicated in FIG. **1** are of two types, one set (A**1**-A**4**) configured for optimal operation over a first wavelength/frequency range, and another set (B**1**-B**3**) configured for optimal operation over a second wavelength/frequency range. (The numbering of the shells is of course arbitrary and can be reordered, e.g., reversed.)

For an exemplary embodiment of system **100**, the outer set of shells (A**1**-A**4**, with A**1** being the innermost and A**4** the outmost) had a height of about 3 to 4 inches (e.g., 3.5 inches) and the inner set of shells had a height of about 1 inch less (e.g., about 2.5 to 3 inches). The spacing between the shells with a larger fractal shape (A**1**-A**4**) was about 2.4 cm while the spacing between shells of smaller fractal generator shapes (B**1**-B**3**) was about 2.15 cm (along a radial direction). In a preferred embodiment, shell A**4** was placed between shell B**2** and B**3** as shown. The resonators formed on each shell by the fractal shapes can be configured so as to be closely coupled (e.g., by capacitive coupling) and can serve to propagate a plasmonic wave.

It will be appreciated that while, two types of shells and a given number of shells per set are indicated in FIG. **1**, the number of shell types and number of shells for each set can be selected as desired, and may be optimized for different applications, e.g., wavelength/frequency bands.

FIG. **2** depicts a diagrammatic plan view of a cloaking system (or electrical resonator system) according to an alternate embodiment in which the individual shells have an elliptical cross section. As shown in FIG. **2**, a system **200** for cloaking can include a number of concentric shells (or bands) **202**. These shells can be held in place with respect to one another by suitable fixing means, e.g., they can be placed on a platform (parallel to the plane of the drawing) and/or held with a frame. The shells **202** can include a flexible substrate (e.g., polyimide with or without composite reinforcement) with a close-packed arrangement of electrically conductive material formed on the first surface. As stated previously for FIG. **1**, the closed-packed arrangement can include a number of self-similar electrical resonator shapes. The resonator shapes can be made from conductive traces (e.g., copper, silver, gold, silver-based ink, etc.) having a desired shape, e.g., fractal shape, split-ring shape, and the like. The shells **202** can surround an object to be cloaked, as indicated in FIG. **2**.

As indicated in FIG. **2** (by dashed lines **1** and **2** and arrows), the various shells themselves do not have to form closed surfaces. Rather, one or more shells can form open surfaces. This can allow for preferential cloaking of the object in one direction or over a given angle (solid angle). Moreover, while dashed lines **1** and **2** are shown intersecting shells B**1**-B**3** and A**1**-A**3** of system **200**, one or more shells of each group of shells (B**1**-B**3** and A**1**-A**3**) can be closed while others are open.

With further regard to FIGS. **1**-**2**, it should be appreciated that the cross-sections shown for each shell can represent closed geometric shapes, e.g., spherical and ellipsoidal shells.

As indicated previously, each shell of a cloaking system can include multiple resonators. The resonators can be repeated patterns of conductive traces. These conductive traces can be closed geometric shapes, e.g., rings, loops, closed fractals, etc. The resonator(s) can being self similar to at least second iteration. The resonators can include split-ring shapes, for some embodiments. The resonant structures are not required to be closed shapes, however, and open shapes can be used for such.

In exemplary embodiments, the closed loops can be configured as a fractals or fractal-based shapes, e.g., as depicted by **302** in FIG. **3** for an exemplary embodiment of a shell **300**, or **402** in FIG. **4**. The dimensions and type of fractal shape can be the same for each shell type but can vary between shell types. This variation (e.g., scaling of the same fractal shape) can afford increased bandwidth for the cloaking characteristics of the system (e.g., system **100** of FIG. **1**) This can lead to periodicity of the fractal shapes of common shell types but aperiodicity between the fractal shapes of different shell types.

Examples of suitable fractal shapes (for use for shells and/or a scatting object) can include, but are not limited to, fractal shapes described in one or more of the following patents, owned by the assignee of the present disclosure, the entire contents of all of which are incorporated herein by reference: U.S. Pat. Nos. 6,452,553; 6,104,349; 6,140,975; 7,145,513; 7,256,751; 6,127,977; 6,476,766; 7,019,695; 7,215,290; 6,445,352; 7,126,537; 7,190,318; 6,985,122; 7,345,642; and, U.S. Pat. No. 7,456,799.

Other suitable fractal shape for the resonant structures can include any of the following: a Koch fractal, a Minkowski fractal, a Cantor fractal, a torn square fractal, a Mandelbrot, a Caley tree fractal, a monkey's swing fractal, a Sierpinski gasket, and a Julia fractal, a contour set fractal, a Sierpinski triangle fractal, a Menger sponge fractal, a dragon curve fractal, a space-filling curve fractal, a Koch curve fractal, an Iypanov fractal, and a Kleinian group fractal.

FIG. **3** depicts an exemplary embodiment of a shell **300** (only a portion is shown) that includes repeated conductive traces that are configured in a fractal shape **302** (the individual closed traces). For the exemplary embodiment shown, each resonator shape **302** is about 1 cm on a side. Such resonator could, e.g., be used for the fractal shapes of shells B**1**-B**3** of FIG. **1**, in which case similar fractal shapes of larger size (e.g., about 1.5 cm on a side) could be used for shells A**1**-A**4**. The conductive trace is preferably made of copper. While exemplary fractal shapes are shown in FIG. **3**, the present disclosure is not limited to such and any other suitable fractal shapes (including generator motifs) may be used in accordance with the present disclosure.

It will be appreciated that the resonant structures of the shells may be formed or made by any suitable techniques and with any suitable materials. For example, semiconductors with desired doping levels and dopants may be used as conductive materials. Suitable metals or metal containing compounds may be used. Suitable techniques may be used to place conductors on/in a shell, including, but no limited to, printing techniques, photolithography techniques, etching techniques, and the like.

It will also be appreciated that the shells may be made of any suitable material(s). Printed circuit board materials may be used. Flexible circuit board materials are preferred. Other material may, however, be used for the shells and the shells themselves can be made of non-continuous elements, e.g., a frame or framework. For example, various plastics may be used.

FIG. **4** depicts a perspective view (photograph) of an exemplary embodiment of a cloak system **400** according to the present disclosure. As shown, the system includes a number of resonator shells **402** each having a close-packed arrangement of electrically conductive material (self-similar resonators **404**) formed on one surface. Two different shell configurations are shown, four larger shells and two smaller shells. The smaller shells included close-packed arrangements of resonator structures in which each resonator shape (as shown by **302** in FIG. **3**) was about 1 cm on a side. Similar fractal shapes of larger size (e.g., about 1.5 cm on a side) were used for the larger shells.

In FIG. **4**, a transmitting (source) antenna and a receiving antenna are shown as triangular shapes on the left and right, respectively (though functionally of each could of course be interchanged for the other). Twelve radially arrayed spacers are shown in FIG. **4**. The system **400** is shown supported on a Nalgene tank and Delrin platform and Delrin supports (radial supports) RF absorbers were placed in the immediate vicinity of the set up; further RF tripods (e.g., available from ETS) were used; all such materials were substantially transparent at the RF frequencies investigated/used. The cloak system **400** consists of six belts of fractal metamaterial (i.e., fractal-resonant structures shown in FIG. **3**) on flexible Taconic EF35 (low loss) circuit board. The belts are shown surround a scattering ring (object). The arrangement is supported by RF transparent plastics in a comb support. The entire system **400** was shown to be easily built up and broken down within a minute or two. The scale in FIG. **4** is about 0.7 meters across. The height of each shell can of course be selected as desired depending on the situation/application.

While embodiments are shown and described herein as having shells in the shape of concentric rings (circular cylinders), shells can take other shapes in other embodiments. For example, one or more shells could have a generally spherical shape (with minor deviations for structural support). In an exemplary embodiment, the shells could form a nested arrangement of such spherical shapes, around an object to be shielded (at the targeted/selected frequencies/wavelengths). Shell cross-sections of angular shapes, e.g., triangular, hexagonal, while not preferred, may be used.

One skilled in the art will appreciate that embodiments and/or portions of embodiments of the present disclosure can be implemented in/with computer-readable storage media (e.g., hardware, software, firmware, or any combinations of such), and can be distributed and/or practiced over one or more networks. Steps or operations (or portions of such) as described herein, including processing functions to derive, learn, or calculate formula and/or mathematical models utilized and/or produced by the embodiments of the present disclosure, can be processed by one or more suitable processors, e.g., central processing units ("CPUs") implementing suitable code/instructions in any suitable language (machine dependent on machine independent).

While certain embodiments and/or aspects have been described herein, it will be understood by one skilled in the art that the methods, systems, and apparatus of the present disclosure may be embodied in other specific forms without departing from the spirit thereof.

For example, while certain wavelengths/frequencies of operation have been described, these are merely representative and other wavelength/frequencies may be utilized or achieved within the scope of the present disclosure.

Furthermore, while certain preferred fractal generator shapes have been described others may be used within the scope of the present disclosure. Accordingly, the embodi-

ments described herein are to be considered in all respects as illustrative of the present disclosure and not restrictive.

What is claimed is:

1. An electrical resonator system, comprising:

a plurality of concentric electrical resonator shells, each shell including a substrate having first and second surfaces and a close-packed arrangement of electrically conductive material formed on the first surface, wherein the closed-packed arrangement comprises a plurality of self-similar electrical resonator shapes and is configured to operate at a desired passband of electromagnetic radiation;

wherein the close-packed arrangements of at least two of the electrical resonator shells are different in size and/or shape; and

wherein a resonator in the close-packed arrangement comprises a second order or higher fractal.

2. The system of claim **1**, wherein said passband is about 2:1.

3. The system of claim **2**, wherein said passband is about 3:1.

4. The system of claim **1**, wherein the electrical system is configured and arranged so that radiation incident on the system from a given direction has an intensity on a point-by-point basis such at each respective antipodal point, relative to an object placed at the center of the system, the radiation has the same or similar intensity.

5. The system of claim **1**, wherein the system is configured and arranged so that radiation incident on the system from a direction in cylindrical coordinates has the same or similar intensity at the antipodal point after having traversed the system.

6. The system of claim **1**, wherein the plurality of shells comprises a first pair of shells having similar closed-packed arrangements for operation at a first passband, wherein the two shells are positioned within ⅛λ of one another.

7. The system of claim **6**, wherein the plurality of shells comprises a second pair of shells having similar closed-packed arrangements for operation at a second frequency band, wherein the two shells are positioned within ⅛λ of one another.

8. The system of claim **1**, wherein the plurality of shells are hemispherical.

9. The system of claim **1**, wherein the plurality of shells are cylindrical.

10. The system of claim **1**, wherein the plurality of shells are spherical.

11. The system of claim **1**, wherein said fractal is selected from the group consisting of a Koch fractal, a Minkowski fractal, a Cantor fractal, a torn square fractal, a Mandelbrot, a Caley tree fractal, a monkey's swing fractal, a Sierpinski gasket, and a Julia fractal.

12. The system of claim **1**, wherein the fractal is selected from the group consisting of a contour set fractal, a Sierpinski triangle fractal, a Menger sponge fractal, a dragon curve fractal, a space-filling curve fractal, a Koch curve fractal, a Lypanov fractal, and a Kleinian group fractal.

13. The system of claim **1**, wherein the plurality of concentric electrical resonator shells are configured and arranged for operation at K band, Ka band, or X-band.

14. The system of claim **1**, wherein the system is operational over a bandwidth from about 500 MHz to about 1500 MHz.

(57) **ABSTRACT**

Systems according to the present disclosure provide one or more surfaces that function as power transferring surfaces for which at least a portion of the surface includes or is composed of "fractal cells" placed sufficiently closed close together to one another so that a surface (plasmonic) wave causes near replication of current present in one fractal cell in an adjacent fractal cell. A fractal of such a fractal cell can be of any suitable fractal shape and may have two or more iterations. The fractal cells may lie on a flat or curved sheet or layer and be composed in layers for wide bandwidth or multibandwidth transmission.

RELATED APPLICATION

This application is a continuation of application Ser. No. 14/071,235 filed 4 Nov. 2013, now U.S. Pat. No. 9,134,465, and entitled "Deflective Electromagnetic Shielding," which (i) claims priority to U.S. Provisional Patent Application No. 61/796,119, filed 3 Nov. 2012 and entitled "Deflective Shielding Via Electromagnetic Cloaking," and (ii) is also a continuation-in-part of U.S. patent application Ser. No. 14/043,781 filed 1 Oct. 2013, now abandoned, and entitled "Radiative Transfer and Power Control with Fractal Metamaterial and Plasmonics," which claims priority to U.S. Provisional Patent Application No. 61/744,651, filed 1 Oct. 2012 and entitled "Radiative Transfer and Power Control with Fractal Metamaterial and Plasmonics"; the entire contents of all of which previously-noted applications are incorporated herein by reference.

BACKGROUND

Much time and effort has been devoted to the quest for so-called invisibility machines. Beyond science fiction, however, there has been little if any real progress toward this goal.

Materials with negative permittivity and permeability leading to negative index of refraction were theorized by Russian noted physicist Victor Veselago in his seminal paper in *Soviet Physics* USPEKHI, 10, 509 (1968). Since that time, metamaterials have been developed that produce negative index of refraction, subject to various constraints. Such materials are artificially engineered micro/nanostructures that, at given frequencies, show negative permeability and permittivity. Metamaterials have been shown to produce narrow band, e.g., typically less than 5%, response such as bent-back lensing. Such metamaterials produce such a negative-index effect by utilizing a closely-spaced periodic lattice of resonators, such as split-ring resonators, that all resonate. Previous metamaterials provide a negative index of refraction when a sub-wavelength spacing is used for the resonators.

In the microwave regime, certain techniques have been developed to utilize radiation-absorbing materials or coatings to reduce the radar cross section of airborne missiles and vehicles. While such absorbing materials can provide an effective reduction in radar cross section, these results are largely limited to small ranges of electromagnetic radiation.

SUMMARY

The present disclosure is directed to systems and techniques that provide for desired transfer of radiation by using close packed arrangements of resonators having fractal shapes, i.e., "fractal cells." Systems and techniques according to the present disclosure provide one or more surfaces that act or function as power transfer surfaces or structures for which at least a portion of the surface or structure includes or is composed of "fractal cells" (fractal shapes) (as antennas or resonators) placed sufficiently closed close together to one another (e.g., less than 1/20 wavelength) to produce substantial replication of current present in one fractal cell in an adjacent fractal cell. The size of the fractal cells can be adjusted based on or tailored to a desired wavelength or wavelength range of operation.

A fractal of such a fractal cell can be of any suitable fractal shape and may have two or more iterations. The fractal cells may lie on a flat or curved sheet or layer and be composed in layers for wide bandwidth or multibandwidth transmission. The area of a surface (e.g., sheet) and its number of fractals determines the gain relative to a single fractal cell. As each cell is fed indirectly (e.g., plasmonicly) rather than directly, 'dead' or covered or out of resonance cells do not alter the ability of the other cells to work. The boundary edges of the surface may be terminated resistively so as to not degrade the cell performance at the edges. These surfaces may be referred to as fractal plasmonic surfaces (FPS's) and can provide benefits such as shielding for/against electromagnetic radiation.

Such a fractal plasmonic surface (FPS) may be used to transfer radiation, e.g., via evanescent wave transfer. In doing so such surfaces can be used to remove radiative power from one location to another, or divert it to another location. Such surfaces may be used to essentially diffuse power delivered to a part of the FPS and dissipate and or distribute it to other specific parts or globally. For example, a power "hotspot" supplied or hit with localized power may have the power spread out or diverted to other desired locations, e.g., different areas of a related machine or structure. In some embodiments, a FPS on a closed or curved surface may act as a cloaking device to divert power (in a wavelength or frequency of interest) from one side of the device to the other.

Exemplary embodiments of the present disclosure can provide techniques, including systems and/or methods, for cloaking objects at certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands). Such techniques can provide an effective electromagnetic lens and/or lensing effect for certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands).

In some embodiments, the effects produced by such techniques can include cloaking or so-called invisibility of the object(s) at the noted wavelengths or bands. Representative frequencies of operation can include, but are not limited to, those over a range of 500 MHz to 1.3 GHz, though others may of course be realized. Operation at other frequencies, including for example those of visible light, infrared, ultraviolet, and as well as microwave EM radiation, e.g., K, Ka, X-bands, etc. may be realized, e.g., by appropriate scaling of dimensions and selection of shape of the resonator elements.

Exemplary embodiments of the present disclosure can include a novel arrangement of resonators in a lattice-like configuration. The arrangements can include resonators of several different sizes and/or geometries arranged so that each size or geometry ("grouping") corresponds to a moderate or high quality factor, "Q," (that is moderate or low bandwidth) response that resonates within a specific frequency range.

For exemplary embodiments, fractal resonators can be used for the resonators in such structures because of their control of passbands, and smaller sizes compared to non-fractal based resonators. Their benefit arises from a size standpoint because they can be used to shrink the resonator(s), while control of passbands can reduce or eliminates issues of harmonic passbands that would resonate at frequencies not desired.

Further embodiments of the present disclosure are directed to scatterer or scattering structures. Additional embodiments of the present disclosure are directed to structures/techniques for activating and/or deactivating cloaking structures. Further embodiments of the present disclosure are directed to wideband absorbers.

It should be understood that other embodiments of FPS systems and methods according to the present disclosure will become readily apparent to those skilled in the art from the following detailed description, wherein exemplary embodiments are shown and described by way of illustration. The systems and methods of the present disclosure are capable of other and different embodiments, and details of such are capable of modification in various other respects. Accordingly, the drawings and detailed description are to be regarded as illustrative in nature and not as restrictive.

BRIEF DESCRIPTION OF THE DRAWINGS

Aspects of the disclosure may be more fully understood from the following description when read together with the accompanying drawings, which are to be regarded as illustrative in nature, and not as limiting. The drawings are not necessarily to scale, emphasis instead being placed on the principles of the disclosure. In the drawings:

FIG. **1** depicts a diagrammatic plan view of a fractal plasmonic surface (FPS), in accordance with exemplary embodiments of the present disclosure;

FIG. **2** depicts a diagrammatic plan view of a resonator cloaking system utilizing a number of cylindrical shells, in accordance with exemplary embodiments of the present disclosure; and

FIG. **3** depicts a diagrammatic plan view of a resonator cloaking system utilizing a number of shells having an elliptical cross-section, in accordance with an alternate embodiment of the present disclosure;

FIG. **4**A depicts an example of a fractal shield surrounding or on an arbitrary object; FIG. **4**B depicts exemplary objects for use with a fractal shield;

FIG. **5** illustrates the robustness or anti-fragility presented by a FPS under conditions where some fractal cells are damaged or otherwise inoperative; and

FIG. **6**A depicts an example of a fractal shield dissipating/transferring incident radiation; FIG. **6**B shows another example in which directed radiation is incident on a rectangular shield.

While certain embodiments depicted in the drawings, one skilled in the art will appreciate that the embodiments depicted are illustrative and that variations of those shown, as well as other embodiments described herein, may be envisioned and practiced within the scope of the present disclosure.

DETAILED DESCRIPTION

Systems and techniques according to the present disclosure provide for desired transfer of electromagnetic radiation by using close packed arrangements of resonators having fractal shapes, i.e., "fractal cells." Systems and techniques according to the present disclosure provide one or more surfaces that act or function as shielding and/or cloaking surfaces for which at least a portion of the surface includes or is composed of "fractal cells" (small fractal shapes, functioning as antennas or resonators) placed sufficiently close to one another so that current present in one fractal cell is replicated or reproduced to an extent in an adjacent fractal cell. Without being limited by any theoretical explanation, surface plasmonic waves are believed to cause such replication in conjunction with evanescent waves.

A fractal of such a fractal cell can be of any suitable fractal shape and may have two or more iterations. The fractal cells may lie on a flat or curved sheet or layer and be composed in layers for wide bandwidth or multibandwidth transmission. As each cell is fed plasmonicly rather than directly, "dead" or covered or out of resonance cells do not alter the ability of the other cells to work. The boundary edges of the surface may be terminated resistively so as to not degrade the cell performance at the edges. These surfaces may be referred to as fractal plasmonic surfaces (FPS's) and they can function to shield structures and/or objects by conveying or ducting EM radiation.

Such a fractal plasmonic surface (FPS) may be used to transfer radiation, e.g., via evanescent wave transfer. In doing so such surfaces can be used to remove or transfer radiative power and/or heat from one location (such as a location receiving incident radiation) to another location. Such surfaces may be used to essentially diffuse power delivered to a part of the FPS and dissipate and or distribute it to other specific parts or globally. For example, a power "hotspot" supplied or hit with localized electromagnetic power may have the power spread out or diverted to other desired locations, e.g., different areas of a related machine or structure. Thus, the structure may act as shielding for another structure or the structure itself. In some embodiments, a FPS on a closed or curved surface may act as a cloaking device to divert power (in a wavelength or frequency of interest) from one side of the device to the other. In other embodiments, a refrigeration or cooling effect may be induced by transferring heat away from a FPS.

In some embodiments, power control may also be achieved through wideband absorption by placing a resistive sheet at the edge of the fractal cells, creating a layer adjacent to the cells. Impinging electromagnetic radiation will be absorbed and not reflected or scattered. A FPS may be used to wirelessly couple a device for power transmission by placing the power as electromagnetic radiation on the FPS and then physically placing the (to be) powered device closely to the FPS. A FPS may also work even if some of the cells are damaged or missing as a variety of paths exist to convey the plasmonic transmission.

Exemplary embodiments of the present disclosure can provide techniques, including systems and/or methods, for cloaking objects at certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands). Such techniques can provide an effective electromagnetic lens and/or lensing effect for certain wavelengths/frequencies or over certain wavelength/frequency ranges (bands). In some embodiments, the effects produced by such techniques can include cloaking or so-called invisibility of the object(s) at the noted wavelengths or bands. Representative frequencies of operation can include, but are not limited to, those over a range of 500 MHz to 1.3 GHz, though others may of course be realized. Operation at other frequencies, including for example those of visible light, infrared, ultraviolet, and as well as microwave EM radiation, e.g., K, Ka, X-bands, etc. may be realized, e.g., by appropriate scaling of dimensions and selection of shape of the resonator elements.

The fractal cells of a FPS can be designed or configured (e.g., sized) based on the wavelength or wavelength range of radiation that the FPS is anticipated as working with. In exemplary embodiments, a fractal cell may be sized such that its spatial extent in a given direction (e.g., a minor diameter, a major diameter, a major axis, a minor axis, etc.) is less than a wavelength of the radiation it is intended to work with. For example, a fractal cell may be constructed that has a spatial extent (in a particular direction) that is ⅛, or less, of the wavelength (lambda, λ) of radiation that the cell is intended to work with. For example, considering a roughly hexagonal shaped fractal cell (e.g., as shown in FIG. **1**), the "flat-to-flat" distance of the hexagonal cell may be ⅛ λ or less of the longest wavelength of radiation foreseen for use with the fractal cell. The spacing between the cell and each of the other adjacent cells (e.g., in this case, six other cells) is preferably 1/16 λ to 1/20 λ. When a wavelength range is anticipated for the cell or FPS having the cell, the wavelength used for design purposes can be the greatest wavelength of operation (corresponding to the lowest frequency of operation). Exemplary embodiments can be designed and built to operate to transfer radiation in the near-IR (NIR) wavelength range. Examples of such wavelengths include but are not limited to the edge of the visible red spectrum (~700 nm) through 1 mm. Other embodiments can operate at medium and/or long-wave infrared wavelengths. As stated above, the spacing between fractal cells in preferably sub-wavelength, e.g., 1/20 of a wavelength. For example, for a desired wavelength of operation of 1 mm (corresponding to 300 GHz), the spacing between adjacent fractal cells could be 50 microns (i.e., 1/20 λ).

Exemplary embodiments of the present disclosure can include an arrangement of resonators in a lattice-like configuration. The arrangements can include resonators of several different sizes and/or geometries arranged so that each size or geometry ("grouping") corresponds to a moderate or high quality factor, "Q," (that is moderate or low bandwidth) response that resonates within a specific frequency range.

For exemplary embodiments, fractal resonators can be used for the resonators in such structures because of their control of passbands, and smaller sizes compared to non-fractal based resonators. Their benefit arises from a size standpoint because they can be used to shrink the resonator(s), while control of passbands can reduce or eliminates issues of harmonic passbands that would resonate at frequencies not desired.

Further embodiments of the present disclosure are directed to scatterer or scattering structures. Additional embodiments of the present disclosure are directed to structures/techniques for activating and/or deactivating cloaking structures.

Related fractal technology is described in the following: (i) U.S. patent application Ser. No. 12/732,059 filed 25 Mar. 2010 and entitled "Wideband Electromagnetic Cloaking Systems," which is a continuation-in-part of (ii) U.S. patent application Ser. No. 12/547,104 filed 25 Aug. 2009, now U.S. Pat. No. 8,253,639, which claims benefit of (iii) U.S. Provisional Patent Application No. 61/189,966 filed 25 Aug. 2008 and (iv) U.S. Provisional Patent Application No. 61/163,824 filed 26 Mar. 2009 and entitled "Cloaking Techniques"; (v) U.S. Provisional Patent Application No. 61/163,837, filed 26 Mar. 2009 and entitled "Scatterer"; (vi) U.S. Provisional Patent Application No. 61/163,913, filed 27 Mar. 2009 and entitled "Cloaking Techniques"; and, (vii) U.S. Provisional Patent Application No. 61/237,360, filed 27 Aug. 2009 and entitled "Switching System for Cloak On Command"; the entire contents of all of which applications are incorporated herein by reference.

For exemplary embodiments, fractal resonators can be used for the resonators because of their control of passbands, and smaller sizes. A main benefit of such resonators arises from a size standpoint because they can be used to shrink the resonator(s), while control of passbands can reduce/mitigate or eliminate issues of harmonic passbands that would resonate at frequencies not desired.

Exemplary embodiments of a resonator system for use at infrared (or nearby) frequencies can be built from belts or loops having fractal cells on one or both sides. These belts or loops can function to slip or duct the infrared (heat) energy around an object located within the belts, so the object is effectively invisible and "see thru" at the infrared frequencies. Belts, or shells, having similar closed-packed arrangements for operation at a first passband can be positioned within a wavelength of one another, e.g., 1/10λ, ⅛λ, ¼λ, ½λ, etc.

In exemplary embodiments, as described in further detail below, an observer can observe an original image or signal, without it being blocked by the cloaked object. Using no power, the fractal cloak having FPS can replicate the original signal (that is, the signal before blocking) with great fidelity. Exemplary embodiments can function in the infrared region (e.g., ~700 nm to ~1 mm, corresponding to ~430 THz to ~300 GHz), providing 3:1 bandwidth; operation within or near such can frequencies can provide other bandwidths as well, such as 1:1 up to 2:1 and up to about 3:1.

FIG. **1** depicts a deflective shield system **100** having a fractal plasmonic surface (FPS) **102**, in accordance with the present disclosure. The FPS **102** includes a close packed arrangements of resonators having fractal shapes (e.g., "fractal cells") as denoted by **110** and **120**. The FPS **102** may be part of a larger surface or area **104**. The individual fractal cells are separated from the adjacent fractal cells but are sufficiently close to one another (e.g., preferably less than 1/20 wavelength) so that a surface (plasmonic) wave causes near replication of current present in one fractal cell in an adjacent fractal cell. While preferred fractal shapes are shown in FIG. **1** as being hexagonal or snowflake-like, any suitable fractal shape (e.g., deterministic) may be used and such a fractal may have two or more iterations. The fractal cells may lie on a flat or curved sheet or layer and be composed in layers for wide bandwidth or multibandwidth transmission; the fractal cells can also lie on more complex three-dimensional surfaces and structures of virtually any shape. For embodiments having layers, each layer holding a FPS can utilize fractal cells of different size and shape that those of another layer.

Examples of suitable fractal shapes (for use for shells and/or a scatting object) can include, but are not limited to, fractal shapes described in one or more of the following patents, owned by the assignee of the present disclosure, the entire contents of all of which are incorporated herein by reference: U.S. Pat. No. 6,452,553; U.S. Pat. No. 6,104,349; U.S. Pat. No. 6,140,975; U.S. Pat. No. 7,145,513; U.S. Pat. No. 7,256,751; U.S. Pat. No. 6,127,977; U.S. Pat. No. 6,476,766; U.S. Pat. No. 7,019,695; U.S. Pat. No. 7,215,290; U.S. Pat. No. 6,445,352; U.S. Pat. No. 7,126,537; U.S. Pat. No. 7,190,318; U.S. Pat. No. 6,985,122; U.S. Pat. No. 7,345,642; and, U.S. Pat. No. 7,456,799.

Other suitable fractal shape for the resonant structures can include any of the following: a Koch fractal, a Minkowski fractal, a Cantor fractal, a torn square fractal, a Mandelbrot, a Caley tree fractal, a monkey's swing fractal, a Sierpinski gasket, and a Julia fractal, a contour set fractal, a Sierpinski triangle fractal, a Menger sponge fractal, a dragon curve fractal, a space-filling curve fractal, a Koch curve fractal, an Lypanov fractal, and a Kleinian group fractal. While exemplary fractal shapes are shown in FIG. **1**, the present disclosure is not limited to such and any other suitable fractal shapes (including generator motifs) may be used in accordance with the present disclosure.

With continued reference to FIG. **1**, the fractal cells **110** and **120** can be formed on the FPS **102** by any suitable techniques. Of course, while a space devoid of cells is shown between cell groups **110** and **120**, such is not necessary (and is included in FIG. **1** merely to show the distinction between the individual cells of the two groups). Such techniques can include additive and/or subtractive techniques. Suitable lithography techniques may be used for some embodiments. In exemplary embodiments, the fractal shapes of the fractal cells **110** and **120** can be conductive traces that are deposited on the underlying surface, e.g., a suitable substrate. Any suitable deposition techniques can be utilized. In other embodiments, the fractal cells **110** and **120** can be etched or engraved onto a surface. Any suitable micromachining or nanomachining techniques may be used.

Exemplary embodiments of system **100** can utilize a material for a substrate that has low-loss characteristics in the infrared region to facilitate heat transfer by fractal cells disposed on, disposed in, or supported by the substrate, e.g., on a supporting surface provided by the substrate. Examples of suitable materials for such substrates can include, but are not limited to, the following: chalcogenide-glasses in general; high-purity As—S, As—Se, Ge—As—Se glasses; and, $Ge_{30}As_{10}Se_{30}Te_{30}$ glass, and the like.

FIG. **2** depicts a diagrammatic plan view of a cloaking system **200** and RF testing set up in accordance with exemplary embodiments of the present disclosure. As shown in FIG. **2**, a number of concentric shells (or bands) **202** are placed on a platform (parallel to the plane of the drawing). The shells include a flexible substrate (e.g., polyimide with or without composite reinforcement) with conductive traces (e.g., copper, silver, etc.) in fractal shapes or outlines, each separate shape representing a fractal cell (e.g., similar to cells **110** and **120** of FIG. **1**). The shells **202** surround an object to be cloaked (shown as **204** in FIG. **1**). A transmitting antenna **1** and a receiving antenna **2** are shown at different sides of the system **200**, for the purposes of illustration. The shells **202** can be held in place by suitable radial supports **206**.

The shells indicated in FIG. **2** are of two types, one set (A**1**-A**4**) configured for optimal operation over a first wavelength/frequency range, and another set (B**1**-B**3**) configured for optimal operation over a second wavelength/frequency range. (The numbering of the shells is of course arbitrary and can be reordered, e.g., reversed.)

For an exemplary embodiment of system **200**, the outer set of shells (A**1**-A**4**, with A**1** being the innermost and A**4** the outmost) had a height of about 3 to 4 inches (e.g., 3.5 inches) and the inner set of shells had a height of about 1 inch less (e.g., about 2.5 to 3 inches). The spacing between the shells with a larger fractal shape (A**1**-A**4**) was about 2.4 cm while the spacing between shells of smaller fractal generator shapes (B**1**-B**3**) was about 2.15 cm (along a radial direction). In a preferred embodiment, shell A**4** was placed between shell B**2** and B**3** as shown. The resonators formed on each shell by the fractal shapes can be configured so as to be closely coupled (e.g., by capacitive and/or evanescent-wave coupling) and function to propagate energy by a plasmonic wave.

It will be appreciated that while, two types of shells and a given number of shells per set are indicated in FIG. **2**, the number of shell types and number of shells for each set can be selected as desired, and may be optimized for different applications, e.g., wavelength/frequency bands, including the optical bands, i.e., infrared, visible, and ultraviolet, as well as x-ray.

FIG. **3** depicts a diagrammatic plan view of a cloaking system (or electrical resonator system) according to an alternate embodiment in which the individual shells have an elliptical cross section. As shown in FIG. **3**, a system **300** for cloaking can include a number of concentric shells (or bands) **302**. These shells can be held in place with respect to one another by suitable fixing means, e.g., they can be placed on a platform (parallel to the plane of the drawing) and/or held with a frame. The shells **302** can include a flexible substrate (e.g., polyimide with or without composite reinforcement) with a close-packed arrangement of electrically conductive material formed on the first surface. As stated previously for FIG. **2**, the closed-packed arrangement can include a number of self-similar electrical resonator shapes. The resonator shapes can be made from conductive traces (e.g., copper, silver, gold, silver-based ink, etc.) having a desired shape, e.g., fractal shape, split-ring shape, and the like. The shells **302** can surround an object to be cloaked, as indicated in FIG. **3**.

As indicated in FIG. **3** (by dashed lines **1** and **2** and arrows), the various shells themselves do not have to form closed surfaces. Rather, one or more shells can form open surfaces. This can allow for preferential cloaking of the object in one direction or over a given angle (solid angle). Moreover, while dashed lines **1** and **2** are shown intersecting shells B**1**-B**3** and A**1**-A**3** of system **300**, one or more shells of each group of shells (B**1**-B**3** and A**1**-A**3**) can be closed while others are open. Additionally, it should be appreciated that the cross-sections shown for each shell can represent closed geometric shapes, e.g., spherical and ellipsoidal shells.

As indicated previously, each shell of a cloaking system (e.g., system **300**) include multiple resonators in one or multiple close-packed configurations. The resonators can be repeated patterns of conductive traces. These conductive traces can be closed geometric shapes, e.g., rings, loops, closed fractals, etc. The resonator(s) can being self similar to at least second iteration. The resonators can include splitring shapes, for some embodiments. The resonant structures are not required to be closed shapes, however, and open shapes can be used for such.

In exemplary embodiments of shell **300**, the closed loops can be configured as a fractals or fractal-based shapes, e.g., as depicted by fractal cells **110** and **120** in FIG. **1**. The dimensions and type of a fractal shape for a fractal cell can be the same for each shell type but can vary between shell types. This variation (e.g., scaling of the same fractal shape) can afford increased bandwidth for the cloaking characteristics of the system. This can lead to periodicity of the fractal shapes of common shell types but aperiodicity between the fractal shapes of different shell types.

It will be appreciated that the resonant structures of the shells may be formed or made by any suitable techniques and with any suitable materials. For example, semiconductors with desired doping levels and dopants may be used as conductive materials. Suitable metals or metal containing compounds may be used. Suitable techniques may be used to place conductors on/in a shell, including, but no limited to, printing techniques, photolithography techniques, etching techniques, and the like.

It will also be appreciated that the shells may be made of any suitable material(s). Printed circuit board materials may be used. Flexible circuit board materials are preferred. Other material may, however, be used for the shells and the shells themselves can be made of non-continuous elements, e.g., a frame or framework. For example, various plastics may be used. In exemplary embodiments, the underlying surface or substrate on which a FPS is formed can have low loss with respect to the type of radiation that the FPS is designed for, so as to facilitate the intended heat and/or power transfer or dissipation.

Exemplary embodiments of the present disclosure can provide techniques, including systems and/or methods, for providing a radar cross section of different sizes than as would otherwise be dictated by the physical geometry of an object. Such techniques (objects/methods) can be useful for implementations such as radar decoys where a given object (decoy) is made to appear in radar cross section as like another object (e.g., missile). Representative frequencies of operation can include those over a range of 500 MHz to 1.3 GHz, though others may of course be realized. Other frequencies, include those of visible light may be realized, e.g., by appropriate scaling of dimensions and selection of shape of fractal elements.

FIG. **4**A depicts an example of a system **400** including an arbitrary object **402** surrounded by a fractal shield **404**. FIG. **4**B depicts exemplary objects **402** that may be shielded by or with a fractal shield **404**. Of course, such objects are merely representative and virtually any object or portion thereof may be shielded by EM radiation by a fractal shield designed (e.g., sized) for such radiation.

FIG. **5** illustrates the robustness or anti-fragility presented by a FPS **500** under conditions where some fractal cells are damaged or otherwise inoperative. As shown, FPS **500** has a close-packed arrangement of fractal cells, indicated by circles **502**. The close-packed arrangement provides many paths by which energy may be transferred from one area of the FPS to another, even in the presence of damaged or otherwise inoperative fractal cells (represented by the black squares shown).

FIG. **6**A depicts an example **600** of a FPS-based shield **602** used to dissipate incident radiation, which may be directed radiation of high intensity or fluence. As shown, radiation that is incident on a localized area of the shield **602** can be transferred from an area of incidence, around the object **604**, and dissipated and/or retransmitted via plasmonic coupling and radiative transfer between the fractal cells of the FPS-based shield **602**.

FIG. **6**B shows another example in which directed radiation is incident on a rectangular shield (exemplifying that a shield need not be circular/elliptical or have circular or elliptical symmetry). As shown, the incident radiation is ducted (indicated by flow lines) over the surface of the shield and around the object within the shield.

Accordingly the subject technology in accordance with the present disclosure can provide protection for a desired object (e.g., a person or thing) from incident radiation such as high energy density electromagnetic waves and/or impulses that would otherwise tend to damage or destroy the object(s). Such deflective shields, or deflectors, can be used on or for three-dimensional surfaces in addition to two-dimensional surfaces. Such a deflector allows the electromagnetic waves or impulses to emerge or re-form on the far side of the object, not passing through the object, wand with minimum (or reduced) absorption and reflection of the waves or impulses; moreover, the momentum of the incident radiation is not conveyed to the objected (or such conveyance is reduced compared to the case where no shield is used).

While embodiments are shown and described herein as having fractal-based EM shields in the shape of concentric rings (circular cylinders), EM shields in accordance with the present disclosure can take other shapes in other embodiments. For example, one or more shells could have a generally spherical shape (with minor deviations for structural support). In an exemplary embodiment, the shells could form a nested arrangement of such spherical shapes, around an object to be shielded (at the targeted/selected frequencies/wavelengths). Shell cross-sections of angular shapes, e.g., triangular, hexagonal, while not preferred, may be used. Further, shields may be placed on or integrated with one or more surfaces of a particular object to be shielded. Such shields and shield structures may be implemented in or configured as conformable surfaces which adapt or conform to any underlying surface or structure.

One skilled in the art will appreciate that embodiments and/or portions of embodiments of the present disclosure can be implemented in/with computer-readable storage media (e.g., hardware, software, firmware, or any combinations of such), and can be distributed and/or practiced over one or more networks. Steps or operations (or portions of such) as described herein, including processing functions to derive, learn, or calculate formula and/or mathematical models and geometric shapes utilized and/or produced by the embodiments of the present disclosure, can be processed by one or more suitable processors, e.g., central processing units ("CPU's") implementing suitable code/instructions in any suitable language (machine dependent on machine independent).

While certain embodiments and/or aspects have been described herein, it will be understood by one skilled in the art that the methods, systems, and apparatus of the present disclosure may be embodied in other specific forms without departing from the spirit thereof.

For example, while certain wavelengths/frequencies of operation have been described, these are merely representative and other wavelength/frequencies may be utilized or achieved within the scope of the present disclosure.

Furthermore, while certain preferred fractal generator shapes have been described others may be used within the scope of the present disclosure. Accordingly, the embodiments described herein are to be considered in all respects as illustrative of the present disclosure and not restrictive.

What is claimed is:

1. A fractal-cell deflective shield system comprising:

a plurality of close-packed fractal cells disposed on a supporting surface, wherein each fractal cell includes a fractal shape defining an electrical resonator, wherein each fractal cell has a spatial extent in a given direction of less than ⅛ of an operational wavelength of incident radiation, and wherein the plurality of fractal cells are positioned sufficiently close to one another to support plasmonic transfer of energy between the fractal cells;

wherein the supporting surface has a configuration adapted to surround an object.

2. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a vehicle.

3. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a satellite.

4. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is an automobile.

5. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a tower.

6. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a person.

7. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a vessel.

8. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is an antenna.

9. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a weapon.

10. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a ship.

11. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a rocket.

12. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a spacecraft.

13. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is an aircraft.

14. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a piece of artillery.

15. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a radome.

16. The system of claim **1**, wherein the object, corresponding to the configuration of the supporting surface, is a body covering.

17. A fractal-cell shield system comprising:

a first plurality of concentric first shells, each first shell including a substrate having first and second surfaces and a plurality of close-packed fractal cells disposed on a supporting surface disposed on the first surface, wherein each fractal cell includes a fractal shape defining an electrical resonator, and wherein the plurality of fractal cells are positioned sufficiently close to one another to support plasmonic transfer of energy between the fractal cells;

wherein the first plurality of concentric first shells have a configuration adapted to surround an object.

18. The system of claim **17**, further comprising:

a second plurality of concentric second shells, each second shell including a substrate having first and second surfaces and a plurality of close-packed fractal cells disposed on a supporting surface disposed on the first surface, wherein each fractal cell includes a fractal shape defining an electrical resonator, and wherein the plurality of fractal cells are positioned sufficiently close to one another to suppoli plasmonic transfer of energy between the fractal cells;

wherein at least one of the second plurality of second shells is configured at a greater distance from the object than at least one of the first plurality of first shells.

19. The system of claim **18**, wherein each of the second shells are configured at a respective greater distance from the object than the first plurality of first shells.

20. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a vehicle.

21. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a satellite.

22. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is an automobile.

23. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a tower.

24. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a person.

25. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a vessel.

26. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is an antenna.

27. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a weapon.

28. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a ship.

29. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a rocket.

30. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a spacecraft.

31. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is an aircraft.

32. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a piece of artillery.

33. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a radome.

34. The system of claim **17**, wherein the object, corresponding to the configuration of the first plurality of concentric first shells, is a body covering.

ELECTROMAGNETIC CLOAKING METHOD

BACKGROUND

[0001] In order to exploit electromagnetism, materials are commonly used to control and direct the electromagnetic fields. For example, a glass lens in a camera directs the rays of light to form an image, metal cages are used to screen sensitive equipment from electromagnetic radiation, and various forms of 'black bodies' are utilised to prevent unwanted reflections. One aspect of electromagnetism which is of particular interest, is the use of materials in the manipulation of electromagnetic waves such as to conceal or cloak objects or volumes of space from detection by an outside observer.

[0002] Several known methods exist which attempt to achieve electromagnetic concealment of objects. For example, it is possible to use a series of cameras to project an image to an observer of what he would see if an object in question were not blocking his view path. As a result, the observer does not realise that the object is present. This method, however, relies on the use of active components, and depends heavily on the relative positioning of the object, cameras and observer at all times.

[0003] Further known concealment methods include traditional "stealth technology" and the use of low radar cross section structures. These are designed to minimize back reflection of radar or other electromagnetic waves. Whilst these structures can provide a reduced or altered electromagnetic signature, because they involve either the scattering of incident waves away from the target or absorbing incident waves, the objects which they hide are still detectable in transmission.

[0004] In their paper, Physics Rev. E95, 016623 (2005), A Alu and N Engheta suggest a scheme for the concealment of spherical and cylindrical objects through the use of plasmonic and metamaterial 'cloaks' or covers. Whilst this paper provides a method of reducing the total scattering cross section of such objects, it relies on a specific knowledge of the shape and material properties of the object being hidden. In particular, the electromagnetic cloak and the concealed object form a composite, whose scattering properties can be reduced in the lowest order approximation. Therefore, if the shape of the object changes, the shape of the cloak must change accordingly. Furthermore, this method relies on a resonance effect, such that if the frequency drifts away from its resonant peak, the method is less effective. It is therefore a narrowband method, which cannot be implemented for broadband applications.

[0005] A further aspect of electromagnetism which is of interest is the use of materials in electromagnetic sensing and energy harvesting applications. Several known devices exist in this area, such as satellite dishes and solar energy panels. Whilst such prior art devices are operable to collect or detect electromagnetic radiation incident upon them from a number of different directions, and can be moveable to capture radiation incident from any desired direction, they do not have the capability to capture electromagnetic radiation incident from all directions at any given time. Problems therefore arise in applications when the direction of the electromagnetic source is initially unknown or constantly changing, such as in solar energy collection and microwave energy beaming on mobile platforms.

SUMMARY

[0006] The invention is set out in the claims. According to a first embodiment, because a method is provided in which those rays which would have passed through a particular volume of space are deflected around the volume and returned to their original trajectory, an observer would conclude that the rays had passed directly through that volume of space. This will be the case regardless of the relative positioning of the observer and the concealed volume. Furthermore, because no radiation can get into the concealed volume nor any radiation gets out, an object of any shape or material placed in the concealed volume will be invisible to the observer.

[0007] In one aspect, the invention utilises a co-ordinate transformation approach which is independent of the sizes of the concealed and concealing volume and does not suffer from any of the fundamental scaling issues which affect known concealment schemes. It is also possible to use the transformation method for any shape of concealed or concealing volume. The wavelength of the electromagnetic radiation does not appear in the solution, such that the invention can be applied for any size structure and for any wavelength, and for near and far fields.

[0008] In a further embodiment of the invention, all electromagnetic fields which are incident on an outer surface of a particular volume of space are concentrated into a inner core region, regardless of their direction of incidence on the outer surface. This enables a detector or collector to be placed at the inner core into which the electromagnetic fields have been concentrated, allowing it to interact with the intensified fields from all directions at that location. Because a method is described in which those rays which pass through the particular volume of space are returned to their original trajectory outwards of its outer surface, an observer would conclude that the rays had passed directly through that volume of space, regardless of the relative positioning of the observer and the volume in question. In addition, the present invention enables a detector placed within the inner core region to have its material properties matched to the surrounding layer such that it will also be invisible to an observer viewing the set up from any direction.

BRIEF DESCRIPTION OF THE DRAWINGS

[0009] FIG. **1** is a cross-sectional ray trajectory diagram for a sphere of radius $r<R_1$ cloaked within an annulus of radius $R_1<r<R_2$, assuming that $R_2>>\lambda$;

[0010] FIG. **2***a* shows a field line in free space plotted on a Cartesian mesh;

[0011] FIG. **2***b* shows the field line and background coordinates of FIG. **2***a* both distorted by the same transformation;

[0012] FIG. **3** is a cross-sectional view of the electrostatic displacement field lines for a sphere of radius $r<R_1$ cloaked within an annulus of radius $R_1<r<R_2$, located close to a point charge, assuming that $R_2<<\lambda$;

[0013] FIG. **4***a* is a three-dimensional depiction of the diversion of electromagnetic rays around a cloaked volume, according to the present invention;

[0014] FIG. **4***b* is a three-dimensional depiction of the diversion of electromagnetic rays around a cloaked surface, according to the present invention;

[0015] FIG. **5** shows a front perspective view of a 'Swiss-roll' metamaterial;

[0016] FIG. **6** shows a top view of the 'Swiss-roll' metamaterial of FIG. **5**;

[0017] FIG. **7** shows a single split ring metamaterial;

[0018] FIG. **8** shows a plan view of a split ring structure in a square array, lattice spacing a;

[0019] FIG. **9** depicts the building of three-dimensional split ring resonator (SRR) at unit cell level;

[0020] FIG. **10** is a prior-art negative index metamaterial comprising SRR's and wires;

[0021] FIG. **11** is a cross-sectional ray trajectory diagram of a concentration device of radius R_3 in which a spherical volume of space radius R_2 is compressed to a smaller volume of space radius R_1; and

[0022] FIG. **12** is a cross-sectional ray trajectory diagram in which rays from a point source incident on a sphere radius R_3 are concentrated into an inner sphere radius R_1.

DETAILED DESCRIPTION

[0023] In overview, according to a first embodiment the invention provides a method of concealing an object or volume of space by means of redirecting the electromagnetic field lines around it. Any field lines which normally would flow through the concealed volume are redirected through a surrounding concealing volume. Outside of the cloaking structure, the field lines remain unperturbed. The cloaking structure is formed from a metamaterial, that is a material designed to exhibit the specific material parameters required for cloaking the object or volume in question. In particular, the electric permittivity ϵ and magnetic permeability μ and hence the refractive index n of the cloaking metamaterial can be varied effectively continuously spatially in order to manipulate the electromagnetic field lines and hence effectively conceal the enclosed volume. As a result of the invention, the concealed volume is undetectable to an outside observer, and any electromagnetic radiation produced by an object within the concealed volume cannot escape from it.

[0024] In a further embodiment the invention provides a method of concentrating the electromagnetic fields incident upon the outer surface of a concentrator device into an inner core region. The concentrator structure comprises a concentrating volume and a collecting volume. Any field lines which would normally flow through the concentrating volume are redirected into an inner collecting volume. Outside of the concentrator annulus surrounding the concentrating volume, the field lines remain unperturbed. The concentrator structure is formed from a metamaterial in a similar manner to that described above for the cloaking structure above.

[0025] Whilst, as is outlined in more detail below, the transformation method described herein can be applied to conceal any desired volume using any desired cloaking structure, for simplicity it will first be described in relation to the simple spherical case as shown in FIG. **1**. According to FIG. **1**, the volume to be hidden is a sphere **100** of radius R_1 and the cloaking material is contained within the annulus **102** of radius $R_1<r<R_2$. In order to create a secure, radiation-free volume within the sphere **100** of radius R_1, all those electromagnetic field lines **104** which normally would flow through the sphere **106** of radius $r<R_2$ must therefore be compressed into the cloaking annulus **102** $R_1<r<R_2$. That is, in order to remove the sphere **100** of radius R_1 from view, the volume within that sphere **100** plus the volume within the annulus **102** must all be mapped onto the annulus **102** of radius $R_1<r<R_2$. In the medium outside of the sphere **106** $r<R_2$, the electromagnetic field lines **104** must remain unperturbed.

[0026] The theory of propagation of electromagnetic waves is well known and so only the relevant aspects are summarised here in the context of the invention. In free space, the magnetic field strength H is related to the magnetic field intensity B and the magnetic permeability of free space, μ_0, via the equation $B=\mu_0 H$. The electric field E in free space is related to the electric displacement field D and electric permittivity of free space ϵ_0 via the equation $D=\epsilon_0 E$. In a dielectric the value of ϵ and μ are modified by the relative permittivity and permeability value ϵ_r, μ_r and the refractive index of the invention is given by

$$n_r = \sqrt[\pm]{\varepsilon\mu}\,.$$

As will be well known to the skilled person in the art, the three vectors E, H, and S are mutually orthogonal, with the Poynting vector S being calculable via the vector cross product $S=E\times H$. The Poynting vector S gives the direction and magnitude of energy flow per unit area per unit time of an electromagnetic wave, and in a ray trajectory diagram such as that shown in FIG. **1**, the direction of the rays of light correspond to the electromagnetic field lines and follow the direction of the Poynting vector. In order to implement this invention therefore, it is necessary to focus or redirect any of the electric displacement field D, the magnetic field intensity B, and the Poynting vector S so that they avoid the sphere **100** of radius R_1, and return undisturbed to their original trajectories.

[0027] As described in more detail below the approach further requires solution of Maxwell's equations in relation to the redirected fields. For ease of depiction, redirection of the Poynting vector in particular will be addressed in the following description.

[0028] In order to calculate the electromagnetic properties which a cloaking structure must possess in order to effectively implement the desired cloaking effects, the first step is to calculate the distortion which must be applied to the Poynting vector S so that the rays do not pass through the sphere **100** of radius R_1. As shown in FIGS. **2***a* and **2***b*, this is achieved by recording the initial configuration of each ray, which would occur in the absence of a cloaked volume and cloaking material, on a known geometric mesh, such as a spherical or Cartesian mesh. For example in FIG. **2***a*, a single ray **200** is plotted on a Cartesian mesh **202**: Once the appropriate rays **200** have been plotted on it, the Cartesian mesh **202** is stretched or distorted in such a manner that the rays plotted thereon become distorted to follow their new desired path, avoiding the cloaked volume. The distortions which are imposed on the Cartesian mesh **202** in order to achieve this can then be recorded as a coordinate transformation between the original Cartesian mesh **202** and a second transformed mesh **204**, wherein the second mesh is defined by:

$$q_1(x,y,z),\ q_2(x,y,z),\ q_3(x,y,z) \qquad (1)$$

[0029] In this second mesh **204**, lines of constant q_2, q_3 define the generalized q_1 axis, and so on. It will be seen that conversely if the second mesh **204** comprised a set of points defined by equal increments along the q_1, q_2, q_3 axes, it would appear distorted in the x, y, z Cartesian frame, as a comparison of FIGS. **2***a* and **2***b* clearly demonstrates.

[0030] The benefit of performing this transformation is that, as described below, it can be shown that it is possible to solve Maxwell's equations in the same form in the transformed geometry as in the original geometry, with only a corresponding transform of the spatially distributed values of ϵ and μ being required. This can be understood intuitively from the recognition that variation of the permittivity ϵ and permeability μ values, and hence the refractive index n in a space, is equivalent to distorting the geometry of the space as seen by a light ray. It will be noted that the approach specifically addresses modification of the value of ϵ and μ individually rather than of the refractive index $n=\pm\sqrt{\epsilon\mu}$. In particular this allows reflection between interfaces of different media to be removed by ensuring impedance (Z) matching where

$$Z = \sqrt{\frac{\mu}{\varepsilon}}.$$

[0031] As will be known to the skilled person, Maxwell's equations in a system of Cartesian coordinates take the form:

$$\nabla\times E=-\mu\mu_0\partial H/\partial t$$

$$\nabla\times H=+\epsilon\epsilon_0\partial E/\partial t \tag{2}$$

where both electric permittivity ϵ and magnetic permeability μ depend on position. As described in Annex 1, when a coordinate transformation is applied to these equations, in the new co-ordinate system they take the form:

$$\nabla_q\times\hat{E}=-\mu_0\hat{\mu}\partial\hat{H}/\partial t,$$

$$\nabla_q\times\hat{H}=+\epsilon_0\hat{\epsilon}\partial\hat{E}/\partial t \tag{3}$$

where ϵ and μ are in general tensors, and Ê, Ĥ are renormalized electric and magnetic fields. All four quantities are simply related to originals. In other words the form of Maxwell's equation is preserved by a co-ordinate transformation: the co-ordinate transformation does not change the fact that we are still solving Maxwell's equations, it simply changes the definition of ϵ, μ.

[0032] In particular, as is shown in detail in Annex 1, the effect of the transformation on μ and ϵ is to scale them both by a common factor. A generalized solution to this is shown in Annex 1, however in the case of an orthogonal geometry (Cartesian, spherical or cylindrical) but the renormalized values of the permittivity and permeability are:

$$\varepsilon'_u = \varepsilon_u\frac{Q_uQ_vQ_w}{Q_u^2}, \tag{4}$$

$$\mu'_u = \mu_u\frac{Q_uQ_vQ_w}{Q_u^2}, \text{ etc.}$$

$$E'_u = Q_uE_u,\ H'_u = Q_uH_u, \text{ etc.} \tag{5}$$

where,

-continued

$$Q_u^2 = \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 + \left(\frac{\partial z}{\partial u}\right)^2 \tag{6}$$

$$Q_v^2 = \left(\frac{\partial x}{\partial v}\right)^2 + \left(\frac{\partial y}{\partial v}\right)^2 + \left(\frac{\partial z}{\partial v}\right)^2$$

$$Q_w^2 = \left(\frac{\partial x}{\partial w}\right)^2 + \left(\frac{\partial y}{\partial w}\right)^2 + \left(\frac{\partial z}{\partial w}\right)^2$$

And:

$$B'\mu_0\mu'H' \text{ and } D' = \varepsilon_0\varepsilon E' \tag{7}$$

[0033] Referring back to the spherical case as shown in FIG. **1**, the natural choice of mesh on which to plot the original ray configuration is a spherical one, which uses the co-ordinates r, θ and ϕ. The co-ordinate transformation operates by taking all the fields in the sphere **106** of radius $r<R_2$ and compressing them into the annulus **102** of radius $R_1<r<R_2$. This is achieved by any transformation of the form:

$$r' = R_1 + \frac{f(r)-f(0)}{f(R_2)-f(0)}(R_2-R_1), \tag{8}$$

$$\theta' = \theta,$$

$$\phi' = \phi$$

where *f* (r) is a monotonically increasing function of r, this will map the entire interior of a sphere **106** of radius R_2 into an annulus bounded by two spheres **100**, **106** radii R_1 and R_2 respectively. There is symmetry for ϕ and θ because the field lines are being compressed radially only, so their angular positioning is not distorted.

[0034] The simplest solution to equation (8) arises when f(r)=r, which simplifies to give:

$$r'=R_1+r(R_2-R_1)/R_2,$$

$$\theta'=\theta,$$

$$\phi'=\phi \tag{9}$$

[0035] In order to ascertain the electromagnetic properties which will be required of the cloaking annulus **102** material so that it achieves the desired result of cloaking any object in the sphere **100** R_1 the transformation which has been imposed on r, ϕ and θ must be applied in an analogous manner to ϵ and μ, as shown for the general case in Annex 1. At each point (x, y, z) in space, ϵ and μ will have component (ϵ_x, ϵ_y, ϵ_z), (μ_x, μ_y μ_z) which must be transformed to spherical coordinate valve (ϵ'_r, $\epsilon'_\ominus$, ϵ'ø), (μ_r, · μ⊖.. μ'ø) in the transformed geometry.

[0036] We do this in two steps:

First transform to spherical coordinates without any compression,

[0037]

$$x=r\cos\phi\sin\theta,\ y=r\sin\phi\sin\theta,\ Z=r\cos\theta \tag{A1}$$

so that, as shown in equation (4) above, in the new frame,

$$\tilde{\varepsilon}_i = \varepsilon_i \frac{Q_1 Q_2 Q_3}{Q_i^2}, \qquad \text{(A2)}$$

$$\tilde{\mu}_i = \mu_i \frac{Q_1 Q_2 Q_3}{Q_i^2}$$

We calculate,

[0038]

$$Q_r^2 = \left(\frac{\partial x}{\partial r} = \cos\phi\sin\theta\right)^2 + \left(\frac{\partial y}{\partial r} = \sin\phi\sin\theta\right)^2 + \left(\frac{\partial z}{\partial r} = \cos\theta\right)^2 = 1 \qquad \text{(A3)}$$

$$Q_\theta^2 = \left(\frac{\partial x}{\partial \theta} = r\cos\phi\cos\theta\right)^2 + \left(\frac{\partial y}{\partial \theta} r\sin\phi\cos\theta\right)^2 + \left(\frac{\partial z}{\partial \theta} = -r\sin\theta\right)^2 = r^2$$

$$Q_\phi^2 = \left(\frac{\partial x}{\partial \phi} = -r\sin\phi\sin\theta\right)^2 + \left(\frac{\partial y}{\partial Z} = +r\cos\phi\sin\theta\right)^2 + \left(\frac{\partial z}{\partial Z} = 0\right)^2 = r^2\sin^2\theta$$

and hence,

$$\begin{aligned} \tilde{\varepsilon}_r = \tilde{\mu}_r &= \frac{Q_r Q_\theta Q_\phi}{Q_r^2}\varepsilon_r \\ &= \frac{r^2\sin\theta}{1}\varepsilon_r \\ &= r^2\sin\theta\varepsilon_r \end{aligned} \qquad \text{(A4)}$$

$$\begin{aligned} \tilde{\varepsilon}_\theta = \tilde{\mu}_\theta &= \frac{Q_r Q_\theta Q_\phi}{Q_\theta^2}\varepsilon_\theta \\ &= \frac{r^2\sin\theta}{r^2}\varepsilon_\theta \\ &= \sin\theta\varepsilon_\phi \end{aligned}$$

$$\begin{aligned} \tilde{\varepsilon}_\phi = \tilde{\mu}_\phi &= \frac{Q_r Q_\theta Q_\phi}{Q_\phi^2}\varepsilon_\phi \\ &= \frac{r^2\sin\theta}{r^2\sin^2\theta}\varepsilon_\phi \\ &= \frac{1}{\sin\theta}\varepsilon_\phi \end{aligned}$$

where ϵ_r, ϵ_θ, ϵ_ϕ, the three components of the permittivity tensor in the original Cartesian frame, and we assume that the permittivity and permeability are equal. Note that we can easily extract the Cartesian view of ϵ_r, ϵ_θ, ϵ_ϕ from (A4) by removing the appropriate factors of r.

[0039] In order to create a protected space inside the sphere radius R_1 we make a further transformation to a new cylindrical system in which the radius is compressed taking any ray trajectories with it. It is noted that computer programs work in Cartesian coordinates and therefore that it is possible to re-express the compressed radial coordinate system in terms of a compressed Cartesian system, x' y' z', by removing factors of r'.

Consider the transformation from equation (9),

[0040]

$$r' = R_1 + r(R_2 - R_1)/R_2,\ \theta' = \theta,\ \phi' = \phi \qquad \text{(A5)}$$

which can be re-expressed as,

$$r = \frac{(r' - R_1)R_2}{R_2 - R_1},\ \theta' = \theta,\ \phi' = \phi \qquad \text{(A6)}$$

We calculate,

[0041]

$$Q_{r'}^2 = \left(\frac{\partial r}{\partial r'} = \frac{R_2}{R_2 - R_1}\right)^2 + \left(\frac{\partial \theta}{\partial r'} = 0\right)^2 + \left(\frac{\partial \phi}{\partial r'} = 0\right)^2 = \left[\frac{R_2}{R_2 - R_1}\right] \qquad \text{(A7)}$$

$$Q_{\theta'}^2 = \left(\frac{\partial r}{\partial \theta'} = 0\right)^2 + \left(\frac{\partial \theta}{\partial \theta'} = 1\right)^2 + \left(\frac{\partial \phi}{\partial \theta'} = 0\right)^2 = 1$$

$$Q_{\phi'}^2 = \left(\frac{\partial r}{\partial \phi'} = 0\right)^2 + \left(\frac{\partial \theta}{\partial \phi'} = 0\right)^2 + \left(\frac{\partial \phi}{\partial \phi'} = 1\right)^2 = 1$$

so that in the new frame,
for $R_1 < r' < R_2$

$$\begin{aligned} \tilde{\varepsilon}_{r'} = \tilde{\mu}_{r'} &= \tilde{\varepsilon}_r \frac{Q_{r'} Q_{\theta'} Q_{\phi'}}{Q_{r'}^2} \\ &= \frac{(R_2 - R_1)}{R_2} r^2 \sin\theta\varepsilon_r \\ &= \frac{(R_2 - R_1)}{R_2}\left[\frac{(r' - R_1)R_2}{R_2 - R_1}\right]^2 \sin\theta\varepsilon_r \\ &= \frac{R_2 (r' - R_1)^2}{R_2 - R_1}\sin\theta\varepsilon_r \end{aligned} \qquad \text{(A8a)}$$

$$\begin{aligned} \tilde{\varepsilon}_{\theta'} = \tilde{\mu}_{\theta'} &= \tilde{\varepsilon}_\theta \frac{Q_{r'} Q_{\theta'} Q_{\phi'}}{Q_{\theta'}^2} \\ &= \frac{R_2}{R_2 - R_1}\sin\theta\varepsilon_\theta \end{aligned}$$

$$\begin{aligned} \tilde{\varepsilon}_{\phi'} = \tilde{\mu}_{\phi'} &= \tilde{\varepsilon}_\phi \frac{Q_{r'} Q_{\theta'} Q_{\phi'}}{Q_{\phi'}^2} \\ &= \frac{R_2}{R_2 - R_1}\frac{1}{\sin\theta}\varepsilon_\phi \end{aligned}$$

[0042] Alternatively we can reinterpret these values in a Cartesian coordinate frame, x'y'z', which is easily done by comparison with (A4),

$$\begin{aligned} \varepsilon_{r'} = \mu_{r'} &= \frac{R_2}{R_2 - R_1}\frac{(r' - R_1)^2}{r'^2}\varepsilon_r \end{aligned} \qquad \text{(10)}$$

-continued

$$\begin{aligned}\varepsilon_{\theta'} &= \mu_{\theta'}\\ &= \frac{R_2}{R_2 - R_1}\varepsilon_\theta\\ \tilde{\varepsilon}_{\phi'} &= \tilde{\mu}_{\phi'}\\ &= \frac{R_2}{R_2 - R_1}\varepsilon_\phi\end{aligned}$$

where we have assumed that the starting material is vacuum. for $R_2<r'$

$$\begin{aligned}\tilde{\varepsilon}_{r'} &= \tilde{\mu}_{r'} = r'^2\sin\theta'\varepsilon_{r'}\\ \tilde{\varepsilon}_{\theta'} &= \tilde{\mu}_{\theta'} = \sin\theta'\varepsilon_{\theta'}\\ \tilde{\varepsilon}_{Z'} &= \tilde{\mu}_{Z'} = \frac{1}{\sin\theta'}\varepsilon_{\phi'}\end{aligned} \tag{A7b}$$

In free space, $\epsilon_r'=\mu_r'=\epsilon_\theta'=\mu_\theta'\epsilon_\varnothing'=\mu_\varnothing'=1$ (11)

for $r'<R_1$ we may choose any value we please for the dielectric functions since radiation never penetrates into this region. In this region ϵ', μ' are free to take any value without restriction whilst still remaining invisible, and not contributing to electromagnetic scattering. This will be the case for all cloaked volumes, regardless of their shape or size.

[0043] If a suitable cloaking material can be implemented for the annulus **102** of radius $R_1<r<R_2$, this will exclude all fields from entering the central region **100** of radius R_1 and, conversely, will prevent all fields from escaping from this region. The cloaking structure itself and any object placed in the concealed sphere **100** R_1 will therefore be undetectable in either reflection or transmission. It will be noted that at all points in the medium the impedance

$$z = \sqrt{\frac{\mu}{\varepsilon}} = 1$$

such that no unwanted reflection in the medium, caused by impedance mismatch, takes place.

[0044] It is noted that if the impendance $z=\sqrt{\mu/\epsilon}=1$ is achieved at all points in the metamaterial, the cloaking structure and concealed volume will appear to contain only free space, and so will be invisible if embedded in free space. If the cloaking structure is embedded in another medium the effect will differ, for example if embedded in water it would have the appearance of a bubble. In order to make the cloaking structure invisible in another medium it is necessary to match the ratio of μ and ε in the metamaterial to that of the surrounding medium at the interface between the two. As the skilled person will appreciate, whilst this changes the numerical values of ε and μ in the cloaking structure metamaterial, the general transformation theory outlined in Annex 1 remains the same. That is, because the present invention enables ε and μ to be controlled in a metamaterial independently of one another, it is possible to achieve any desired value of z, to match the impedance of the metamaterial to that of its surroundings.

[0045] Whilst in FIG. **1** the cloaking annulus **102** is depicted as being relatively thick, this does not have to be the case. The solution is not dependent on shell thickness or any other length scales, such that it does not suffer from any scaling issues. Additionally, the solution provided holds in both in the near and far fields, because the solution does not depend on the wavelength λ. This is demonstrated in FIGS. **1** and **3**. For purposes of illustration, suppose that $R_2>>\lambda$ where λ is the wavelength so that we can use the ray approximation to plot the Poynting vector. If our system is then exposed to a source of radiation at infinity we can perform the ray tracing exercise shown in FIG. **1**. Rays **104** in this figure result from numerical integration of a set of Hamilton's equations obtained by taking the geometric limit of Maxwell's equations with anisotropic, inhomogeneous media. This integration provides an independent confirmation that the configuration specified by (9) and (10) excludes rays from the interior region **100**. Alternatively if $R_2<<\lambda$ and we locate a point charge **306** nearby, the electrostatic (or magnetostatic) approximation applies. A plot of the local electrostatic displacement field which results is shown in FIG. **3**.

[0046] The theoretical solution outlined above can be demonstrated using a ray-tracing program to calculate the ray trajectories. According to such a program, a specified material is assumed to exist around a central volume that is to be 'cloaked', or rendered invisible to the user. Using the specified parameters as input, the ray-tracing code confirms the theoretical prediction. Ray tracing programs of this type will be well known to those skilled in the art, although some existing programs will not be able to deal with the complexity of the problem for this invention. In FIGS. **4*a*** and **4*b***, a ray tracing program has been used which was developed from a custom ray tracing code based on a Hamiltonian formulation to solve Maxwell's equations in the geometric limit (ie zero wavelength limit). The results are shown for a spherical structure **400** and a cylindrical structure **402** respectively, wherein the transformed parameters ε and μ in the cylindrical case are calculated in a similar manner to those for the sphere, as shown below:

[0047] First transform to cylindrical coordinates without any compression,

$x=r\cos\theta$, $y=r\sin\theta$, $Z=z$ (A8)

so that in the new frame,

$$\tilde{\varepsilon}_i = \varepsilon_i\frac{Q_1Q_2Q_3}{Q_i^2}, \qquad \tilde{\mu}_i = \mu_i\frac{Q_1Q_2Q_3}{Q_i^2} \tag{A9}$$

We calculate,

[0048]

$$\begin{aligned}Q_r^2 &= \left(\frac{\partial x}{\partial r} = \cos\theta\right)^2 + \left(\frac{\partial y}{\partial r} = \sin\theta\right)^2 + \left(\frac{\partial z}{\partial r} = 0\right)^2 = 1\\ Q_\theta^2 &= \left(\frac{\partial x}{\partial \theta} = -r\sin\theta\right)^2 + \left(\frac{\partial y}{\partial \theta} = +r\cos\theta\right)^2 + \left(\frac{\partial z}{\partial \theta} = 0\right)^2 = r^2\\ Q_Z^2 &= \left(\frac{\partial x}{\partial Z} = 0\right)^2 + \left(\frac{\partial y}{\partial Z} = 0\right)^2 + \left(\frac{\partial z}{\partial Z} = 1\right)^2 = 1\end{aligned} \tag{A10}$$

and hence,

$$\tilde{\varepsilon}_r = \tilde{\mu}_r = \frac{Q_rQ_\theta Q_Z}{Q_r^2}\varepsilon_r = r\varepsilon_r \tag{A11}$$

$$\tilde{\varepsilon}_\theta = \tilde{\mu}_\theta = \frac{Q_rQ_\theta Q_Z}{Q_\theta^2}\varepsilon_\theta = r^{-1}\varepsilon_\theta$$

$$\tilde{\varepsilon}_Z = \tilde{\mu}_Z = \frac{Q_rQ_\theta Q_Z}{Q_Z^2}\varepsilon_Z = r\varepsilon_Z$$

where $\epsilon_r, \epsilon_\theta, \epsilon_Z$ the three components of the permittivity tensor in the original Cartesian frame, and we assume that the permittivity and permeability are equal. Note that we can easily extract the Cartesian view of $\epsilon_r, \epsilon_\theta, \epsilon_Z$ from (A13) by removing the appropriate factors of r.

[0049] In order to create a protected space inside a cylinder radius R_1, we make a further transformation to a new cylindrical system in which the radius is compressed taking any ray trajectories with it. It is noted that computer programs work in Cartesian coordinates and therefore that it is possible to re-express the compressed radial coordinate system in terms of a compressed Cartesian system, x'y'z', by removing factors of r'.

Consider the transformation,

[0050]

$$r' = R_1 + r(R_2 - R_1)/R_2,\ \theta' = \theta,\ Z' = Z \tag{A12}$$

or,

$$r = \frac{(r' - R_1)R_2}{R_2 - R_1},\ \theta' = \theta,\ Z' = Z \tag{A13}$$

We calculate,

[0051]

$$Q_{r'}^2 = \begin{matrix}\left(\frac{\partial r}{\partial r'} = \frac{R_2}{R_2 - R_1}\right)^2 + \left(\frac{\partial \theta}{\partial r'} = 0\right)^2 + \\ \left(\frac{\partial Z}{\partial r'} = 0\right)^2 + \left[\frac{R_2}{R_2 - R_1}\right]^2\end{matrix} \tag{A14}$$

$$Q_{\theta'}^2 = \left(\frac{\partial r}{\partial \theta'} = 0\right)^2 + \left(\frac{\partial \theta}{\partial \theta'} = 1\right)^2 + \left(\frac{\partial Z}{\partial \theta'} = 0\right)^2 = 1$$

$$Q_{Z'}^2 = \left(\frac{\partial r}{\partial Z'} = 0\right)^2 + \left(\frac{\partial \theta}{\partial Z'} = 0\right)^2 + \left(\frac{\partial Z}{\partial Z'} = 1\right)^2 = 1$$

so that in the new frame,
for $R_1 < r' < R_2$

$$\begin{aligned}\tilde{\varepsilon}_{r'} &= \tilde{\mu}_{r'} \\ &= \tilde{\varepsilon}_r\frac{Q_{r'}Q_{\theta'}Q_{Z'}}{Q_{r'}^2} \\ &= \frac{(R_2 - R_1)}{R_2}r\varepsilon_r \\ &= \frac{(R_2 - R_1)}{R_2}\frac{(r' - R_1)R_2}{R_2 - R_1}\varepsilon_r \\ &= (r' - R_1)\varepsilon_r\end{aligned} \tag{A15a}$$

-continued

$$\begin{aligned}\tilde{\varepsilon}_{\theta'} &= \tilde{\mu}_{\theta'} \\ &= \tilde{\varepsilon}_\theta\frac{Q_{r'}Q_{\theta'}Q_{Z'}}{Q_{\theta'}^2} \\ &= \frac{R_2}{R_2 - R_1}r^{-1}\varepsilon_\theta \\ &= \frac{R_2}{R_2 - R_1}\frac{R_2 - R_1}{(r' - R_1)R_2}\varepsilon_\theta \\ &= \frac{1}{(r' - R_1)}\varepsilon_\theta\end{aligned}$$

$$\begin{aligned}\tilde{\varepsilon}_{Z'} &= \tilde{\mu}_{Z'} \\ &= \tilde{\varepsilon}_Z\frac{Q_{r'}Q_{\theta'}Q_{Z'}}{Q_{Z'}^2} \\ &= \frac{R_2}{R_2 - R_1}r\varepsilon_Z \\ &= \frac{R_2}{R_2 - R_1}\frac{(r' - R_1)R_2}{R_2 - R_1}\varepsilon_Z \\ &= \left[\frac{R_2}{R_2 - R_1}\right]^2(r' - R_1)\varepsilon_Z\end{aligned}$$

for $R_2 < r'$

$$\tilde{\epsilon}_{r'} = \tilde{\mu}_{r'} = r'\epsilon_{r'}$$

$$\tilde{\epsilon}_{\theta'} = \tilde{\Xi}_{\theta'} = r'^{-1}\epsilon_{\theta'}$$

$$\tilde{\epsilon}_{Z'} = \tilde{\mu}_{Z'} = r'\epsilon_{Z'} \tag{A15b}$$

for $r' < R_1$ we may choose any value we please for the dielectric functions since radiation never penetrates into this region.

Alternatively we can reinterpret these values in a Cartesian coordinate frame, x'y'z', which is easily done by comparison with (A4),

[0052]

$$\begin{aligned}\varepsilon_{r'} &= \mu_{r'} \\ &= \frac{r' - R_1}{r'}\end{aligned} \tag{A16}$$

$$\begin{aligned}\varepsilon_{\theta'} &= \mu_{\theta'} \\ &= \frac{r'}{(r' - R_1)}\end{aligned}$$

$$\begin{aligned}\varepsilon_{Z'} &= \mu_{Z'} \\ &= \left[\frac{R_2}{R_2 - R_1}\right]^2\frac{r' - R_1}{r'}\end{aligned}$$

where we have assumed that the starting material is vacuum.

[0053] FIGS. **4***a* and **4***b* show that the incident rays **404**, **406** are diverted around a central region **400**, **402** and emerge from the cloaking region **408**, **410** apparently unperturbed, as predicted by the theoretical solution.

[0054] Whilst the theoretical solution has been confirmed by ray-tracing methods, in order to put the invention into effect a suitable material to form the cloaking structure has been developed.

[0055] The material parameters of the cloaking structure require that the components of ϵ' equal those of μ', that ϵ' and μ' vary throughout space, and that the tensor components of $\epsilon'$and μ' vary independently. The anticipated material is thus inhomogeneous and anisotropic. Moreover, the material parameters ϵ' and μ' must assume values less than unity and approach zero at the interface between the concealed region and the cloaking shell. Furthermore, it is noted that equation (6) is singular at $r'=R_1$. This is unavoidable as can be seen by considering a ray headed directly towards the centre of the sphere **100** (FIG. **1**). This ray does not know whether to be deviated up or down, left or right. Neighbouring rays **104** are bent around tighter and tighter arcs closer to the critical ray they are. This in turn implies very steep gradients in ϵ' and μ'. Parameters ϵ' and μ' are necessarily anisotropic in the cloaking material because space has been compressed anisotopically. This set of constraints is not attainable by conventional materials for example because finding matching values for ϵ and μ in the same waveband does not occur. However, given the rapid progress that has occurred over the past several years in artificial materials, a metamaterial can be practically designed that satisfies the specifications.

[0056] Metamaterials are artificially constructed 'materials' which can exhibit electromagnetic characteristics that are difficult or impossible to achieve with conventional materials. From an electromagnetic point of view, the wavelength, λ, of a wave passing through a material determines whether a collection of atoms or other objects can be considered a material and properties at the atomic level determine ϵ and μ. However, the electromagnetic parameters ϵ and μ need not arise strictly from the response of atoms or molecules: Any collection of objects whose size and spacing are much smaller than λ can be described by an ϵ and μ. In that case, the values of ϵ and μ are determined by the scattering properties of the structured objects. Although such an inhomogeneous collection may not satisfy an intuitive definition of a material, an electromagnetic wave passing through the structure cannot tell the difference, and, from the electromagnetic point of view, we have created an artificial material, or metamaterial. This properties of metamaterials are explained further in "Metamaterials and Refractive Index", D R Smith, J B Pendry, MCK. Wiltshire, VOL 305, SCIENCE 061081 (2004).which is incorporated herein by reference.

[0057] One useful property exhibited by certain metamaterials is that of artificial magnetism. It has been found that structures consisting of non-magnetic arrays of wire loops in which an external field can induce a current consequently produce an effective magnetic response. One such design is the so-called 'Swiss-roll' structure, as shown in FIG. **5**. The roll **500** is manufactured by rolling an insulated metallic sheet around a cylinder **504**. A design with about 11 turns on a 1-cm-diameter cylinder gives a resonant response at 21 MHz. The metamaterial is formed by stacking together many of these cylinders. In this structure, the coiled copper sheets have a self-capacitance and self-inductance that create a resonance. The currents that flow when this resonance is activated couple strongly to an applied magnetic field, yielding an effective permeability that can reach quite high values. No current can flow around the coil except by self capacitance. As is shown in FIG. **6**, when a magnetic field parallel to the cylinder **600** is switched on it induces currents (j) in the coiled sheets **602**, which are spaced a distance d apart from one another. Capacitance between the first **604** and last **606** turns of the coil enables current to flow. This is described further in "Magnetism from Conductors and Enhanced Non-Linear Phenomena", J B Pendry, A J Holden, D J Robbins and W J Stewart IEEE Trans. Micr. Theory and Techniques, 47, 2075 (1999), which is incorporated herein by reference.

[0058] One problem with the Swiss-roll structures is that the continuous electrical path provided by metal cylinders can cause the metamaterial to respond like an effective metal when the electric field applied is not parallel to the cylinders, hence restricting its usefulness in certain applications. An adaptation described in the same paper which avoids this undesirable effect is the split ring resonator (SRR). The SRR is built up from a series of split rings, as shown in FIG. **7**. Each split ring **700** comprises at least two concentric thin metal rings **702**, **704** of width c, spaced apart by a distance d, each one with a gap, **706**, **708**. By eliminating the continuous conducting path which the cylinders provide, an SRR eliminates most of the electrical activity along this direction.

[0059] As shown in FIG. **8**, it is possible to form a planar split ring structure **800** from a series of split rings **802**, spaced a distance a apart. The two dimensional square array **800** shown in FIG. **8** can be made by printing with metallic inks. If each printed sheet is then fixed to a solid block of inert material, thickness a, the blocks can be stacked to give columns of rings. This would establish magnetic activity along the direction of stacking, z-axis.

[0060] The unit cell **900** of the stacked SRR structure is shown in FIG. **9** on the left. It is possible to form a symmetrical three dimensional structure starting from such a structure comprising successive layers of rings stacked along the z-axis. This is achievable by cutting up the structure into a series of slabs thickness a, making incisions in the y-z plane and being careful to avoid slicing through any of the rings. Each of the new slabs contains a layer of rings but now each ring is perpendicular to the plane of the slab and is embedded within. The next stage is to print onto the surface of each slab another layer of rings and stack the slabs back together again. The unit cell **902** of this second structure is shown in the middle of FIG. **9**. In the final step, a third set of slabs is produced by cutting in the x-z plane, printing on the surface of the slabs, and reassembling. This results in a structure with cubic symmetry whose unit cell **904** is shown on the right of FIG. **9**.

[0061] Similarly ϵ can be governed by an array of thin wires as described in "Extremely Low Frequency Plasmas in Metallic Mesostructures", J B Pendry, A J Holden, W J Stewart, I Youngs, Phys Rev Lett, 76, 4773 (1996) which is incorporated herein by reference.

[0062] Hence known techniques can be applied to construct the metamaterial required to put the current invention as described above into practice. The materials comprise many unit cells, each of which is designed to have a predetermined value for ϵ' and μ', such that they correspond to the values determined by equation (4) above (or for the non-orthogonal case, equation (23) of Annex 1). As will be apparent to the skilled reader, this may involve each unit cell having slightly different values of ϵ' and μ' to those of its radially neighbouring cells. Each unit cell in the metamaterial acts as a concealing volume element. The concealing volume elements are assembled in the correct respective spatial positions to form the cloaking structure, as calculated by the methods outlined above. The cloaking structure will, as a result, possess the spatially distributed material parameter values required for electromagnetic concealment of the enclosed volume.

[0063] For practical implementation of the theory outlined above, a three dimensional cloaking structure will be necessary in most cases. A solid composite metamaterial structure can be formed using fabrication techniques similar to those used to manufacture a gradient index lens. One such known structure **1000** is shown in FIG. **10**, in which SRR's and wires are deposited on opposite sides lithographically on a standard circuit board to provide a desired material response. This is described in more detail in "Reversing Light with Negative Refraction", J B Pendry, D R Smith, Physics Today, June 2004, which is incorporated herein by reference.

The unit cell structure of the metamaterial used ensures that anisotropy and continuous variation of the parameters, as required by the theoretical solution, can be achieved. Unrelated to cloaking, another application of the transformation theory described above is a device for concentrating fields. FIG. **11** shows a concentrator that concentrates electromagnetic fields incident upon its outer surface (**110**) onto an inner core region (**114**). The transformation that characterizes the concentrator, for the spherical geometry, is shown in FIG. **11**. The outer radius of the device (**110**) is R_3. A concentrating volume of space (**112**) with radius $R_2<R_3$ is compressed to a collecting volume (**114**) of radius R_1. The shell volume (**116**) that lies between R_2 and R_3 is expanded to fill the region (**118**) between R_1 and R_3, as FIG. **11** depicts. A simple example of this transformation that compresses the core (**112**) uniformly and stretches the shell region (**116**) with a linear radial function is given by

$$r = \begin{cases} \frac{R_2}{R_1} r' & 0 < r' < R_1 \\ \frac{R_2 - R_1}{R_3 - R_1} R_3 + \frac{R_3 - R_2}{R_3 - R_1} r' & R_1 < r' < R_3 \\ r' & R_3 < r' \end{cases} \tag{12}$$

$$\theta = \theta'$$

$$\phi = \phi' \tag{13}$$

The resulting material properties of permitting and permeability in the concentration device are then

[0064]

$$\begin{aligned} [\varepsilon'_{r'}, \varepsilon'_{\theta'}, \varepsilon'_{\phi'}] &= [\mu'_{r'}, \mu'_{\theta'}, \mu'_{\phi'}] \\ &= \begin{cases} \frac{R_2}{R_1}[1, 1, 1] & 0 < r' < R_1 \\ \frac{R_3 - R_2}{R_3 - R_1}\left[\left(1 + \frac{R_2 - R_1}{R_3 - R_2}\frac{R_3}{r'}\right)^2, 1, 1\right] & R_1 < r' < R_3 \\ [1, 1, 1] & R_3 < r' \end{cases} \end{aligned} \tag{15}$$

where the material properties are given relative to the external environment. As with the cloaking structure, the external environment may be free space or any other medium.

[0065] In order to concentrate fields into an arbitrarily small volume, we let $R_1 \rightarrow 0$ and obtain

$$\begin{aligned} [\varepsilon'_{r'}, \varepsilon'_{\theta'}, \varepsilon'_{\phi'}] &= [\mu'_{r'}, \mu'_{\theta'}, \mu'_{\phi'}] \\ &= \begin{cases} \frac{R_3 - R_2}{R_3}\left[\left(1 + \frac{R_3}{R_3 - R_2}\frac{R_2}{r'}\right)^2, 1, 1\right] & 0 < r' < R_3 \\ [1, 1, 1] & R_3 < r' \end{cases} \end{aligned} \tag{16}$$

[0066] If we wish the concentration cross section of the sphere to equal it's outer radius, then we let $R_2 \rightarrow R_3$.

$$\begin{aligned} \lim_{R_3 \to R_3} [\varepsilon'_{r'}, \varepsilon'_{\theta'}, \varepsilon'_{\phi'}] &= \lim_{R_3 \to R_3} [\mu'_{r'}, \mu'_{\theta'}, \mu'_{\phi'}] \\ &= \begin{cases} [+\infty, 0, 0] & 0 < r' < R_3 \\ [1, 1, 1] & R_3 < r' \end{cases} \end{aligned} \tag{17}$$

[0067] This is the perfect field concentrator. The material parameters which are required in the concentrator can be achieved through the use of metamaterials as described in relation to the cloaking structure. The permittivity ϵ and permeability μ can be controlled independently of one another in each of three dimensions within each unit cell of the metamaterial.

[0068] The concentrator device is unique, and different from focusing lenses and mirrors, in that it operates on fields incident from any direction. For electromagnetic sensing or energy harvesting applications, a detector or collector would be placed at the core (**114**) to interact with the intensified fields at that location. Part of the utility of this device is concentration of fields when the direction of their source is initially unknown or constantly changing e.g. solar energy collection or microwave energy beaming on mobile platforms.

[0069] A detector placed at the concentrator's core (**114**) could easily be configured to provide accurate directional information as well as collect the energy. This could be accomplished by, for example, using a spherical shaped detector patterned into eight quadrants. By comparing the energy collected from each quadrant, accurate directional information will be obtained. The detector need not be spherical. A transformation could be used that results in a core region that is a thin circular disk. This would make the concentrator compatible with common planar detectors.

[0070] The device can also provide impedance matching to the detector. This is achieved by applying the inverse transformation to the desired detector, expanding it from the core radius, R_1, to the radius R_2. It is then possible to design an impedance matching layer, (between R_1 and R_3), to match the transformed detector to its environment. This impedance matching layer is then transformed with the forward transformation expanding it to fill the region (**118**) between R_1 and R_3. The resulting shell layer between R_1 and R_3, provides both concentration and impedance matching functions.

[0071] Like the cloak structures the concentrator (**110**) can be perfectly matched to its environment, so that if the fields are not disturbed in the core (**114**) by a detector, the device (**110**) is undetectable by external electromagnetic probing. This device (**110**) can operate in both near and far field regimes and at any size scale and wavelength. The basic formalism of this transformation can be applied to other basic geometries, (e.g. cylindrical) or applied conformally to an arbitrarily shaped object.

FIG. 12 demonstrates the concentration of rays or field lines from a point source (**120**) incident upon a sphere (**122**) radius R_3, into an inner core region (**124**) radius R_1.

[0072] The co-ordinate transfer mapping theory outlined above has been described with respect to diverting the propagation of electromagnetic waves. However it is noted that there is a significant analogy between electromagnetic and other propagating waves such as acoustic waves. In particular, this theory may be applied to obtain specifications for the mechanical properties of a material such as density and stiffness that yield acoustic cloaking. Such a cloak may be used for example to conceal bodies from sonar detection.

[0073] Whilst the description of the cloaking theory above is directed mainly to concealing objects, it will be appreciated that the diversion of electromagnetic disturbances from the cloaked volume into a cloaking shell creates an electromagnetic quiet zone inside. Equation (9) dictates that any electromagnetic radiation produced by an object inside the quiet zone will not be able to emerge from it. This may be put to use in electromagnetic interference shielding applications, for example inside MRI machines. Analogously, acoustic quiet zones may also be achieved.

[0074] The application of the present invention is not limited to the cloaking and concentrator structures as shown in the Figures. As demonstrated clearly in Annex 1, the mathematical solution provided herein applies to cloak a structure of any shape. Furthermore, if a volume is cloaked, an object of any shape or material placed therein will not be detectable by an outside observer, either in reflection mode or transmission mode.

[0075] The methods described herein can be used to apply any appropriate coordinate transformation between any appropriate co-ordinate systems and using any appropriate function of the co-ordinates in the original frame. The cloaking structure used to conceal the material within it can be of any shape or thickness. In particular, the cloaking structure does not have to follow the same shape as the object within that is to be concealed. It will be apparent to the skilled reader that the methods described herein can be used to transform all frequencies of electromagnetic radiation, and for a given application can be applied to radiation in any specific frequency range of the electromagnetic spectrum, including infrared, radio, visible light, x-rays, microwaves and radar.

[0076] In the examples shown impedance matching has been achieved by the ratio

$$\frac{\mu}{\varepsilon} = 1.$$

As will be apparent to the skilled reader, impedance matching of the sort described herein can be achieved for

[0077]

$$\frac{\mu}{\varepsilon} = m$$

where m is any real constant value. In particular, the desired ratio of μ/ϵ will depend on the medium in which the cloaking structure is to be embedded.

[0078] While this invention has been particularly shown and described with references to preferred embodiments thereof, it will be understood by those skilled in the art that various changes in form and details may be made therein without departing from the scope of the invention encompassed by the appended claims.

What is claimed is:

1. A method of constructing a concealing volume comprising constructing a plurality of concealing volume elements around a concealable volume, each concealing volume element having a material parameter arranged to direct a propagating wave around a concealable volume.

2. A method as claimed in claim **1** in which the material parameter comprises one of refractive index, electrical permittivity, magnetic permeability.

3. A method as claimed in claim **2** in which the propagating wave comprises an electromagnetic wave.

4. A method as claimed in claim **1** in which the material parameter comprises each of electrical permittivity and magnetic permeability.

5. A method as claimed in claim **2** in which the concealing volume is a metamaterial.

6. A method as claimed in claim **5** in which each element comprises at least one of a split ring and a conductive wire providing a respective permeability and permittivity value.

7. A method as claimed in claim **1** in which the concealing volume is designed to divert incoming propagating waves such that outgoing propagating waves appear to be unperturbed to an observer.

8. A method of designing a concealing volume for provision around a concealable volume comprising identifying a co-ordinate transform mapping a concealable volume space onto a concealing volume space and applying a corresponding transform to spatially distributed material parameter values in the concealable volume space.

9. A method as claimed in claim **8** in which the material parameter comprises at least one of the refractive index, electrical permittivity, magnetic permeability.

10. A method of constructing a concealing volume comprising designing a concealing volume as claimed in claim **8**, constructing a plurality of elements having said transformed material parameter values and assembling said elements at the respective transformed spatial positions.

11. A method as claimed in claim **10** in which the assembled elements form a metamaterial.

12. A concealing volume for concealing a concealable volume comprising a plurality of concealing volume elements each having a material parameter arranged to divert a propagating wave around a concealable volume.

13. A concealing volume as claimed in claim **12** in which the material parameter is at least one of refractive index, electrical permittivity and magnetic permeability.

14. A concealing volume as claimed in claim **12** in which the concealing volume elements form a metamaterial.

15. A concealing volume as claimed in claim **12** in which each concealing volume element comprises at least one of a split ring and an electrically conductive wire providing a respective magnetic permeability or electrical permittivity value.

16. A concealing volume as claimed in claim **12** further comprising a concealed volume within said concealing volume.

17. A concealing volume as claimed in claim **12** further comprising a plurality of bandwidth enhancing elements.

18. A computer readable medium comprising a set of instructions for implementing a method as claimed in claim **1**.

19. A computer configured to operate under the instructions of a computer readable medium as claimed in claim **18**.

20. A computer readable medium storing concealing volume element material parameter data derived according to the method of claim **8**.

21. A concealing volume as claimed in claim **12** configured for cloaking in at least one of the following electromagnetic spectrum bands: visible, infrared, ultraviolet, x-ray, radio, radar, microwave.

22. A computer readable medium as claimed in claim **18** in which the propagating wave is an acoustic wave and the material parameter comprises at least one of density and stiffness.

23. A method of constructing a concentrator comprising constructing a plurality of concentrator elements to form a concentrating volume and a collecting volume, each concentrator element having a material parameter arranged to direct a propagating wave from the concentrating volume to the collecting volume.

24. A method as claimed in claim **23** in which the material parameter comprises one of refractive index, electrical permittivity, magnetic permeability.

25. A method as claimed in claim **24** in which the propagating wave comprises an electromagnetic wave.

26. A method as claimed in claim **23** in which the material parameter comprises each of electrical permittivity and magnetic permeability.

27. A method as claimed in claim **24** in which the concentrator is a metamaterial.

28. A method as claimed in claim **27** in which each element comprises at least one of a split ring and a conductive wire providing a respective permeability and permittivity value.

29. A method as claimed in claim **23** in which the concentrator is designed to divert incoming propagating waves such that outgoing propagating waves appear to be unperturbed to an observer.

30. A method of designing a concentrator for provision around a concentrating volume comprising identifying a co-ordinate transform mapping the concentrating volume space onto a collecting volume space and applying a corresponding transform to spatially distributed material parameter values in the concentrator space.

31. A method as claimed in claim **30** in which the material parameter comprises at least one of the refractive index, electrical permittivity, magnetic permeability.

32. A method of constructing a concentrator comprising designing a concentrator as claimed in claim **36**, constructing a plurality of elements having said transformed material parameter values and assembling said elements at the respective transformed spatial positions.

33. A method as claimed in claim **32** in which the assembled elements form a metamaterial.

34. A concentrator for concentrating a concentrating volume comprising a plurality of concentrator elements each having a material parameter arranged to divert a propagating wave from the concentrating volume to a collecting volume.

35. A concentrator as claimed in claim **34** in which the material parameter is at least one of refractive index, electrical permittivity and magnetic permeability.

36. A concentrator as claimed in claim **34** in which the concentrator elements form a metamaterial.

37. A concentrator as claimed in claim **34** in which each concentrator element comprises at least one of a split ring and an electrically conductive wire providing a respective magnetic permeability or electrical permittivity value.

38. A concentrator as claimed in claim **34** further comprising a collecting volume within said concentrating volume.

39. A concentrator as claimed in claim **34** further comprising a plurality of bandwidth enhancing elements.

40. A computer readable medium comprising a set of instructions for implementing a method as claimed in claim **23**.

41. A computer configured to operate under the instructions of a computer readable medium as claimed in claim **40**.

42. A computer readable medium storing concentrator element material parameter data derived according to the method of claim **30**.

43. A concentrator as claimed in claim **34** configured for concentrating in at least one of the following electromagnetic spectrum bands: visible, infrared, ultraviolet, x-ray, radio, radar, microwave.

44. A method for controlling a propagating wave within a material comprising controlling the values of electrical permittivity and magnetic permeability exhibited by the material independently of one another.

45. A method as claimed in claim **44** in which the material is a metamaterial.

46. A method as claimed in claim **44** in which the propagating wave is an electromagnetic wave.

47. A method as claimed in claim **44** wherein the propagating wave is controlled to circumvent a concealable volume.

48. A method as claimed in claim **44** wherein the propagating wave is directed from a concentrating volume to a collecting volume.

49. A method of defining a spatial distribution of material parameter values of an object comprising performing a spatial coordinate transformation in relation to a volume having a pre-transformation material parameter value spatial distribution, and constructing an object from a metamaterial having a post-transformation material parameter value spatial distribution.

50. A method of defining a spatial distribution of material parameter values of an object comprising performing a spatial coordinate transformation in relation to a volume having a pre-transformation material parameter value spatial distribution having an effect on a volume surrounding the object, in which the spatial transformation is selected so that the post-transformation material parameter value spatial distribution achieves the same effect on the volume surrounding the object.

51. A method as claimed in claim **50** in which the effect on the surrounding volume is non-perturbation of electromagnetic radiation by virtue of presence of the object.

(57) **ABSTRACT**

An apparatus and method of cloaking is described. An object to be cloaked is disposed such that the cloaking apparatus is between the object and an observer. The appearance of the object is altered and, in the limit, the object cannot be observed, and the background appears unobstructed. The cloak is formed of a metamaterial where the properties of the metamaterial are varied as a function of distance from the cloak interfaces, and the permittivity is less than unity. The metamaterial may be fabricated as a composite material having a dielectric component and inclusions of particles of sub-wavelength size, so as to have a permeability substantially equal to unity.

SYSTEM, METHOD AND APPARATUS FOR CLOAKING

[0001] This application claims the benefit of U.S. provisional application Ser. No. 60/857,526, filed on Nov. 8, 2006, which is incorporated herein by reference.

STATEMENT OF GOVERNMENT SUPPORT

[0002] This application is based on research sponsored by the U.S. Army Research Office under 50342-PH-MUR.

TECHNICAL FIELD

[0003] This application relates to a system, method and apparatus for the modification of the scattering properties of an object. In particular, the effect may be achieved using non-magnetic materials.

BACKGROUND

[0004] An object may be sought to be made invisible at least over some frequency range. This has been termed a “cloak of invisibility”; the invisibility sought may be partial at a specific frequency, or over a band of frequencies, so the term “cloak of invisibility” or “cloak” may take on a variety of meanings. The cloak may be designed to decrease scattering (particularly “backscattering”) from an object contained within, while at the same time reducing the shadow (“forward scattering”), so that the combination of the cloak and the object contained therein have a resemblance to free space. When the phrase “cloaking”, “cloak of invisibility” or the like, is used herein, the effect is generally acknowledged to be imperfect, and the object may appear in a distorted or attenuated form, or the background obscured by the object may be distorted or partially obscured.

[0005] In an aspect the cloak has a similarity to “stealth” technology where the objective is to make the object as invisible as possible in the reflection or backscattering direction. One means of doing this is to match the impedance of the stealth material to that of the electromagnetic wave at the boundary, but where the material is strongly attenuating to the electromagnetic waves, so that the energy backscattered from the object within the stealth material is strongly attenuated on reflection, and there is minimal electromagnetic reflection at the boundary within the design frequency range. This is typically used in evading radar in military applications. Shadowing may not be a consideration in stealth technology.

[0006] The materials used for the cloak may have properties where, generally the permeability and permittivity tensors are anisotropic and where the magnitudes of the permeability and permittivity are less than one, so that the phase velocity of the electromagnetic energy being bent around the cloaking region is greater than that of the group velocity.

[0007] Materials having such properties have not been discovered as natural substances, but may be produced as artificial, man-made materials, where the permittivity and permeability are less than unity, and may be negative. Metamaterials, an extension of the concept of artificial dielectrics, were first designed in the 1940s for microwave frequencies. They typically consist of periodic geometric structures of a guest material embedded in a host material. Analogous to the circumstance where homogeneous dielectrics owe their properties to the nanometer-scale structure of atoms, metamaterials derive their properties from the sub-wavelength structure of its component materials. At wavelengths much longer than the unit-cell size, the structure can be assigned parameters that may be used describe homogeneous dielectrics, such as electric permittivity and refractive index.

[0008] A first experimental demonstration of a cloak operating over a narrow band of microwave frequencies was recently reported. Cloaking was achieved by varying the dimensions of a series of split ring resonators (SRRs) to yield a desired gradient of permeability in the radial direction. However, there appear to be limits to size scaling of SRRs so as to exhibit magnetic responses in the optical range. Replacing the SRRs with other optical magnetic structures like paired nano-rods or nano-strips may be difficult, primarily due to fabrication issues. Moreover, optical magnetism based on, for example, resonant plasmonic structures is usually associated with a high loss factor, which may be detrimental to the performance of cloaking devices.

SUMMARY

[0009] An apparatus is disclosed, the apparatus being a structure formed of a material having a permittivity less than unity and a permeability approximately equal to unity. The structural material may be a metamaterial: for example, a material having a permittivity greater than or equal to unity, partially filled with a material having a negative permittivity at a design wavelength. The permittivity of the material may be anisotropic.

[0010] In an aspect, the apparatus is sized and dimensioned such that the structure is disposable between an object and an observer.

[0011] A method of cloaking an object is described, the method including providing a structure formed of a metamaterial, and disposing the object to be cloaked such that the structure is positioned between the object and an observer. The metamaterial has a permittivity less than unity and a permittivity approximately equal to unity. The metamaterial may be fabricated from a dielectric with sub-wavelength inclusions of a material having a permittivity less than zero.

[0012] In another aspect, method of designing a cloaking structure includes, selecting a dielectric material; selecting a filler material having a permittivity less than zero; and, adjusting at least one of a distribution, a quantity or a dimension of the filler material within the dielectric material such that, at a design wavelength, a permittivity of a composite material comprised of the dielectric material and the filler material varies with a distance such that a visibility of an object disposed within the cloaking structure is reduced, and the region behind the object is visible.

[0013] In yet another aspect, a cloaked object, includes an object having a electromagnetic scattering property and a structure disposable between the object and an observer. The structure may be fabricated from a material having a permeability approximately equal to unity and a permittivity between approximately unity and approximately zero. The properties of the material may be selected so that a visibility of the object is reduced and a visibility of region behind the cloaked object may be substantially unaffected.

BRIEF DESCRIPTION OF THE DRAWINGS

[0014] FIG. **1**A illustrates the coordinate transformation that compresses a cylindrical region r<b into a concentric

cylindrical shell a<r<b; and, **1**B the structure of a non-magnetic optical cloak, together with a portion of the inner surface thereof;

[0015] FIG. **2**A is a graph of the functions f_0 and f_1 as defined by (8) for a silver-silica composite with aspect ratios of 10:1, 20:1 and 50:1, respectively; **2**B, the operational point determined by (11) for a cloak consisting of silver wires of $\alpha=10.7$ in silica; and, **2**C, the material parameters $\in_r$, $\in_\theta$ and μ_z of the cloak operating at $\lambda=632.8$ nm, where the solid line (—) represents the exact set of reduced parameters by Eq. 2, and the diamond (◇): parameters of the metal wire composite cloak; and

[0016] FIG. **3** is a cross-sectional view of finite-element simulations of the magnetic field mapping around the cloaked object with TM illumination at $\lambda=632.8$ nm when the object is surrounded by: A, a cloak with the exact set of reduced parameters; B, the metal wire composite cloak; and C, a vacuum (no cloak).

[0017] FIG. **4** shows a comparison of the anisotropic material properties for of the anisotropic material properties for the optimal quadratic design ($p=a/b^2$), solid lines and the linear transformation ($p=0$), dashed lines. The shape factor a/b is 0.31 and the diameter **2***b* is 4 microns.

[0018] FIG. **5** shows the results of full-wave field-mapping simulations of the magnitudes of the normalized scattered field for a metal cylinder with: A, no cloak; B, an ideal cloak; C, a linear transformation non-magnetic cloak; and D, an optimal quadratic transformation nonmagnetic cloak; and

[0019] FIG. **6** shows scattering patterns from the four cases shown in FIG. **5**; where A shows the metal cylinder scatterer with no cloak and the cylinder with the ideal cloak; and B shows the cylinder with a linear nonmagnetic cloak and the cylinder with an optimal quadratic nonmagnetic cloak.

DETAILED DESCRIPTION

[0020] Exemplary embodiments may be better understood with reference to the drawings, but these embodiments are not intended to be of a limiting nature.

[0021] When the phrase “cloaking”, “cloak of invisibility” or the like is used herein, the effect is generally acknowledged to be imperfect in practice, and the object may appear in a distorted or attenuated form, or the background obscured by the object may be distorted or partially obscured. Therefore, “cloak” should not be interpreted so as to require that the object within the cloak be “invisible” even at a design wavelength.

[0022] Reference may be made in this application to systems, apparatus, components, or techniques that are known, so as to enable a person of ordinary skill in the art to be able to comprehend the examples disclosed in the specification. The examples are intended to enable a person of ordinary skill in the art to practice the inventive concepts as claimed herein, using systems, apparatus, components, or techniques that may be known, disclosed herein, or hereafter developed, or combinations thereof. Where a comparison of performance is made between the examples disclosed herein and any known system, apparatus, component, or technique, such comparison is made solely to permit a person of skill in the art to more conveniently understand the present novel system, apparatus, component, or technique, and it should be understood that, in complex systems, various configurations may exist where the comparisons made may be better, worse, or substantially the same, without implying that such results are invariably obtained or constitute a limitation on the performance which may be obtained.

[0023] A non-magnetic cloak structure of cylindrical geometry which may be operable at visible wavelengths is described. The cloak may be designed to be effective at other wavelengths, and in other geometries.

[0024] In a first example, a cylindrical geometry is selected. A coordinate transformation may be used where a cylindrical region r<b is compressed into a concentric cylindrical shell a<r<b as shown in FIG. **1**A. There is no variation of permittivity or permeability along the z direction in the model geometry of this example.

[0025] Using a linear coordinate transformation results in the following properties for the anisotropic permittivity and permeability in a cloaking shell or structure:

$$\varepsilon_r = \mu_r = \frac{r-a}{r}, \qquad (1)$$

$$\varepsilon_\theta = \mu_\theta = \frac{r}{r-a},\ \varepsilon_z = \mu_z = \left(\frac{b}{b-a}\right)^2 \frac{r-a}{r}$$

[0026] Mathematically, there are a variety of coordinate transformations that may be used, and while a linear transformation is used in this example, the optimization of a quadratic coordinate transformation is described in a second example. Such mathematical examples are convenient for discussion, but more complex transformations may be used and, in conjunction with electromagnetic finite-element analysis, to design more complex structures having differing properties, and include the effects of lossy materials.

[0027] For transverse electromagnetic (TE) illumination of the cylindrical system with the incident electrical field polarized along the z axis, only ϵ_z, μ_r and μ_θ in (1) enter into Maxwell’s equations. The dispersion properties and wave trajectory in the cloaking shell remain the same as long as the values of the products $\epsilon_i\mu_j$ are maintained constant, where i and j represent any of the two distinct subscripts among r, θ and z.

[0028] For transverse magnetic (TM) illumination of the cylindrical system with the incident magnetic field polarized along the z axis is considered, only μ_z, ϵ_r and ϵ_θ may need to satisfy the requirements in (1), and the dispersion relations inside the cloak may remain unaffected as long as the product of $\mu_z\epsilon_r$ and $\mu_z\epsilon_\theta$ are maintained the same as the values determined by (1). Unlike the TE case, under TM illumination only one component of μ is of interest in the model. By multiplying ϵ_r and ϵ_θ by the value of μ_z, a reduced set of cloaking shell parameters is obtained:

$$\mu_z = 1 \qquad (2a)$$

$$\varepsilon_\theta = \left(\frac{b}{b-a}\right)^2 \qquad (2b)$$

$$\varepsilon_r = \left(\frac{b}{b-a}\right)^2 \left(\frac{r-a}{r}\right)^2 \qquad (2c)$$

[0029] By the process of normalizing the parameters to the permeability such that $\mu_z=1$, a material that does not exhibit magnetic properties within the effective frequency regime of the cloak may be used. The reduced set of parameters of (2) results in the same electromagnetic wave trajectories as for materials meeting the requirements of (1).

[0030] The ideal parameters in (1) result in a perfectly-matched impedance of $Z=\sqrt{\mu_z/\epsilon_\theta}=1$ at r=b, while the reduced set in (2) produces an impedance at the outer boundary of $Z=1-R_{ab}$, where R_{ab}=a/b denotes the ratio between the inner and outer radii. R_{ab} may be termed the "shape factor" of the cylindrical structure. The level of power reflection or back-scattering due to using reduced parameters in the design with a linear transformation can be estimated as $|(1-Z)/(1+Z)|^2=[R_{ab}/(2-R_{ab})]^2$.

[0031] The azimuthal permittivity ϵ_θ is a constant with a value larger than 1, which can be achieved with the usual dielectric materials, although specially designed materials are not intended to be excluded. The cylindrical shell may be constructed with a desired radial distribution of ϵ_r which may vary from 0 at the inner boundary (r=a) of the cloak to 1 at the outer surface (r=b).

[0032] The effect of using a material meeting the electromagnetic and spatial requirements of (2) is to guide incident electromagnetic waves such that they are excluded from the region interior to r=a, and which exit the cloaking region with minimal disturbance to the originally incident ray paths. As such, the background behind the object may appear to be substantially undisturbed by the presence of the object being cloaked.

[0033] Artificial dielectrics, such as metamaterials, with a positive permittivity ϵ_r less than unity are known. In this example, the characteristics of ϵ_r may be realized, for example, by using metal wires of sub-wavelength size disposed in a radial direction and embedded in a dielectric material, as shown FIG. **1**B. The wires may be disposed perpendicular to the cylinder inner and outer surfaces. The spatial positions may not be periodic and may be random. For large cloaks, the wires may be broken into smaller pieces. The aspect ratio of the metal wires, defined by the ratio of the length to the radius of the wire, is denoted by α. The whole structure of the cloaking system may conceptually resemble a round hair brush (except that the "bristles" of such a "hair brush" may consist of disconnected smaller pieces, with either random or periodic distribution within the cylinder).

[0034] The metal material may be chosen so as to have a negative permittivity in the wavelength regime chose for the design. Metals from the noble metals such as gold, silver, tantalum, platinum, palladium or rhodium may be used. Other materials are known to exhibit negative permittivity, such as silicon carbide. These materials may be combined with dielectric materials having a permittivity greater than unity, so as to result in a metamaterial with an effective permittivity between about zero and unity.

[0035] The shape-dependent electromagnetic response of a sub-wavelength particle can be characterized by the Lorentz depolarization factor q. For an ellipsoid of semiaxes a_i, a_j and a_k with electric field polarized along a_i, the depolarization factor may be expressed by:

$$q_i=\int_0^\infty \frac{a_i a_j a_k ds}{2(s+a_i^2)^{3/2}(s+a_j^2)^{1/2}(s+a_k^2)^{1/2}} \tag{3}$$

Another commonly used parameter, the screening factor κ of a particle, is related to q by κ=(1−q)/q. A long wire with large aspect ratio α results in a small depolarization factor and a large screening factor, which generally indicates strong interactions between the electromagnetic fields and the wire.

[0036] For a composite cloak with metal wires as inclusions in a dielectric, the electromagnetic properties may be described by "shape-dependent" effective-medium theory (EMT) that describes composites with particles of different shapes and thus different κ-factors. The effective permittivity ϵ_{eff} for a composite material comprising metal particles with permittivity ϵ_m a volume filling factor f and screening factor κ, along with a dielectric component with permittivity ϵ_d and a filling factor $1-f$ is given by:

$$f\frac{\varepsilon_m-\varepsilon_{eff}}{\varepsilon_m+\kappa\varepsilon_{eff}}+(1-f)\frac{\varepsilon_d-\varepsilon_{eff}}{\varepsilon_d+\kappa\varepsilon_{eff}}=0 \tag{4}$$

For spherical particles with q=⅓ and κ=2, (4) reduces to the common EMT expression which is a quadratic equation with the following solutions:

$$\varepsilon_{eff}=\frac{1}{2\kappa}\left\{\bar{\varepsilon}\pm\sqrt{\bar{\varepsilon}^2+4\kappa\varepsilon_m\varepsilon_d}\right\} \tag{5}$$

where $\bar{\epsilon}=[(\kappa+1)f-1]\epsilon_m+[\kappa-(\kappa+1)f]\epsilon_d$. The sign in (5) may be chosen such that $\epsilon_{eff}>0$.

[0037] When using metal wires in a composite cloak, the radial permittivity ϵ_r determined by (5) may exhibit a positive value less than 1 with a minimal imaginary part. Metamaterials having a metallic component may exhibit a permittivity that differs from unity, while having a permeability close to unity, and such material may be termed substantially non-magnetic so as to suggest that the permittivity characteristics are more important in achieving the cloaking.

[0038] For the structure in FIG. **1**B, the volume filling fraction is inversely proportional to r. The filling fraction in the EMT formula for calculating ϵ_r using (5) may be $f(r)=P_a\cdot(a/r)$, with P_a being the surface cover ratio of metal at the inner surface of the cloak (r=a). The filling fractions f at the inner and outer surface of the cloak are P_a and $P_a\cdot(a/b)$ respectively, and the overall metal filling fraction in the whole cloak layer is $P_a\cdot 2a/(a+b)$. The azimuthal permittivity ϵ_θ inside the cloak is substantially the same as that of the dielectric material because a response of wires to the angular electrical field E_θ oriented normally to the wires is small and, at low metal filling factors, it may generally be neglected.

[0039] The reduced set of cloak parameters in (2) is consistent with a smooth variation of the radial permittivity from 0 to 1 as r varies from a to b. That is,

$$\begin{cases}\varepsilon_{eff,r}(P_a)=0\\ \varepsilon_{eff,r}(P_a\cdot a/b)=1\end{cases} \tag{6}$$

[0040] The gradient in $\epsilon_{eff,r}$ may follow the function described in (2c) such that

$$\varepsilon_{eff,r}(P_a\cdot a/r)=\left(\frac{b}{b-a}\right)^2\left(\frac{r-a}{r}\right)^2 \tag{7}$$

[0041] In an actual design, $\epsilon_{eff,r}$ may have some deviation from the value given by (2c) inside the cloak. For example, in the reported microwave cloak with a layered structure, the desired permeability was fulfilled at only a few discrete positions along the radial direction, while in the majority of the cloak the material was air. At the inner and outer surfaces of the cloak, the conditions of (6) should be satisfied as closely as practical, although the conditions at the inner surface may be relaxed where there is a lossy component to the material. This may result in impedance index matching at r=b and minimal leaking energy at r=a.

[0042] To determine all the parameters of the design shown in FIG. **1**B, the general properties of a metal-dielectric composite with thin metal wires in the radial direction as the inclusion are modeled. Two filling fraction functions $f_0(\lambda)$ and $f_1(\lambda)$ are such that for given constituent composite materials and for a fixed aspect ratio α of the wires, the effective radial permittivity is.

$$\epsilon_{eff,r}(\lambda, f_0(\lambda))=0 \tag{8a}$$

and

$$\epsilon_{eff,r}(\lambda, f_1(\lambda))=1 \tag{8b}$$

The values of $f_0(\lambda)$ and $f_1(\lambda)$ calculated from (5) and (8) for a silver-silica composite with α=10, 20 and 50 at visible wavelengths are plotted in FIG. **2**A. In the calculation the metal permittivity is approximated by the Drude model, and the permittivity of the dielectric is calculated using Sellmeier equation.

[0043] Combining (6) and (8), at the design wavelength λ,

$$\begin{cases} f_0(\lambda) = P_a \\ f_1(\lambda) = P_a \cdot a/b \end{cases} \tag{9}$$

[0044] From the above equations R_{ab} may be expressed as:

$$R_{ab}=f_1(\lambda)/f_0(\lambda) \tag{10}$$

[0045] Using (10) with (2b), the operating condition of the cloak is obtained as:

$$f_1(\lambda)/f_0(\lambda)=1-\sqrt{1/\epsilon_\theta(\lambda)}, \tag{11}$$

where $\epsilon_\theta(\lambda)$ is the permittivity of the dielectric material surrounding the metal wires in the cloak. Thus, the geometrical factors of the cloak including R_{ab}, P_a and α are determined. The same design may work for similar cylindrical cloaks with the same shape factor R_{ab}. In FIG. **2**B we show the operational point obtained by (11) is shown for a cloak consisting of silver wires with α=10.7 in silica.

[0046] A cloaking device or structure may be designed for operating at an operational wavelength λ_{op}. A method of designing a cloaking device may include the steps of: choosing materials that are available for the metal wires and the surrounding dielectric, or other metamaterials; and, calculating the values of f_0 and f_1 as functions of the aspect ratio α at λ_{op} using, for example, the EMT model in (5). Other models may also be used. The desired aspect ratio for λ_{op} corresponds to the fulfillment of (12).

$$\varepsilon_\theta(\lambda_{op}) = \left(\frac{f_0(\lambda_{op}, \alpha)}{f_0(\lambda_{op}, \alpha) - f_1(\lambda_{op}, \alpha)}\right)^2 \tag{12}$$

Then, the structure of the cloak can be determined from (9) and (10).

[0047] The "round brush" design for a non-magnetic cloak may permit constructing an appropriate device operating at desired wavelength, which may be an optical wavelength, by choosing the proper materials and structures. As an example, the design of an optical cloak operating at the frequently-used wavelength of 632.8 nm (He—Ne laser), and consisting of silver and silica is described.

[0048] Expressions (5), (8), and (12) yield the aspect ratio α=10.7, and the volume filling fractions at the two boundaries are f_0=0.125 and f_1=0.039, respectively. From (9) and (10) the shape factor of the cylindrical cloak is Rab=0.314 while the surface cover ratio at the inner boundary is P_a=12.5%. The effective parameters of μ_z, ϵ_r and ϵ_θ from for this design and the set of reduced parameters from (2) are shown in FIG. **2**C. As seen in FIG. **2**C, μ_z and ϵ_θ match the theoretical requirements throughout the cylindrical cloak. In this example, the radial permittivity ϵ_r fits the values required by (2) exactly at the two boundaries of the cloak, and follows the overall tendency relatively well inside the cloak. The imaginary part of ϵr is almost zero at r=b where $\epsilon_r'(\lambda_{op}, b)=1$ and reaches around 0.6 at the inner surface where $\epsilon_r'(\lambda_{op}, a)=0$. These quantities are similar to reported low-index metamaterials with periodic-metal-wire arrays.

[0049] The effects of loss can be addressed in several ways. As an example, if the aspect ratio of the wires is varied along the radial direction, the imaginary part of ϵ_r may be smaller than 0.1 throughout the cloak. It may possible to compensate the loss by using a gain medium.

[0050] To illustrate the performance of the non-magnetic optical cloak with a design corresponding to FIG. **2**C, a finite element method simulation using the commercial finite element package COMSOL Multiphysics (available from COMSOL, Inc. Burlington, Mass.) was performed. An ideal metallic cylinder with radius r=a is disposed within the cloaked region. The simulated results of magnetic field distribution around the cloaked object together with the power flow lines are illustrated in FIG. **3** for three cases. As shown in FIG. **3**A, the cloak with the reduced set of material parameters represented by the solid curves in FIG. **2**C leads to a small perturbation of the external fields, which is limited by imperfect impedance matching. FIG. **3**B corresponds to a cloak with parameters given by the diamond shaped markers in FIG. **2**C. Comparing the field maps in FIGS. **3**A and **3**B, the simulations for the designed cloak are in good agreement with the exact case. Without the cloak (FIG. **3**C), the waves around the object are severely distorted and a clear shadow is cast behind the cylinder. These simulations show the capability of the structure described in reducing the scattering from the object inside the cloaked region.

[0051] The achievable invisibility with the example designed cloak is not perfect due to impedance mismatch associated with the reduced material specifications and the energy loss in a metal-dielectric structure.

[0052] In another aspect, a cloaking device can be based on vertical metal strips (instead of rods) placed in the radial directions within the cloaking structure. These strips can also be randomly or periodically disposed and may also consist of disconnected smaller strips. Chains of metal particles of various shapes may also be used.

[0053] In a second example, the coordinate transformation applied to (1) may be a high-order transformation such as a quadratic instead of the linear transformation. This example is one of a number of different analytic coordinate transformations which may be employed and illustrates a particular situation where the impedance is matched at the boundary between the cloaking cylinder and the assumed free space propagation medium of the incident electromagnetic wave.

[0054] By constraining the impedance of the outer boundary to be equal to that of the external propagation medium, an optimal quadratic coordinate transformation may be obtained as:

$$r=[(a/b((r'/b-2)+1]r'+a \tag{13}$$

[0055] The shape factor a/b should be less than 0.5 in order to have a monotonic transformation. When evaluating the material properties at the outer boundary, r=b, the material parameters ϵ_r, ϵ_θ, μ_r, are each equal to unity. As such, the impedance mismatch at the boundary has been obviated for the case of reduced parameters.

[0056] FIG. **4** compares the material properties of the nonmagnetic cloak structures of the first and the second examples, where the shape factor a/b is 0.31, and the diameter (**2***b*) is 4 micrometers and the wavelength λ=632.8 nanometers. The object disposed inside of the cloaks is an ideal metal cylinder with a radius that is the same as the inner surface; that is r=a. This may be a worst-case condition, and an arbitrarily shaped object of any configuration may be disposed inside of the inner surface with the same, similar, or better results.

[0057] The results were computed using the same finite-element software package as used for the first example, and the normalized magnitudes of the scattered fields are shown in FIG. **5**.

[0058] The scattered field from the cloaked metallic cylinder is itself is shown in FIG. **5**A. The strong forward scattering observed at the right-hand side of the diagram corresponds to a shadow cast behind the object. An idealized cloak is shown in FIG. **5**B, where the scattered field would be essentially zero in magnitude in all directions in the plane. These examples may be compared with the results obtained for the linear transformation (FIG. **5**C) and the quadratic case (FIG. **5**D). The linear case exhibits a scattering pattern from the outer boundary of the system, primarily due to the impedance mismatch. On the other hand, the quadratic transformation function results in substantially less scattering from the cloaking system. A figure of merit for cloaking, which may be defined as the ratio of the scattering cross sections with and without the cloak, is about 10 for quadratic cloak of the dimensions modeled, and it increases as the size of the cloaking system increases.

[0059] FIGS. **6** A and B. show the scattering radiation patterns corresponding to the four cases of FIG. **5**. The curves in FIG. **6** show the energy flow in the radial direction normalized by the maximum value in the noncloaked case at a boundary outside the outer surface of the cloak structures. In the ideal cloaking system, the scattering energy flow is zero, which is indicated by the solid inner circle in FIG. **6**A.

[0060] FIG. **6**B shows that the linear cloak structure with reduced parameters exhibits a noticeable although smaller scattering, and has and strongly directional scattering pattern. However, for the nonmagnetic quadratic cloak, the overall scattering is much less significant. The peak value of the radial Poynting vector in the quadratic cloak is more than six times smaller than that of the linear example. Moreover, the directivity in the scattering pattern is substantially suppressed.

[0061] In another aspect, a cloaking device or structure may be a spherical or other shaped cloaking structure. The specific geometrical shape, the size and other design parameters of the structure, such as the spatial variation of permittivity, may be chosen using the general approach described herein so as to be adaptable to the wavelength, the degree of cloaking, and the properties of the object to be cloaked. Loss and gain may be introduced in various portions of the structure.

[0062] The examples shown herein have used analytic profiles for the material properties so as to illustrate certain of the principles which may influence design of cloaking structures. However, since electromagnetic simulations using finite element methods are commonly used in design of complex shapes, and have been shown herein to yield plausible results, the use of such simulations are envisaged as useful in design.

[0063] Certain aspects, advantages, and novel features of the claimed invention have been described herein. It would be understood by a person of skill in the art that not all advantages may be achieved in practicing a specific embodiment. The claimed invention may be embodied or carried out in a manner that achieves or optimizes one advantage or group of advantages as taught herein without necessarily achieving other advantages as may have been taught or suggested.

[0064] It is therefore intended that the foregoing detailed description be regarded as illustrative rather than limiting, and that it be understood that it is the following claims, including all equivalents, that are intended to define the spirit and scope of this invention.

What is claimed is:

1. A cloaking apparatus, comprising:

a structure formed of a material having a permittivity less than unity and a permeability approximately equal to unity,

wherein the material is a metamaterial.

2. The apparatus of claim **1**, wherein the structure is disposable between an object and an observer.

3. The apparatus of claim **1**, wherein the structure has a first surface and a second surface such that an object is disposable so that the second surface lies between the object and the first surface.

4. The apparatus of claim **3**, wherein the permittivity of the metamaterial varies between approximately zero at an interface with the void and approximately unity at an outer radius of the cylinder.

5. The apparatus of claim **3**, wherein the properties of the metamaterial are selected so that the power flow crossing the second surface in the direction of an object to be cloaked is minimized.

6. The apparatus of claim **3**, wherein the properties of the metamaterial are selected so that the backscattering coefficient and the forward scattering coefficient of a combination of the structure and an object disposed such that the first and second surfaces are disposed between the object and a source of electromagnetic radiation are reduced.

7. The apparatus of claim **3**, wherein the properties of the metamaterial include a variation of permittivity with distance between the first and the second surface.

8. The apparatus of claim **3**, wherein the metamaterial has permittivity that is a function of the distance between the first surface and the second surface, and the variation of the permittivity is selected so that the impedance of the metamaterial at the first surface is the substantially the same as the impedance of a region outside of the structure and abutting the first surface.

9. The apparatus of claim **1**, wherein the structure has at least one axis of symmetry.

10. The apparatus of claim **1**, wherein the structure has a cylindrical symmetry, and an inner void.

11. The apparatus of claim **10**, wherein an object is disposable in the inner void.

12. The apparatus of claim **10**, wherein the permittivity of the metamaterial varies in a radial direction.

13. The apparatus of claim **1**, wherein the permittivity is anisotropic.

14. The apparatus of claim **1**, wherein the metamaterial comprises a dielectric material having a permittivity greater than or equal to unity partially filled with a material having a negative permittivity at a design wavelength.

15. The apparatus of claim **14**, wherein the filler material is a plurality of sub-wavelength sized structures.

16. The apparatus of claim **14**, wherein the material having a negative permittivity is a metal.

17. The apparatus of claim **16**, wherein the metal is selected from a noble metal group.

18. The apparatus of claim **1**, wherein the properties of the metamaterial are selected so that an impedance discontinuity between the metamaterial and an external environment is minimized.

19. The apparatus of claim **18**, wherein a refractive index of the external environment is unity.

20. The apparatus of claim **1**, wherein the properties of the metamaterial are selected so that the backscattering coefficient and the forward scattering coefficient of the structure are reduced.

21. The apparatus of claim **1**, wherein the rate of change of an outer geometrical shape of the structure is slow when compared with a value of a design wavelength.

22. The apparatus of claim **1**, wherein the metamaterial is lossless.

23. The apparatus of claim **1**, wherein the metamaterial has a permeability of unity.

24. The apparatus of claim **1**, wherein the properties of the metamaterial are selected so that a cloaking effect is a maximum at a visible wavelength of light.

25. The apparatus of claim **1**, wherein the metamaterial includes a gain medium material.

26. A method of cloaking an object, the method comprising:

providing a structure formed of a metamaterial; and

disposing the object to be cloaked such that the structure is positioned between the object and an observer,

wherein the metamaterial has a permittivity less than unity and a permittivity approximately equal to unity.

27. The method of claim **16**, wherein the metamaterial is a dielectric with sub-wavelength inclusions of a material having a permittivity less than zero.

28. The method of claim **26**, wherein the object is surrounded by the structure.

29. A method of designing a cloaking structure, the method comprising:

selecting a dielectric material;

selecting a filler material having a permittivity less than zero; and

adjusting at least one of a distribution, a quantity or a dimension of the filler material within the dielectric material such that, at a design wavelength, a permittivity of a composite material comprised of the dielectric material and the filler material varies with a distance such that a visibility of an object disposed within the cloaking structure is reduced, and the region behind the object is visible.

30. The method of claim **29**, where the energy reflected from a surface of the cloaking structure is substantially less than the energy that reflectable by the object without the cloaking structure.

31. The method of claim **29**, wherein an outer geometrical shape of the cloaking structure is slowly varying with respect to the design wavelength.

32. The method of claim **29**, wherein the composite material further includes a gain medium.

33. A cloaked object, the object comprising:

an object having a electromagnetic scattering property; and

a structure disposable between the object and an observer, wherein the structure further comprises:

a material having a permeability approximately equal to unity and a permittivity between approximately unity and approximately zero.

34. The cloaked object of claim **33**, wherein the properties of the material are selected so that a visibility of the object is reduced and a visibility of region behind the cloaked object is substantially unaffected.

35. The cloaked object of claim **33**, wherein the properties of the metamaterial include the variation of permittivity as a function of a location within the structure.

36. The cloaked object of claim **33**, wherein a design wavelength is within a visible light spectrum.

37. The cloaked object of claim **33**, wherein the material further includes a gain medium.

38. The cloaked object of claim **33**, where an outer geometrical shape of the structure varies slowly compared with a value of a design wavelength.

(57) **ABSTRACT**

An apparatus and method of cloaking is described. An object to be cloaked is disposed such that the cloaking apparatus is between the object and an observer. The appearance of the object is altered and, in the limit, the object cannot be observed, and the background appears unobstructed. The cloak is formed of a metamaterial where the properties of the metamaterial are varied as a function of distance from the cloak interfaces. The metamaterial may be fabricated as a composite material having a dielectric component and inclusions of particles of sub-wavelength size, and may also include a gain medium.

SYSTEM, METHOD AND APPARATUS FOR CLOAKING

[0001] This application claims the benefit priority to U.S. provisional application Ser. No. 61/103,025, filed on Oct. 6, 2008, which is incorporated herein by reference.

STATEMENT OF GOVERNMENT SUPPORT

[0002] This work was supported in part Army Research Office grant W911NF-04-1-0350 and by ARO-MURI award 50342-PH-MUR.

TECHNICAL FIELD

[0003] This application relates to a system, method and apparatus for the modification of the observability properties of an object by a structure.

BACKGROUND

[0004] An object may be made effectively invisible at least over some frequency range. This has been termed a "cloak of invisibility"; the invisibility sought may be partial at a specific frequency, or over a band of frequencies, so the term "cloak of invisibility" or "cloak" may take on a variety of meanings. The cloak may be designed to decrease scattering (particularly "backscattering") from an object contained within, while at the same time reducing the shadow cast by the object, so that the combination of the cloak and the object contained therein have a resemblance to free space. When the phrase "cloaking," "cloak of invisibility," or the like, is used herein, the effect is generally acknowledged to be imperfect, and the object may appear in a distorted or attenuated form, or the background behind the object by the object may be distorted or partially obscured.

[0005] As will be understood by a person of skill in the art a "frequency" and a "wavelength" are inversely related by the speed of light in vacuo, and either term would be understood when describing an electromagnetic signal.

[0006] In some aspects, the cloak has a superficial similarity to "stealth" technology where the objective is to make the object as invisible as possible in the reflection or backscattering direction. One means of doing this is to match the impedance of the stealth material to that of the electromagnetic wave at the boundary, but where the material is strongly attenuating to the electromagnetic waves, so that the energy backscattered from the object within the stealth material is strongly attenuated on reflection, and there is minimal electromagnetic reflection at the boundary within the design frequency range. This is typically used in evading radar detection in military applications. Shadowing may not be a consideration in stealth technology. Shadowing may be understood as the effect of the object in blocking the observation of anything behind the object, for example the background, where the object is disposed between the observer and the background. A perfect cloak would result in no shadowing.

[0007] The materials used for the cloak may have properties where, generally, the permeability and permittivity tensors are anisotropic and where the magnitudes of the permeability and permittivity are less than one, so that the phase velocity of the electromagnetic energy being bent around the cloaking region is greater than that of the group velocity.

[0008] Materials having such properties have not been discovered as natural substances, but have been produced as artificial, man-made composite materials, where the permittivity and permeability of the bulk material are less than unity, and may be negative. They are often called "metamaterials" an extension of the concept of artificial dielectrics, that were first designed in the 1940s for microwave frequencies. Such materials typically consist of periodic geometric structures of a guest material embedded in a host material.

[0009] Analogous to the circumstance where homogeneous dielectrics owe their properties to the nanometer-scale structure of atoms, metamaterials may derive their properties from the sub-wavelength structure of its component materials. At wavelengths much longer than the unit-cell size of the material, the structure can be represented by effective electromagnetic parameters that are also used describe homogeneous dielectrics, such as an electric permittivity and a refractive index.

[0010] Cloaking has been experimentally demonstrated over a narrow band of microwave frequencies by achieved by varying the dimensions of a series of split ring resonators (SRRs) to yield a desired gradient of permeability in the radial direction.

SUMMARY

[0011] A apparatus for modifying the visibility properties of an object is disclosed, including a structure formed of a metamaterial. The metamaterial properties are selected so that an electromagnetic wave incident on the apparatus is guided around the object at plurality of wavelengths.

[0012] In an aspect, a method of designing a structure for use as a cloak effective at a plurality of wavelengths, includes the steps of: selecting a design wavelength; selecting a metamaterial having the property of having a low loss at the design wavelength and at least a permeability or a permittivity of less than unity; and determining, for a selected shape and size of structure, the variation of metamaterial properties as a function of position in the structure so as to guide electromagnetic waves of the design wavelength and polarization around a object disposed within the structure. A second design wavelength is selected and the design process is repeated for the second design wavelength.

[0013] In another aspect, a method of modifying the observability of an object, includes the steps of: providing a structure fabricated from a plurality of metamaterials, the metamaterials selected so as to guide electromagnetic waves around an object at a plurality of wavelengths; and disposing the structure between an observer and the object.

BRIEF DESCRIPTION OF THE DRAWINGS

[0014] FIG. **1** is a representation of a transformation of a vector field;

[0015] FIG. **2** is (a) an example of a general orthogonal cylindrical coordinate system; and, (b) a domain transformation for a cylindrical cloaking device where the larger initial domain in the left panel is mapped onto a scaled smaller annular domain shown in the right panel, leaving the central domain inaccessible to light; the initial and scaled domains share the same exterior boundary and the common space beyond;

[0016] FIG. **3** is a schematic representation of a cloaking system for multiple wavelengths or a finite bandwidth, with $w_1 > w_2 > w_3$, shown in (a), (b), and (c) respectively; the outer and inner circles represent the physical boundaries the cloaking device, and the circle between the two refers to an inner material boundary for each design wavelength;

[0017] FIG. **4** shows design constraints for constructing a non-magnetic cloak in the TM mode with high-order transformations; the thick solid and dashed lines represent the two Wiener bounds $\epsilon_{\|}(f)$ and $\epsilon_{\perp}(f)$, respectively: the basic material properties for this calculation are: $\epsilon_1=\epsilon_{Ag}=-10.6+0.14i$ and $\epsilon_2=\epsilon_{SiO2}=2.13$ at $\lambda=532$ nm;

[0018] FIG. **5** is a perspective view of a cylindrical non-magnetic cloak using the high-order transformations for TM polarization;

[0019] FIG. **6** is a graph of the anisotropic material parameters ϵ_r and ϵ_θ of a non-magnetic cloak made of silver-silica alternating slices corresponding to the third row ($\lambda=532$ nm) in Table 1; the solid lines represent the exact parameters determined by equation 35, and the diamond markers show the parameters on the Wiener's bounds given by equation (37);

[0020] FIG. **7** is a perspective view of a cylindrical non-magnetic cloak with high-order transformations for TE polarization; and

[0021] FIG. **8** shows a comparison of the theoretical and the calculated values of effective parameters μ_r and ϵ_z for a cylindrical TE cloak with SiC wire arrays at a design wavelength of $\lambda=13.5$ μm.

DETAILED DESCRIPTION

[0022] Exemplary embodiments of the apparatus and method may be better understood with reference to the drawings, but these embodiments are not intended to be of a limiting nature.

[0023] When the phrase "cloaking," "cloaking structure," "cloak of invisibility" or the like is used herein, the effect may be imperfect in practice, and the object may appear in a distorted or attenuated form, or the background obscured by the object may be distorted or partially obscured or attenuated, or the perceived color of the background may be modified. Therefore, "cloak" should not be interpreted so as to require that the object within the cloak be "invisible" even at a design wavelength, nor that the background be free of shadowing or distortion. Of course, a design objective may be to approach the ideal cloak at a wavelength or a range of wavelengths. A plurality of non-contiguous wavelength ranges may also be considered in a design for a structure.

[0024] The examples disclosed herein are intended to enable a person of ordinary skill in the art to practice the inventive concepts as claimed herein, using systems, apparatus, components, or techniques that may be known, disclosed herein, or hereafter developed, or combinations thereof. Where a comparison of performance is made between the examples disclosed herein and any known system, apparatus, component, or technique, such comparison is made solely to permit a person of skill in the art to more conveniently understand the present novel system, apparatus, component, or technique, and it should be understood that, in complex systems, various configurations may exist where the comparisons made may be better, worse, or substantially the same, without implying that such results are invariably obtained or constitute a limitation on the performance which may be obtained.

[0025] Broadband cloaking of electromagnetic waves can be understood by a person of skill in the art using a simplified example of a scaling transformation of a general cylindrical coordinate system. A generalized form of the transformation equations is presented so as to permit the application of this approach to other related designs.

[0026] The apparatus design may use metamaterials with specifically engineered dispersion. Constraints on the signs of gradients in the dispersion dependencies of dielectric permittivity and magnetic permeability for different operation wavelengths may result. Some constraints may be obviated by gain-assisted compensation for losses or electromagnetically induced transparency (EIT) are included in the design of cloaking system. So, when a structure, or a portion thereof, is described as "transparent," the transparency may be at a wavelength or a range of wavelengths, and should be understood to be achievable either by low loss materials, or materials with loss that has be compensated by a gain medium.

[0027] Electromagnetically induced transparency (EIT) is a coherent nonlinear process that may occur in some highly dispersive optical systems. EIT creates a narrow transparency window within an absorption peak. The anomalous dispersion along with a low optical loss available in an EIT system may be used for broadband optical cloaking. Similarly, in a gain medium the imaginary part of the refractive index has a negative value, and the dispersion curve exhibits an anti-Lorentz line shape. This property may result in anomalous dispersion with a low loss. Examples of EIT systems are three-state lead vapors. Examples of gain media include electrically or optically pumped semiconductors, dye modules, and quantum structures.

[0028] Examples of electromagnetic wave propagation in an isotropic bi-layer or for multilayer sub-wavelength inclusions of ellipsoidal (spheroidal or spherical) shapes in a dielectric host media are presented. Other geometrical shapes may be used. Such shapes may be known geometrical shapes, portions thereof, or shapes that are composites of geometrical shapes, including shapes that are arbitrary, but slowly varying with respect to the design wavelength.

[0029] In addition to numerical and theoretical studies of composite materials described herein, broadband transparency achieved by using multiphase spherical inclusions with appropriate layered geometries and materials is described. These examples are useful for estimating local electromagnetic fields and effective optical properties of heterogeneous media with binary or multi-phase inclusions, and as the starting point for more complex designs in accordance with the concepts described herein.

[0030] The basics of transformation optics (TO) approach to designing cloaking structures described herein may follow from the fundamental theoretical results of Dolin (Dolin. L. S., Izzv. Vyssh. Uchebn. Zaved., Radiofiz. 4, 694-7, 1961) which showed that Maxwell's equations can be considered to be form-invariant under a space-deforming transformation.

[0031] The underlying theoretical basis for the transformational optics (TO) approach is presented so as to enable a person of skill in the art to generalize the examples which follow. The transformation may be used at any wavelength, but the selection of materials and geometries may depend on the specific application of the design. As such, the terms "light," "optics," and the like, are understood to be interchangeable with "electromagnetic wave" at an appropriate frequency, and not to be limited to light visible to the human eye, infrared light, or the like. Specific examples are provided at visible (to the human eye) wavelengths, and in the mid infrared, so as to illustrate the concepts presented herein.

[0032] Consider an initial material space defined by its radius-vector $\tilde{r}(\tilde{x}, \tilde{y}, \tilde{z})$ and an inhomogeneous distribution of an anisotropic material property (e.g., either anisotropic permittivity, $\in$, or anisotropic permeability, μ), given by a tensor, $\tilde{m}=\tilde{m}(r)$ Suppose that the initial distribution of coupled vector fields, $\tilde{v}=\tilde{v}(\tilde{r})$ and $\tilde{u}=\tilde{u}(\tilde{r})$ is modified using a tensor j. The transformation may be formally achieved by mapping the initial space, using a coordinate transformation ($r=r(\tilde{r})$, i.e. $x=x(\tilde{x}, \tilde{y}, \tilde{z})$, $y=y(\tilde{x}, \tilde{y}, \tilde{z})$, $z=z(\tilde{x}, \tilde{y}, \tilde{z})$) with a non-singular Jacobian matrix j, ($|j|\neq 0$), so that it is a one-to-one transformation in a neighborhood of each point. The Jacobian matrix j is arranged from the columns of base vectors,

$$j=(r^{(x)}r^{(y)}r^{(z)}), \tag{1}$$

or its transposition can be arranged from the columns of gradients

$$j^T=(\tilde{\nabla}x\tilde{\nabla}y\tilde{\nabla}z). \tag{2}$$

In equation (1) and equation (2), $f^{(\cdot)}$ and $\tilde{\nabla}f=f^{(x)}\hat{x}+f^{(y)}\hat{y}+f^{(z)}\hat{z}$ denote a partial derivative and a gradient, respectively. The Jacobian determinant $|j|$ is equal to the triple vector product, $r^{(x)}r^{(y)}r^{(z)}$. Vectors $\tilde{v}$ and $\tilde{v}$ are have scalar components, as $\tilde{v}=\tilde{v}_x\hat{x}+\tilde{v}_y\hat{y}+\tilde{v}_z\tilde{z}$ and $v=v_x\hat{x}+v_y\hat{y}+v_z\hat{z}$, respectively.

[0033] Thus, a general invertible field-deforming transformation,

$$\tilde{v}=j^Tv, \tilde{u}=j^Tu, \tag{3}$$

links the vectors of the initial vector-space $\tilde{v}=\tilde{v}(\tilde{r})$ and $\tilde{u}=\tilde{u}(\tilde{r})$ with the new vectors of a deformed vector-space $v=v(r)$ and $\tilde{u}=\tilde{u}(\tilde{r})$ obtained at the corresponding points of the new material domain.

[0034] A solution may be sought so as to achieve a given transformation of the fields in equation (3). The initial material properties, $\tilde{m}=\tilde{m}(r)$, are modified in order to obtain the required transformation of the vector fields as determined by equation (3). A formal connection between the expressions for gradients before and after the change of variables may be expressed as:

$$x=x(\tilde{x},\tilde{y},\tilde{z}), y=y(\tilde{x},\tilde{y},\tilde{z}), z=z(\tilde{x},\tilde{y},\tilde{z})$$

where

$\tilde{\nabla}f(x, y, z)=f^{(x)}\tilde{\nabla}x+f^{(y)}\tilde{\nabla}y+f^{(x)}\tilde{\nabla}z$, which yields a general result that is analogous to equation (3)

$$\tilde{\nabla}=j^T\nabla. \tag{4}$$

[0035] The transformation identity for the curl can be derived first for pseudo-vectors $p=u\times v$ and $\tilde{p}=\tilde{u}\times\tilde{v}$. The standard vector algebra gives

$$\tilde{u}\times\tilde{v}=(j^Tu)\times(j^Tv)=|j|j^{-1}(u\times v), \tag{5}$$

connecting pseudo-vectors p and $\tilde{p}$ through

$$p=|j|^{-1}j\tilde{p}. \tag{6}$$

[0036] To obtain a formalism that is closer to Maxwell's curl equations, another product of the material tensor m and a vector u can be defined as $(mu)^{(t)}=\nabla\times v$, such that for time-independent material properties, $(mu)^{(t)}=mu^{(t)}$. This yields:

$$mu^{(t)}=\nabla\times v. \tag{7}$$

[0037] The right hand side of equation (7) is identical to $p=u\times v$, provided that vector u is replaced with ∇, following the result shown in equation (4). The use of the same sets of vector components, i.e. $\nabla\times\tilde{v}=(j^Tu)\times(j^Tv)=|j|j^{-1}(\nabla\times v)$ gives $mu^{(t)}=\nabla\times v$. Finally, using $\tilde{m}=|j|j^{-1}m(j^T)^{-1}$, equation (7) can be rewritten as,

$$\tilde{m}\tilde{u}^{(t)}=\tilde{\nabla}\times\tilde{v}. \tag{8}$$

[0038] Then, the required transform for tensors $\tilde{m}$ and m is given by

$$m=|j|^{-1}j\tilde{m}j^T. \tag{9}$$

[0039] As shown in FIG. **1**, the spatial transformation of the vector fields performed by tensor j through equation (3) can be considered as a spatial transformation $r=r(\tilde{x}, \tilde{y}, \tilde{z})$, with j being its Jacobian matrix, $j=(r^{(x)}\ r^{(y)}\ r^{(z)})$.

[0040] For the divergence relationships in Maxwell's equations, the derivation uses a scalar product of vector v and pseudo-vector p, which gives a scalar q (i.e., $v\cdot p=q$). Then, using equation (6) the scalar products yields $\tilde{v}\cdot\tilde{p}=(j^Tv)\cdot(|j|j^{-1}p)=|j|v\cdot p)=|j|v\cdot p$, and an equivalent divergence equation is obtained through substitution of v and $\tilde{v}$ with ∇ and $\tilde{\nabla}$, resulting in:

$$\tilde{\nabla}\cdot\tilde{p}=|j|\nabla\cdot p. \tag{10}$$

[0041] Equation (8) has cast the Maxwell curl equations $\nabla\times E=-\mu H^{(t)}$ and $\nabla\times H=\in E^{(t)}$ into a new set of similar equations, $\tilde{\nabla}\times\tilde{E}=-\tilde{\mu}\tilde{H}^{(t)}$ and $\tilde{v}\times\tilde{H}=\tilde{\in}\tilde{E}^{(t)}$, where

$$H=(j^T)^{-1}\tilde{H}, E=(j^T)^{-1}\tilde{E}, \tag{11}$$

and

$$\in=|j|^{-1}j\tilde{\in}j^T, \mu=|j|^{-1}j\tilde{\mu}j^T. \tag{12}$$

$(j^T)^{-1}$ in (11) is a matrix of the columns of reciprocal vectors $(j^T)^{-1}=(r^{(y)}\times r^{(z)}\ r^{(z)}\times r^{(x)}\ r^{(x)}\times r^{(y)})|j|^{-1}$.

[0042] Thus, provided that the electromagnetic properties of the new material space follow equation (12), the Poynting vector in the new space,

$$S=\frac{1}{2}(E\times H^*),$$

will obey equation (6), satisfying the following transformation of the initial Poynting vector

$$\tilde{S}=\frac{1}{2}(\tilde{E}\times\tilde{H}^*)$$

$$S=|j|^{-1}j\tilde{S}. \tag{13}$$

[0043] An analogous result would also be valid for other pseudo-vectors, e.g., the time derivatives of magnetic flux densities $B^{(t)}$ and $\tilde{B}^{(t)}$, and displacement currents, $D^{(t)}$ and $\tilde{D}^{(t)}$.

[0044] In a similar way, the divergence equations $\tilde{\nabla}\cdot\tilde{D}=\tilde{q}$ and $\nabla\cdot D=q$ would link the charge densities through equation (10) as

$$q=|j|^{-1}\overline{q}. \tag{14}$$

[0045] The above conversions provide a method of designing a continuous material space for a required spatial transformation of electromagnetic vectors and, therefore, achieving a desired functionality. That is, for the physical Poynting vector, S, to match the required transformation of the Poynting vector, $S=|j|^{-1}jS$, the material properties in the new space, $r=r(\tilde{r})$, should satisfy $\in=|j|^{-1}\,j\in j^{T}$ and $\mu=|j|^{-1}\,j\mu j^{T}$.

[0046] The result of Dolin is repeated here as equation (15), as the original work is in Russian and not readily available. The radially anisotropic permeability and permittivity of a spherical material inhomogeneity may be expressed as:

$$\|\varepsilon_{ik}\| = \|\mu_{ik}\| = \begin{vmatrix} \frac{R^2}{r^2(R)}\frac{dr(R)}{d(R)} & 0 & 0 \\ 0 & \frac{1}{\frac{dr(R)}{dR}} & 0 \\ 0 & 0 & \frac{1}{\frac{dr(R)}{dR}} \end{vmatrix} \tag{15}$$

corresponding to a spatial transformation from the spherical coordinates r, Q, j to the coordinates R (r), Q, j . A plane wave incident from infinity on an inhomogeneity with parameters in accordance with equation (15) would pass through the inhomogeneity without apparent distortion to the external observer.

[0047] A method is described herein for the design of broadband cloaking apparatus and systems comprising binary or multiphase metamaterials, where different optical paths are arranged for different wavelengths inside the macroscopic cloaking structures. The cloaking design requirements may be satisfied through appropriate dispersion engineering of metamaterials.

[0048] The concept of an electromagnetic cloak is to create a structure, whose permittivity and permeability distributions allow the incident waves to be directed around the inner region and be (at least ideally) emitted on the far side of the structure without distortion arising from propagating through the structure. From among simple geometries, including spherical, square and elliptical varieties, cloaking in a cylindrical system is may be the most straightforward to describe mathematically, and is used for the examples herein. However, solutions in other than cylindrical coordinate systems arise from the general transformational optics theory presented herein. A person of skill in the art would understand that such structures may not need to be solved analytically, as numerical analysis methods may be effectively used. Such numerical analysis techniques may also be used for more complex structures. For some scale sizes, ray tracing in an inhomogeneous anisotropic medium may be used. For numerical analysis of cloaking devices, there are a variety of numerical electromagnetic approaches that can be used, such as the finite-element methods (FEM), the finite-difference time-domain (FDTD) methods, the finite integration technique (FIT), and the method of moments (MoM). A number of commercial packages are widely, including COMSOL MULTIPHYSICS, CST MICROWAVE STUDIO, RSoft FULLWAVE, and others may be used to perform the numerical analysis and design.

[0049] A class of a general orthogonal cylindrical coordinate system (OCCS) can be arranged by translating an x-y-plane map ($x=x(\tilde{\nu},\tilde{\tau})$, $y=y(\tilde{\nu},\tilde{\tau})$) perpendicular to itself; the resulting physical coordinate system forms families of concentric cylindrical surfaces. Since the unit vectors are orthogonal, $\hat{e}_{\nu}\times\hat{e}_{\tilde{\tau}}=\hat{e}_{z}$, $\hat{e}_{\tilde{\tau}}\times\hat{e}_{z}=\hat{e}_{\nu}$, and $\hat{e}_{z}\times\hat{e}_{\nu}=\hat{e}_{\tilde{\tau}}$, the complexity of TO problems in TE or TM formulations can be significantly reduced.

[0050] Consider the initial OCCS, where a 2D radius-vector is defined by a parametric vector function $\tilde{r}(\tilde{\nu},\tilde{\tau})$, and a 2D vector $\tilde{\mu}$ is defined as $\tilde{u}=\tilde{\nu}_{\mu}\hat{e}_{\nu}+\tilde{\nu}_{\tilde{\tau}}\hat{e}_{\tilde{\tau}}$. The Jacobian matrix is the diagonal matrix, s%=diag(s$_{1\%}$s$_{1\%}$), with the metric coefficients $\tilde{s}=\mathrm{diag}(s_{\tilde{\nu}},s_{\tilde{\tau}})$ and $s_{\tilde{\nu}}=\sqrt{\tilde{r}^{(\tilde{\nu})}\cdot\tilde{r}^{(\tilde{\nu})}}$. Then, the following scalar wave equation may be obtained from the Maxwell curl equations in an orthogonal cylindrical basis for a general anisotropic media. Thus, from

$$\tilde{u}_{\tilde{\nu}}=\omega^{-1}\tilde{m}_{\tilde{\nu}}^{-1}\tilde{s}_{\tilde{\tau}}^{-1}\tilde{\nu}^{(\tilde{\tau})},\ \tilde{u}_{\tilde{\tau}}=-\omega^{-1}\tilde{m}_{\tilde{\tau}}^{-1}\tilde{s}_{\tilde{\nu}}^{-1}\tilde{\nu}^{(\tilde{\nu})},\ -\omega\tilde{m}_{z}\tilde{\nu}=|\tilde{s}|^{-1}[(\tilde{s}_{\tilde{\tau}}\tilde{u}_{\tilde{\tau}})^{(\tilde{\nu})}-(\tilde{s}_{\tilde{\nu}}\tilde{u}_{\tilde{\nu}})^{(\tilde{\tau})}], \tag{16}$$

we arrive at

$$(\tilde{s}_{\tilde{\tau}}\tilde{m}_{\tilde{\tau}}^{-1}\tilde{s}_{\tilde{\nu}}^{-1}\tilde{\nu}^{(\tilde{\nu})(\tilde{\nu})}+(\tilde{s}_{\tilde{\nu}}\tilde{m}_{\tilde{\nu}}^{-1}\tilde{s}_{\tilde{\tau}}^{-1}\tilde{\nu}^{(\tilde{\tau})})^{(\tilde{\tau})}-\omega^{2}\tilde{m}_{z}|s|\nu=0, \tag{17}$$

where $\tilde{m}_{\nu}$ and $\tilde{m}_{\tilde{\tau}}$ are the only components of a diagonal material property tensor, i.e., anisotropic permeability or anisotropic permittivity (for TM or TE polarization respectively); the scalar $\tilde{\nu}$ is the only component of the , transverse field: i.e., the magnetic field, $H=\hat{e}_{x}H_{z}$ (TM), or the electric field, $E=\hat{e}_{z}E_{z}$ (TE).

[0051] Similar to equation (17), another wave equation in a new physical OCCS, (ν, τ, z), can be written as

$$(s_{\tau}m_{r}^{-1}s_{\nu}^{-1}\nu^{(\nu)})^{(\nu)}+(s_{\nu}m_{\nu}^{-1}s_{\tau}^{-1}\nu^{(\tau)})^{(\tau)}-\omega^{2}m_{z}|s|\nu=0 \tag{18}$$

To mimic the behaviour of light waves obeying equation (16), a scaling transformation $\nu=\nu(\tilde{\nu})$ (with $\tau=\tilde{\tau}$, $z=\tilde{z}$, and $\nu^{1}=\nu^{(\tilde{\nu})}$) is introduced. Thus, to get closer to equations (16), equations (18) are expressed as

$$\left(\left[\frac{1}{v'}\frac{s_{T}\tilde{m}_{T}\tilde{s}_{\tilde{v}}}{\tilde{s}_{\tilde{T}}m_{T}s_{v}}\right]\frac{\tilde{s}_{\tilde{T}}}{\tilde{m}_{\tilde{T}}\tilde{s}_{\tilde{v}}}v^{(\tilde{v})}\right)^{(\tilde{v})}+\left(\left[v'\frac{s_{v}\tilde{m}_{\tilde{v}}\tilde{s}_{T}}{\tilde{s}_{v}m_{v}s_{T}}\right]\frac{\tilde{s}_{v}}{\tilde{m}_{v}\tilde{s}_{T}}v^{(\tilde{T})}\right)^{(\tilde{T})}-w^{2}\left(v'\frac{m_{z}|s|}{\tilde{m}_{z}|\tilde{s}|}\right)\tilde{m}_{z}|\tilde{s}|v=0.. \tag{19}$$

It follows that equation (19) is may be made to be the same as equation (16), provided that the ratios in the square brackets can be eliminated. Thus, the TO identities

$$\frac{1}{v'}\frac{s_{T}\tilde{m}_{\tilde{T}}\tilde{s}_{\tilde{v}}}{\tilde{s}_{T}m_{T}s_{v}}=1,\ v'\frac{s_{v}\tilde{m}_{\tilde{v}}\tilde{s}_{T}}{\tilde{s}_{v}m_{v}s_{T}}=1,\ v'=\frac{m_{z}|s|}{\tilde{m}_{z}|\tilde{s}|}=1, \tag{20}$$

should be valid in a new material space (m_{ν}, m_{τ}, and m_{z}) in order to mimic the behaviour of light in the initial material space ($\tilde{m}_{\nu}$, $\tilde{m}_{\tilde{\tau}}$, and $\tilde{m}_{z}$). The above identities define the material transformation requirements which may be used for cloaking design and other applications.

[0052] Equations (20) are a solution to the problem of designing an anisotropic continuous material space supporting a required electromagnetic wave behavior, which is equivalent to the behavior of the electromagnetic waves mapped back onto the initial space. Scaling transformations that expand the initially small domain onto a larger physical domain are pertinent to imaging or light concentration while a typical cloaking application uses scaling transforms that shrink the initially larger space to produce voids excluded from the initial domain. Such voids are therefore inaccessible to electromagnetic waves at least the design frequency. The initial virtual space shares a common exterior boundary with the rest of the transformed physical world. An example is shown in FIG. **2**.

[0053] In the circular cylindrical coordinates ($\nu=\rho$, $\tau=\phi$), and $s_\rho=1$, $s_\phi=\rho$, equations (20) give

$$m_\phi = \frac{\rho}{\rho'\tilde{\rho}}\tilde{m}_\phi,\ m_\rho = \frac{\rho'\tilde{\rho}}{\rho}\tilde{m}_\rho,\ m_z = \frac{\tilde{\rho}}{\rho\rho'}\tilde{m}_z, \tag{21}$$

which are the material space parameters for an exact cloak, which is analogous to a cylindrical free-space domain, and is defined by the following inhomogeneous and anisotropic material properties:

$$\in_\rho=\mu_\rho=\wp\rho^1/\rho;\ \in_\phi=\mu_\phi=\in_\rho^{-1};\ \in_z=\mu_z=\wp/(\rho^1\rho). \tag{22}$$

[0054] The constraints on the material properties may be relaxed in some circumstances. For example, for TM polarization with the magnetic field polarized along the z-axis, multiply $\in^\tau$ and $\in_\phi$ by μ_z in equation (22) to obtain the following reduced set of non-magnetic cloak parameters:

$$\in_\rho=(\wp/\rho)^2;\ \in_\phi=(\rho^1)^{-2};\ \mu_z=1. \tag{23}$$

[0055] Similarly, for the TE polarization, the required parameters for a general transformation are:

$$\mu_\rho=(\wp/\rho)^2(\rho^1)^2,\ \mu_\phi=1,\ \in_z=(\rho^1)^{-2}. \tag{24}$$

In equations (22)-(24), $\wp$ could be replaced by $\wp=\wp(\rho)$ to obtain closed-form expressions. Such closed form expressions are useful to verify numerical analysis results for a corresponding geometrical configuration. The numerical analysis may then be extended to situations where the geometry of the apparatus or the complexity of the material spatial variations may make a closed-form solution impractical as a design tool. A person of skill in the art would use the numerical analysis methods so as to extend the scope of the types of apparatus, materials and wavelength regimes which may be used in designs based on the theoretical analysis presented herein.

[0056] Consider the bandwidth of a cloaking structure when a design for a single specific central wavelength is used. A broadband cloak may be designed to function in a wavelength multiplexing manner. Since the anisotropic constituent materials of a cloak for one wavelength may not be transparent at other frequencies, cloaks for the wavelengths being considered should share the same outer boundary, may be is the physical outer boundary of the device. The inner boundary and the transformation for each operating wavelength is dependent on the wavelength. Thus, a number of different inner boundaries and different transformations may be used to provide a broadband cloaking capability.

[0057] In practice, the registration of the outer boundaries of the different material layers may have some variation without appreciable degeneration of the overall effectiveness of the broadband guidance. This follows from simulations which have suggested that variations from the ideal material parameter profile may be tolerated.

[0058] Moreover, as the theoretical results here and elsewhere in the description herein are obtained from analytic models, some adjustment of the results may be needed in practice to, for example, take account of the refraction of a signal of a wavelength that differs from the design wavelength, or which passes through a shell of another design wavelength prior to being refracted by a shell designed for the signal. In another aspect, while gain media may be needed in some cases for an exact cloaking result, some loss may be tolerated in the structure, depending on the application, and the sensitivity of the viewer or viewing device to changes in the strength of the background signal, the transmitted signal or the like.

[0059] FIG. **3** is a schematic representation of a cloaking system for multiple wavelengths or a finite bandwidth, with $w_1>w_2>w_3$, shown in (a), (b), and (c) respectively; the outer and inner circles represent the physical boundaries the cloaking device, and the circle between the two refers to an inner material boundary for each design wavelength;.

[0060] Since the wave components at different frequencies go through the system following different physical paths, the proposed system may permit the cloaking parameters to be appropriately realized over a finite bandwidth without violating basic physical laws or giving rise to a superluminal group velocity. As a result, a 'colorful' (multi-frequency) image would appear transparently through the cloaking device. At the central wavelength of each of the various designs, an image of the background region behind the cloaking structure in the design wavelength ("color") would be seen. This would be the situation for each of the design wavelengths of the structure.

[0061] The device may be constructed using multiple shells of material, where the material properties of each shell is appropriate for the wavelengths propagating therein. Further, it would be understood that each shell may also be comprised of a number of conformal shells with material properties that vary with a geometric dimension such as the radius. Such a construction may facilitate the manufacturing process. Further, although not shown, some shells may be a gain material, or dielectric materials or various types of materials may be fabricated as a composite material.

[0062] In order to better understand the limitations on cloaking over a contiguous band of frequencies, consider the TE propagation mode with material properties given in equation (24), which allows for flexible parameters at the outer boundary of $\rho=b$. Assume that at frequency ω_0, the material properties required by a TE cloak are exactly satisfied based on the transformation $\rho=\rho(\wp)$ within the range, $\alpha\leqq\rho\leqq b$;

$$\mu_\rho(\omega_0,\rho)=(\wp/\rho)^2(\rho^1)^2,\ \mu_\phi(\omega_0,\rho)=1,\ \in_z(\omega_0,\rho)=(\rho^1)^{-2}. \tag{25}$$

[0063] Dispersion needs to be considered for broadband performance of a cloaking system. Assuming that the cloaking materials exhibit a linear dispersion around the initial frequency ω_0 the dispersion function may be expressed in a Taylor series expansion:

$$\mu_\rho(\omega,\rho)=\mu_\rho(\omega_0,\rho)+\mu_\rho^{(\omega)}(\omega_0,\rho)(\omega-\omega_0), \tag{26}$$

and

$$\in_z(\omega,\rho)=\in_z(\omega_0,\rho)+\in_z^{(\omega)}(\omega_0,\rho)(\omega-\omega_0), \tag{27}$$

[0064] In equations (26) and (27) the two frequency derivatives $\mu_\rho^{(\omega)}$ and $\in_z^{(\omega)}$ are continuous functions of ρ. Since there is no magnetic response along the ϕ direction at ω_0, it may be reasonable to choose that $\mu_\phi(\omega,\tau)=\mu_\phi(\omega_0,\tau)=1$.

[0065] The initial formulation of the analysis is to determine, at a frequency $\omega_1=\omega_0+\delta\omega$, a combination of the transformation $\rho_1=\rho_1(\wp)$ along with yet another inner radius a_1 such that the function $\rho_1(\wp)$ maps [0, b] onto [a_1, b] with $a<a_1<b$, while satisfying the boundary conditions

$$\rho_1(0)=a_1\rho_1(b)=b \tag{28}$$

along with the monotonicity condition:

$$\rho_1{}^1>0 \tag{29}$$

and, the material transforms of the reduced TE cloak:

$$\mu_\rho(\omega_1,\rho_1)=(\varrho/\rho_1)^2(\rho_1{}^1)^2,\ \in_z(\omega_1,\rho_1)=(\rho_1{}^1)^{-2} \tag{30}$$

where $\varrho=g_1{}^{-1}(\rho)$, $a_1\leqq\rho\leqq b$.

[0066] The transformation $\rho_1(\varrho)$ for $\omega_1=\omega_0+\delta\omega$ is related to the original transformation at ω_0 and the dispersion functions by:

$$(\varrho(\rho_1)/\rho_1)^2(\rho_1{}^1)^2=(\varrho(\rho)/\rho)^2(\rho^1)^2+\mu_\rho{}^{(\omega)}(\omega_0,\rho)(\omega-\omega_0), \tag{31}$$

and

$$(\rho_1{}^1)^{-2}=(\rho^1)^{-2}+\in_z{}^{(\omega)}(\omega_0,\rho)(\omega-\omega_0), \tag{32}$$

within the range of $a_1\leqq\rho_1\leqq b$ with the boundary conditions mentioned above. It would appear that equations (31) and (32) may not be fulfilled exactly for arbitrary gradients of dispersion functions $\mu_\rho{}^{(\omega)}(\omega_0,\rho)$ and $\in_z{}^{(\omega)}(\omega_0,\rho)$.

[0067] Therefore, achieving complete cloaking over a bandwidth involves computational methods and materials for dispersion management. This requirement may be expressed as: What physically-possible functions $\mu_\rho{}^{(\omega)}(\omega_0,\rho)$ and $\mu_\rho{}^{(\omega)}(\omega_0,\rho)$ should be engineered to make the cloaking effect possible at a given frequency $\omega_1=\omega_0+\delta\omega$ in addition to cloaking at ω_0?

[0068] After some algebra, it may be seen that equations (28) to (32) can be satisfied by

$$\mu_\rho{}^{(\omega)}(\omega_0,\rho)\in_z{}^{(\omega)}(\omega_0,\rho)<0. \tag{33}$$

That is, equation (33) indicates that the dispersion of the radial permeability $\mu_\rho(\omega,\rho)$ and the axial permittivity $\in_z(\omega,\rho)$ should have opposite slopes as functions of the frequency.

[0069] The effective bandwidth of a transformation-based cloaking device is determined by the frequency range over which the material properties in equations (22)-(24) are substantially satisfied. The curved trajectory of the electromagnetic waves within the cloak implies a refractive index n of less than 1 in order to satisfy the minimal optical path requirement of the Fermat principle. However, a metamaterial with n<1 should be dispersive to fulfill causality.

[0070] In practice, the bandwidth of the apparatus may largely be determined by the performance tolerances. That is, how close to the performance of an ideal cloak over a bandwidth is achieved. The needed performance may be dependent on the application for which the structure is intended. So, while mathematically there may be a single wavelength value where the cloaking conditions are exactly fulfilled, the undesired scattering and distortion arising from the cloak structure may remain at a low level over a finite bandwidth. As such, cloaks share the property of many engineering solutions in that compromises in performance may be accepted as a trade-off with respect to cost, complexity, and the like.

[0071] Specifically engineered strong anomalous dispersion may be needed as equation (33) is not satisfied with normal dispersion, where $\partial\in(\omega)/\partial\omega>0$ and $\partial\mu(\omega)/\partial\omega>0$. However, anomalous dispersion characteristics are normally associated with substantial loss. In such designs, a broadband cloaking solution may need additional loss-compensation by incorporating gain media in the structure.

[0072] Passive materials exhibit normal dispersion away from the resonance band. Because anomalous dispersion usually occurs only around the absorption bands, a wavelength multiplexing cloak with broadband capability may be achievable when gain materials or electromagnetically induced transparency or chirality are introduced to make low-loss anomalous dispersion possible. For example, in an active medium, where the optical gain is represented by a negative imaginary part of permittivity over a finite bandwidth, the real part of permittivity around the active band will exhibit an anti-Lorentz line shape, as governed by the Kramers-Kronig relations. As a result, anomalous dispersion with relatively low loss can occur in the wings of the gain spectrum. Incorporating gain materials into plasmonics and metamaterials has been proposed and demonstrated in related applications such as, a near-field superlens, tunneling transmittance, enhanced surface plasmons, and lossless negative-index materials.

[0073] We present two structures for optical cloaking based on high-order transformations for TM and TE polarizations respectively. These designs are realizable for at least visible and infrared light wavelengths.

[0074] The constitutive dimensional and electromagnetic parameters of the cloak are determined by the specific form of the spatial transformation used. The parameters are usually anisotropic with gradient requirements that may be achieved using artificially engineered structures

[0075] Two design examples of optical cloaks based on high-order transformations are described. Specifically: i) a non-magnetic cylindrical cloaking system for TM incidence (magnetic field polarized along the cylindrical axis) which consists of a layered metal-dielectric without any variation in either material or structure along the vertical direction; and, ii) a magnetic cylindrical cloak for TE incidence (electric field polarized parallel to axis) utilizing Mie resonance in periodic rod-shaped high-permittivity materials.

[0076] For a cloak in the cylindrical geometry, a coordinate transformation function $r=g(r^1)$ from (r^1, θ^1, z^1) to (r, θ, z) is used to compress the region $r^1\leqq b$ into a concentric shell of $a\leqq r\leqq b$, and the permittivity and permeability tensors required for an exact cloak can be determined as:

$$\in_r=\mu_r=(r^1/r)\partial g(r^1)\partial r^1;\ \in_\theta=\mu_\theta=1/\in_r;\ \in_z=\mu_z=(r^1/r)[\partial g(r^1)/\partial r^1]^{-1} \tag{34}$$

For the standard states of incident polarization, the requirement of equation (34) can be relaxed such that only three of the six components are relevant. For example, for TE (TM) polarization, only μ_z, μ_r and μ_θ(μ_z, $\in_\tau$ and $\in_\theta$) enter into Maxwell's equations. As would be understood, the TM and the text in parenthesis are read in lieu of the TE and corresponding parameters so as to provide a compact presentation of the discussion

[0077] The parameters can be further simplified to form reduced parameters which are more realistic for practical applications. Since the trajectory of the waves is determined by the cross product components of the $\in$ and μ tensors instead of the two tensors individually, the cloaking performance is sustained as long as $n_\theta=\sqrt{\in_z\mu_r}$ and $n_r=\sqrt{\in_s\mu_\theta}$ ($n_0=\sqrt{\mu_z\in_r}$ and $n_r=\sqrt{\mu_z\in_\theta}$) meet equation (34). This technique results in a specific set of reduced parameters which allow for a permeability gradient along only the radial direction for the TE mode:

$$\mu_r=(r^1/r)^2[\partial g(r^1)/\partial r^1]^2;\ \mu_\theta=1;\ \in_z=[\partial g(r^1)/\partial r^1]^{-2} \tag{35}$$

and can be purely non-magnetic for the TM mode:

$$\in_r=(r^1/r)^2;\ \in_\theta=[\partial g(r^1)/\partial r^1]^{-2};\ \mu_z=1 \tag{36}$$

[0078] The designs of the example electromagnetic cloaks herein use known structures and materials to achieve the set of parameters corresponding to any of equations (34)-(36). Recently a demonstration of a microwave cloak satisfying equation (35) was reported and the previously described nonmagnetic optical cloak in U.S. patent application Ser. No. 11/983,228, filed on Nov. 7, 2007, and is incorporated herein by reference, corresponds to the case described by equation (36). One common aspect in the previous work is that the designs were based on a standard linear transformation $r=g(r^1)=(1-a/b)r^1+a$.

[0079] Designs based on more general high-order transformations are described. In particular, for the TM polarization, a non-magnetic cloak design which may compatible with mature fabrication techniques such as direct deposition and direct etching is described; for TE incidence, a structure that allows for a radial gradient in the magnetic permeability while avoiding the use of plasmonic metallic inclusions in the optical range is described.

[0080] Consider a non-magnetic cloak for the TM mode with parameters given in equation (36). In this case, the cloak material is designed to produce the required gradients in $\in_r$ and $\in_\theta$ using readily available materials. In an aspect, the design may employ the flexibility in realizing the effective permittivity of a general two-phase composite medium.

[0081] When an external field interacts with a composite material comprising two elements with permittivity of $\in_1$ and $\in_2$ respectively, minimal screening occurs when all internal boundaries between the two constituents are parallel to the electric field, and maximal screening occurs when all boundaries are aligned perpendicular to the field. These two extremes of orientation can be achieved by using an alternating layered structure, provided that the thickness of each layer is much less than the wavelength of the incident electromagnetic radiation. The two extreme values of the effective permittivity can be approximated as:

$$\in_{\|}=f\in_1+(1-f)\in_2;\ \in_{\perp}=\in_1\in_2/(f\in_2+(1-f)\in_1) \qquad (37a,\ b)$$

where f and $1-f$ denote the volume fractions of components **1** and **2**, and the subscripts $\|$ and $\perp$ indicate the cases with electric field polarized parallel and perpendicular to the interfaces of the layers, respectively. Such layered structures have been studied extensively in recent years for various purposes, especially in sub-diffraction imaging for both the near field and the far zone.

[0082] The alternating layers may be a plurality of layers, each layer having a bulk material property appropriate to a particular wavelength and the shape of the cloaking structure being designed, and some of these layers may be, for example gain media so as to compensate for the loss in passive layers.

[0083] The two extrema in equation (4) are termed the Wiener bounds on the permittivity, which set the bounds on the effective permittivity of a two-phase composite material. Other limits, for example those from the spectral representation developed by Bergman and Milton (see Bergman, D. J., Phys. Rev. Lett. 44, 1285-1287, 1980; Milton, G. W., Appl. Phys. Lett. 37 , 300-302, 1980) may also apply in addition to the Wiener bounds, but equation (37) nonetheless provides a straightforward way to evaluate the accessible permittivity range in a composite with specified constituent materials. The Wiener bounds can be illustrated on a complex $\in$-plane with the real and imaginary parts of $\in$ being the x and y axis, respectively. In this plane, the low-screening bound in equation (37a) corresponds to a straight line between $\in_1$ and $\in_2$, and the high-screening bound in equation (4b) defines an arc which is part of the circle determined by the three points: $\in_1$, $\in_2$ and the origin.

[0084] The material properties for the cloak design corresponding to equation (36) are such that, for a non-magnetic cylindrical cloak with any transformation function, $\in_r$ varies from 0 at the inner boundary of the cloak (r=a) to 1 at the outer surface (r=b), while $\in_\theta$ is a function of r with varying positive value, except for the linear transformation case where $\partial g(r^1)/\partial r^1$ is a constant.

[0085] Fulfilling the parameters in equation (36) may use, for example, alternating metal-dielectric slices whose properties may be estimated by equation (37). Phase **1** is a metal ($\in_1=\in_m<0$) and phase **2** is a dielectric ($\in_2=\in_d>0$), and the desired material properties of the cloak are achieved when the slices are within the r-z plane of the cylindrical coordinates. $\in_r$ and $\in_\theta$ correspond to $\in_{\|}$ and $\in_{\perp}$ in equation (37), respectively.

[0086] This situation is illustrated in FIG. **4**. The thick solid and dashed lines represent the two Wiener bounds $\in_{\|}(f)$ and $\in_{\perp}(f)$, respectively. The constituent materials used for the calculation presented in FIG. **4** are silver and silica at a "green" light wavelength of 532 nm. The pair of points on the bounds with the same filling fraction are connected with a straight line for clarity. When $\in_r$ varies between 0 and 1, the value of $\in_\theta$ varies accordingly as shown by the arrow between the two thin dashed lines. Therefore, the construction of a non-magnetic cloak establishes the relationship between the two quantities $\in_{\|}$ and $\in_{\perp}$ (as functions of f) within the range shown in FIG. **4** that fits the material properties given in equation 36 for a particular transformation function: $r=g(r^1)$.

[0087] The example design has a low loss factor. As shown in FIG. **4**, the loss factor described by the imaginary part of the effective permittivity is on the order of 0.01. This is considerably smaller than that of a pure metal or any resonant metal-dielectric structures. A schematic representation of the structure having interlaced metal and dielectric slices is illustrated in FIG. **5**.

[0088] For a selected design wavelength, a transformation together with the cylindrical shape factor a/b that fulfills the following equation may be suitable.

$$\varepsilon_m\varepsilon_d\left(\frac{\partial g(r')}{\partial r'}\right)^2+\left(\frac{r'}{g(r')}\right)^2-\varepsilon_m+\varepsilon_d=0 \qquad (38)$$

and

$$g(0)=a;\ g(b)=b;\ \partial g(r^1)/\partial r^{1>}0 \qquad (39)$$

[0089] An approximate solution to the equations may be found using a polynomial function such as:

$$r=g(r^1)=[1-a/b+p(r^1-b)]r^1+a \qquad (40)$$

with $|p|<(b-a)/b^2$

[0090] Such a quadratic transformation satisfies the boundary and monotonicity requirements in equation (39), and it is possible to fulfill equation (38) with minimal deviation from a theoretical profile when an appropriate shape factor is chosen. Table 1 sets forth transformations, materials and geometries for non-magnetic cloaks designed for several important central wavelengths across the visible wavelength regime including 488 nm (Ar-ion laser), 532 nm (Nd:YAG laser), 589.3 run (sodium D-line), and 632.8 nm (He—Ne laser). In the calculations, the permittivity of silver is taken from well accepted experimental data (see Johnson, P. B., and R. W. Christy, Phys. Rev. B **6 4370-4379** **,1972**), and the dielectric constant of silica is from tabulated data (see Palik, E. D., Handbook of Optical Constants of Solids, Academic Press, New York, 1997. The same design and transformation work for similar cylindrical cloaks with the same shape factor a/b. When the approximate quadratic function is fixed for a given design wavelength, the filling fraction function $f(r)$ is determined by:

$$f(r) = \frac{Re(\varepsilon_d) - (g^{-1}(r)/r)^2}{Re(\varepsilon_d - \varepsilon_m)} \tag{41}$$

TABLE 1

Approximate quadratic transformations and materials for constructing a cloak with alternating slices

λ	ϵ_1	ϵ_2	$p \times (b^2/a)$	a/b
488 nm	$\epsilon_{Ag} = -8.15 + 0.11i$	$\epsilon_{SiO2} = 2.14$	0.0662	0.389
532 nm	$\epsilon_{Ag} = -10.6 + 0.14i$	$\epsilon_{SiO2} = 2.13$	0.0517	0.370
589.3 nm	$\epsilon_{Ag} = -14.2 + 0.19i$	$\epsilon_{SiO2} = 2.13$	0.0397	0.354
632.8 nm	$\epsilon_{Ag} = -17.1 + 0.24i$	$\epsilon_{SiO2} = 2.12$	0.0333	0.347
11.3 nm	$\epsilon_{SiC} = -7.1 + 0.40i$	$\epsilon_{BaF2} = 1.93$	0.0869	0.356

[0091] FIG. **6** shows the calculated anisotropic material properties of a non-magnetic cloak corresponding to the λ=532 nm case. With the approximate quadratic transformation, the effective parameters $\in_r$ and $\in_\theta$ obtained with the Wiener bounds in equation (37) fit with the exact parameters required for this transformation by equation (35) quite well, with the average deviation of less than 0.5%.

[0092] Fabrication of the design is practical, as such vertical wall-like structures are compatible with mature fabrication techniques such as direct deposition and direct etching.

[0093] In another example, a cylindrical cloak for TE mode cloaking operable within the mid-infrared frequency range is described, with a gradient in the magnetic permeability, in accordance with equation (35). This frequency range is of interest as it corresponds to the thermal radiation band from human bodies.

[0094] Several different approaches involving silicon carbide as component of the metamaterial are described. SiC is a polaritonic material with a phonon resonance band falling into the spectral range centered at around 12.5 μm (800 cm^{-1}) This resonance band introduces a sharp Lorentz behavior in the electric permittivity. The dielectric function of SiC at mid-infrared may be described with the following model:

$$\in_{SiC} = \in_\infty[\omega^2 - \omega_L^2 + i\gamma\omega]/[\omega^2 - \omega_T^2 + i\gamma\omega] \tag{42}$$

where $\in_\infty$=6.5, ω_L=972 cm^{-1}, ω_T=796 cm^{-1} and γ=5 cm^{-1}. On the high-frequency side of the resonance frequency, the dielectric function is strongly negative, which makes the optical response similar to that of metals, and the material has been already been utilized in applications such as a mid-infrared superlens. At frequencies lower than the resonance frequency, the permittivity can be strongly positive, which makes SiC a candidate for producing high-permittivity Mie resonators at the mid-infrared wavelength range.

[0095] SiC structures may be used to build mid-infrared cloaking devices in a variety of physical configurations. For example, the needle-based structure may be used for the TM mode, where needles are made of a low-loss negative-∈ polaritonic material such as, for example, SiC or TiO_2, and are embedded in an infra-red-transparent dielectric such as, for example, ZnS.

[0096] In another aspect, a non-magnetic cloak using alternating slices of structure as previously described herein may be used. With SiC as the negative-s material and BaF_2 as the positive-∈ slices, the appropriate transformation function and shape factor that fulfills the material property requirements at a preset wavelength may be determined. The result for λ=11.3 μm (CO_2 laser range) is shown in the last row of Table 1.

[0097] In yet another example, a cylindrical cloak for the TE mode with the required material properties given in equation (35) is described, having a gradient in the magnetic permeability along the radial direction. μ_r may vary from 0 at the inner boundary (r=a) to $[\partial g(r^1)/\partial r^1]^2$: at the outer surface (r=b), while the $\in_z$ changes according to $[\partial g(r^1)/\partial r^1]^{-2}$. The magnetic requirement may be accomplished using metal elements like split-ring resonators, coupled nanostrips or nanowires. However, such plasmonic structures exhibit a high loss. A SiC based structure provides an all-dielectric design to a magnetic cloak for the TE mode due to the Mie resonance in subwavelength SiC inclusions.

[0098] Meta-magnetic responses and a negative index of refraction in structures made from high-permittivity materials have been studied extensively in recently years. Magnetic resonance in a rod-shaped high-permittivity particle can be excited by different polarizations of the external field with respect to the rod axis. When a strong magnetic resonance and an effective permeability substantially distinct from 1 are desired, the rod should be aligned parallel to the electric field to assure the maximum possible interaction between the rod and the external field. In the present example the radial permeability has values of less than (but close to) 1, and resonance behavior in the effective permittivity $\in_z$ should be avoided for a minimal loss. Therefore, with the electrical field polarized along the z axis of the cylindrical system, the SiC rods may be arranged along the r axis and form an array in the θ-z plane. The structure is depicted in FIG. **7**, where arrays of SiC wires along the radial direction are placed between the two surfaces of the cylindrical cloak.

[0099] The effective permeability of the system may be estimated as follows using the approach of O'Brien and Pendry (see O'Brien, S., and J. B. Pendry, J. Phys. Condens. Matter. 14, 4035-4044, 2002)

$$\mu_r = \frac{2}{kL_1^2}\frac{L_1J_1(kL_1) - tJ_1(kt) + a_0tH_1^{(1)}(kt) - a_0L_1H_1^{(1)}(kL_1) + c_0tJ_1(nkt)/n}{J_0(kL_2/2 - a_0H_0^{(1)}(kL_2/2)} \tag{43}$$

where h and ϕ represent the periodicities along the z and θ directions respectively, t denotes the radius of each wire, $n=\sqrt{e_{SiC}}$ is the refractive index, $k=2\pi/\lambda_0$ denotes the wave vector, $L_1=\sqrt{hr\phi/\pi}$ and $L_2=(h+r\phi)/2$ represent the two effective unit sizes based on area and perimeter estimations respectively. $a_0=[nJ_0(nkt)J_1(kt)-J_0(kt)J_1(nkt)]/[nJ_0(nkt)H_1^{(1)}(kt)-H_0^{(1)}(kt)J_1(nkt)]$ and $c_0=[J_0(kt)-a_0H_0^{(1)}(kt)]/J_0(nkt)$ are the scattering coefficients, and the Bessel functions in the equation follow the standard notations. The permittivity along the z direction may be approximated using Maxwell-Garnett method. In the design disclosed herein we choose the appropriate transformation geometry and operational wavelength such that the calculated effective parameters μ_r and $\in_z$ follow equation (35) with tolerable deviations. FIG. **8** shows the theoretically required and the calculated μ_r and $\in_z$ for a TE cloak at λ=13.5 μm. The parameters used for this calculation are a=15 μm, a/b=0.35, t=1.2 μm, h=2.8 μm, ϕ=10.6°, and the p coefficient in the quadratic transformation is $0.5a/b^2$. Good agreement between the required values and the calculated ones based on analytical formulae, and the imaginary part in the effective permeability is less than 0.06. This computation verifies the feasibility of the proposed cloaking system based on SiC wire arrays for the TE polarization. In FIG. **8** the magnetic parameter μ_r is calculated using equation (43), and the electric parameter $\in_z$ is obtained based on Maxwell-Garnett method.

[0100] In another aspect, a cloaking device structure may be a spherical or other shaped cloaking structure. The specific geometrical shape, the size and other design parameters of the structure, such as the spatial variation of material properties, may be chosen using the general approach described herein so as to be adaptable to the wavelength, the degree of cloaking, and the properties of the object to be cloaked. Loss and gain may be introduced in various portions of the structure.

[0101] The examples shown herein have used analytic profiles for the material properties so as to illustrate certain of the principles which may influence design of cloaking structures. However, since electromagnetic simulations using finite element methods, for example, are commonly used in design of complex shapes, and have been shown to yield plausible results, the use of such simulations are envisaged as useful in apparatus design. Ray tracing programs may be effectively used in situations where the spatial component of the material properties, and of the geometry, are slowly varying with respect to a wavelength at the operating frequencies. In optics, this is termed an adiabatic approximation.

[0102] Certain aspects, advantages, and novel features of the claimed invention have been described herein. It would be understood by a person of skill in the art that not all advantages may be achieved in practicing a specific embodiment. The claimed invention may be embodied or carried out in a manner that achieves or optimizes one advantage or group of advantages as taught herein without necessarily achieving other advantages as may have been taught or suggested.

[0103] It is therefore intended that the foregoing detailed description be regarded as illustrative rather than limiting, and that it be understood that it is the following claims, including all equivalents, that are intended to define the spirit and scope of this invention.

What is claimed is:

1. A apparatus for modifying the visibility properties of an object, comprising:

a structure formed of a metamaterial,

wherein the metamaterial properties are selected so that an electromagnetic wave incident on the apparatus is guided around the object at plurality of wavelengths.

2. The apparatus of claim **1**, wherein the structure is disposable between an object and an observer.

3. The apparatus of claim **1**, wherein the structure is comprised of a plurality of metamaterial layers, the layers having electromagnetic properties determined by one or more of the plurality of wavelengths.

4. The apparatus of claim **1**, wherein the structure includes a gain medium.

5. The apparatus of claim **4**, wherein the gain medium is a semiconductor capable of spontaneous emission at least one wavelength of the plurality of wavelengths.

6. The apparatus of claim **3**, where the material properties of each layer are selected so that the outermost boundary of a metamaterial layer of the plurality of metamaterial layers for each design wavelength is substantially coincident with the outer boundary of the structure.

7. The apparatus of claim **3**, where each layer is formed from a plurality of conformal layers.

8. The apparatus of claim **3**, wherein the location of an innermost boundary of a metamaterial layer of the structure is dependent on the design wavelength.

9. The apparatus of claim **3**, wherein a least a portion of the structure is formed of metamaterial layers wherein proximal layers have a effective refractive index of less than unity for an orthogonal polarization of an incident wave.

10. The apparatus of claim **3**, wherein the metamaterial properties of the layers at a first design wavelength are selected such that electromagnetic waves of a second design wavelength may penetrate into the structure so as to be guided by layers having metamaterial properties suitable for guiding the second design wavelength.

11. The apparatus of claim **10**, wherein gain medium layers are included in the layers of the first design wavelength so as to compensate for loss of the metamaterial at the second design wavelength.

12. The apparatus of claim **1**, wherein the structure is a sphere with an interior void containing an object to be cloaked.

13. The apparatus of claim **1**, wherein the structure is a cylinder of finite length having a symmetrical cylindrical void therein.

14. The apparatus of claim **1**, wherein the metamaterial comprises a dielectric having inclusions of a polaritonic material.

15. The apparatus of claim **14**, wherein the polaritonic material is silicon carbide (SiC).

16. The apparatus of claim **14**, wherein the polaritonic material is rod shaped, with the rods oriented in a radial direction.

17. The apparatus of claim **1**, wherein the metamaterial comprises a dielectric having inclusions of a metal.

18. The apparatus of claim **17**, wherein the metal and the dielectric are disposed in wedge shapes oriented in a radial direction.

19. A method of designing a structure for use as a cloak, comprising:

(a) selecting a design wavelength;

(b) selecting a metamaterial having the property of having a low loss at the design wavelength and at least a permeability or a permittivity of less than unity;

(c) determining, for a selected shape and size of structure, the variation of metamaterial properties as a function of position in the structure so as to guide electromagnetic waves of the design wavelength and polarization around a object disposed within the structure;

(d) selecting a second design wavelength and performing steps (a)-(c) for the second design wavelength.

20. The method of claim **19**, wherein the metamaterial includes a gain medium.

21. The method of claim **19**, wherein at least a portion of the metamaterial comprises a metamaterial effective at the first design wavelength, interspersed with a metamaterial effective at the second design wavelength.

22. The method of claim **19**, wherein the metamaterials for the first design wavelength and the second design wavelength are conformal alternating layers at least when proximal to an outer surface of the structure.

23. The method of claim **22**, wherein the step of determining, for a selected shape and size of structure, the variation of metamaterial properties as a function of position in the structure so as to guide electromagnetic waves of the design wavelength and polarization around a object disposed within the structure is performed iteratively to adjust the properties of the metamaterials at each design wavelength to account for the effect of the metamaterial selected for the other design wavelength.

24. The method of claim **22**, wherein the thickness of the metamaterial layers is small compared with either design wavelength.

25. A method of modifying the observability of an object, comprising:

providing a structure fabricated from a plurality of metamaterials, the metamaterials selected so as to guide electromagnetic waves around an object at a plurality of wavelengths; and

disposing the structure between an observer and the object.

METAMATERIAL CLOAKED ANTENNA

CROSS-REFERENCE TO RELATED APPLICATIONS

[0001] This application claims rights under 35 U.S.C. §119 (e) from U.S. Application Ser. No. 61/175,221, filed. May 4, 2009, the contents of which are incorporated herein by reference.

BACKGROUND OF THE INVENTION

[0002] 1. Field of the Invention

[0003] The present invention relates to electromagnetic cloaking and more particularly to metamaterial cloaked antennas.

[0004] 2. Brief Description of Prior Developments

[0005] Prior art metamaterial-based cloaking techniques are described in the following publications, the contents of which are incorporated herein by reference:

[0006] 1. J. B. Pendry, D. Schurig, D. R. Smith, *Science* 312, 1780 (2006).

[0007] 2. U. Leonhardt, *Science* 312, 1777 (2006).

[0008] 3. D. Schurig, J. J. Mock, B. J. Justice, S. A. Cummer, J. B. Pendry, A. F. Starr, D. R. Smith, *Science* 314, 977 (2006).

[0009] 4. W. Cai, U. K. Chettiar, A. V. Kildishev, V. M. Shalaev, *Nature Photonics* 1, 224 (2007).

[0010] The performance of modern and future aircraft and satellites strongly depends on various antennas. Typically, a very large number of different types of antennas are mounted on board aircraft, satellites or other vehicles in order to cover as wide a radio-frequency range and bandwidth as is possible. Because space is at a premium on board, the airborne antennas are usually located in close proximity to each other. This arrangement may cause so-called estate issues with respect to antenna installation.

[0011] A need, therefore, exists for a way of reducing the detrimental effect of co-site interference between multiple antennas densely mounted on aircraft, satellites, ships or other vehicles.

SUMMARY OF INVENTION

[0012] According to the present invention, engineered metamaterial (MM) layers are applied to antenna surfaces to prevent the reflected/scattered radiation return on the active antenna surface. The cloaking effect is based on the ability of specially designed MM devices to prevent reflection of the electromagnetic radiation rays in such manner that the electromagnetic waves go around the object and make the object essentially "invisible". A transformational optics approach is used for the cloaked antenna design. An important feature of method of the present invention is cloaking in the near-field (NF) zone of an antenna. The radiation field distribution in the NF region of an antenna is much more complex than in the far-field (FF) zone. Therefore, the MM structure has to be designed in a different way than has been demonstrated in early cloaks for the FF zone.

[0013] This invention also encompasses the method of improving the performance of multiple antennas mounted on board of the aircraft, satellite, ship, or any vehicle by separating the near field (NF) radiation by the metamaterial cloaks positioned between the neighbor antennas (see FIGS. **1** and **2**). As a result the far field (FF) radiation patterns are significantly improved.

[0014] This invention also encompasses a cloaked antenna which directs the antenna radiation in such manner that it does not reach the neighbor objects and/or other antennas (see FIG. **2**). We would like to emphasize that the metamaterial cloak developed for the purposes of this project has a different configuration than to the conventional cloaks described by the Pendry et al. and Schurig et al. references cited above.

BRIEF DESCRIPTION OF THE DRAWINGS

[0015] The invention will be more closely understood hereinafter by reference to the drawings in which:

[0016] FIGS. **1**A and **1**B show drawings of an antenna cloaking by the coordinate transformation method. By selecting conformal coordinate transformation to curvilinear coordinate system schematically indicated by the black mesh, the donut-shaped region of space on the sides of the antenna is "eliminated": from the point of view of the radiating antenna, the other antennas and/or passive sections of the aircraft located in the donut-shaped cloaked region are located at infinity. As a result, the radiation pattern of the cloaked antenna is insensitive to its ambient. The inset shows gradual change of the metamaterial parameters inside the cloak wall.

[0017] FIGS. **2**A, **2**B, **2**C and **2**D show a COMSOL simulation of the dipole near-field distribution for a single dipole (a), the dipole and metallic cylinder (b), the metallic plate positioned between the dipole and the cylinder (c), and the metamaterial flat cloak located between the dipole and the cylinder (d). In real applications the edges of the cloak will be tapered in order to reduce scattering.

[0018] FIGS. **3**A and **3**B show a COMSOL simulation of the NF H-field of the two dipole antennas separated by the metamaterial cloak.

[0019] FIGS. **4**A, **4**B, **4**C, **4**D and **4**F show the FF radiation pattern calculated for a single patch antenna (a), the active antenna with a neighbor passive antenna at X=0.08λ (b), X=0.24λ (c), and X=0.72λ (d). The FF radiation pattern of the two antennas at X=0.08λ with the metamaterial cloak between them (e). The MM clock (with the width X and the height H) shown green is positioned between the two patch antennas shown pink (f).

[0020] FIG. **5** shows the transmission coefficient S_{12} of the two patch antennas separated by the distance X=0.08λ (a), X=0.24λ (b), X=0.4λ (c), and X=0.72λ (d), as well as with the metamaterial cloak of the height H between the antennas at X=0.08λ and H=0.025λ (e), X=0.08λ and H=0.16λ (f).

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

[0021] Based on the transformational optics approach we have developed a novel concept of the cloaked antenna, which is illustrated in FIG. **1**. The transformational optics approach is based on the conformal coordinate transformations to a specially chosen system of curvilinear coordinates (x_1,y_1,z_1,t_1), which distort the length elements but keep the angles intact. The Maxwell equations in such a curvilinear coordinate system may be written in the usual form by introducing effective anisotropic dielectric permittivity $\epsilon(x_1,y_1,z_1)$ and magnetic permeability $\mu(x_1,y_1,z_1)$ tensors of free space. On the other hand, if the so obtained ϵ and μ distributions will be engineered artificially using specially designed metamaterial medium, electromagnetic fields in such a medium will propagate as if in normal Minkowski space described by the (x_1,y_1,z_1,t_1) coordinates. Thus, transformational optics approach to antenna cloaking is applicable to both near and far fields of a cloaked antenna.

[0022] The schematic drawing in FIG. **1** represents our conceptual approach. In real-life applications the exact configuration of the cloak needs to be tailored in order to avoid undesirable blind spots. The approximate dimensions in FIG.

1 indicate that not much of the antenna field of view will be obscured. Those skilled in the art will appreciate that if any particular application would require an omnidirectional field of view, a combination of our approach with the approach disclosed in the Pendry et al. reference (cited above) may be used, so that antenna may see behind the obscuration.

[0023] The distinctive feature of the metamaterial for cloaking applications is that its properties (dielectric permittivity c and magnetic permeability μ) are gradually changed inside the cloak, while their ratio does not. It is matched to the impedance of free space. FIG. **1** illustrates our MM cloak that is essentially multilayered dielectric structure (with some metallic particles inclusions) each layer ϵ (and μ) being extrapolated by the step function close to desirable ϵ and μ distribution. Our simulations show that significant field distortion is observed when the radiation from the dipole hits metallic objects (e.g. metal cylinder or metal plate), while in the case of the metamaterial cloak positioned between the dipole and the metal object there is no such field distortion (compare FIGS. **2***b*, **2***c* and FIG. **2***d*). Thus, screening the objects by metallic plate or cylinder does not prevent the radiation pattern distortion. On the other hand, two antennas may work independently without interference with each other when each antenna is cloaked, even though they are situated next to each other (FIG. **3**).

[0024] The general algorithm for designing the MM cloak is the following:

Using the desired conformal coordinate transformation tensor we calculate the spatial variations of components of the permittivity $\epsilon(r)$ tensor and the permeability $\mu(r)$ tensor. From the so obtained $\epsilon(r)$ and $\mu(r)$ spatial distribution, the structure and composition of the metamaterial is determined. To simplify the cloak fabrication we will use the multilayered structure (as in the inset in FIG. **1**) where the $\epsilon(r)$ and $\mu(r)$ function are replaced by the step-like approximation.

[0025] An underlying feature of the proposed approach is the use of the metamaterial cloaks to prevent the electromagnetic radiation from the neighbor objects (active and/or passive ones) from hitting the emitting surface of the antenna(s). This returning radiation creates the phase distortion on the surface and deteriorates the FF radiation pattern of the antenna. In the conventional approach to antenna separation one has to position the antennas in such a way that the lateral distance between them is greater than the NF zone as is described in Handbook of Antennas in Wireless Communications, Ch. 5, Antenna Parameters, Various Generic Antennas and Feed Systems, and Available Softwares, CRC, 2002, the contents of which are incorporated herein by reference, size d_{NF} ($d_{NF}>>D$, $d_{NF}>>\lambda$, and $d_{NF}>>2D^2/\lambda$, here D is the antenna size and λ is its wavelength). Therefore, there is a room for $(D+d_{NF})^{-2}$ antennas per unit area. With the proposed metamaterial cloaks the distance d_{MM} between the antenna edges could be 0.08λ or less. Then we may put $(D+d_{MM})^2$ antennas per unit area. For $d_{MM}<<D$ the metamaterial clock permits the position of much more antennas than a conventional spatial separation.

[0026] To evaluate significance of our approach the antenna FF radiation pattern distortion and its correction with the metamaterial cloak have been simulated by HFSS software for a set of two antennas—one is an active patch antenna and second is a passive patch antenna located on a distance X from the edge of the active antenna.

[0027] The results presented in FIG. **4** show the radiation pattern of the active antenna is drastically deteriorated at low X, but the pattern coincides with a single antenna pattern when the distance X becomes larger. Meanwhile the metamaterial clock positioned between the antennas makes the pattern looks as a single antenna one even at $X=0.08\lambda$ (Compare FIGS. **4***a, d*, and *e*). Using HFSS we have also calculated the S-parameters of the set of the two identical patch antennas located at the distance X. One may see from the results presented in FIG. **5** that the closer antennas the higher the transmission S_{12}-parameter. Meanwhile the metamaterial cloak positioned between the antennas significantly decreases the S_{12} magnitude even at the distance as small as 0.08λ with a low value of the scattering S_{11}-parameter.

[0028] Thus, our HFSS simulations demonstrate that the proposed metamaterial cloak of the thickness of only 0.08λ works as the separation of the antennas by the distance of 0.72λ.

[0029] Those skilled in the art will appreciate that any combination of metal, dielectric, ferroelectric and/or ferromagnetic materials may be used in the antenna cloak design, as long as the resulting metamaterial parameters would satisfy the desired spatial distribution of ϵ and μ tensors, as described in FIG. **1**.

[0030] While the present invention has been described in connection with the preferred embodiments of the various figures, it is to be understood that other similar embodiments may be used or modifications or additions may be made to the described embodiment for performing the same function of the present invention without deviating therefrom. Therefore, the present invention should not be limited to any single embodiment, but rather construed in breadth and scope in accordance with the recitation of the appended claims.

What is claimed is:

1. In the method for operating a plurality antenna having near-field (NF) zone mounted on a vehicle, wherein the improvement comprises the step of cloaking in the near-field (NF) zone of each of said plurality of antennas.

2. The method of claim **1** wherein near-field (NF) radiation of neighboring radiation is separated by a plurality of metamaterial cloaks so that the far field (FF) radiator patterns are improved.

3. The method of claim **1** wherein a cloaked antenna is provided which directs radiation in such a way that said radiation is impeded from reaching neighboring antennas.

4. The method of claim **1** wherein a metamaterial cloak is used.

5. The method of claim **4** wherein using a desired conformal coordinate transformation tensor the spatial variations of components of the permittivity $\epsilon(r)$ tensor and the permeability $\mu(r)$ tensor is calculated.

6. The method of claim **5** wherein from $\epsilon(r)$ and $\mu(r)$ spatial distribution, the structure and composition of the metamaterial is determined.

7. The method of claim **6** wherein a multilayered cloak structure is used wherein $\epsilon(r)$ and $\mu(r)$ function are approximated by a step-like approximation.

8. The method of claim **4** wherein the metamaterial cloaks of the antennas prevent electromagnetic radiation from hitting emitting surfaces of the antenna.

UNITED STATES PATENT OFFICE.

HERMANN PLAUSON, OF HAMBURG, GERMANY.

CONVERSION OF ATMOSPHERIC ELECTRIC ENERGY.

Application filed January 13, 1921. Serial No. 437,107.

To all whom it may concern:

Be it known that I, HERMANN PLAUSON, Esthonian subject, residing in Hamburg, Germany, have invented certain new and useful Improvements in the Conversion of Atmospheric Electric Energy, of which the following is a specification.

Methods of obtaining atmospheric electricity by means of metallic nettings set with spikes which are held by means of ordinary or anchored kite balloons made of fabrics and filled with hydrogen, are in theory already known. Atmospheric electricity obtained in this way has been suggested to be used in the form of direct current for the charging of accumulators. This knowledge however is at present only theoretical as the conversion in practice has hitherto been a failure. No means are known of protecting the apparatus from destruction by lightning. The balloons used for collecting the charge must also be made of very large size in order to be able to support the weight of the metallic netting and the heavy cable connections.

Instead of using heavy metallic netting as collectors attached to single air balloons of non-conducting materials which are liable to be torn and are permeable to the gas, it is proposed to use metallic balloon collectors which have the following important advantages—

(*a*) The metallic cases are impenetrable to helium and hydrogen; they also represent large metallic weather-proof collecting surfaces.

(*b*) Radio active means and the like may be easily applied internally or externally; whereby the ionization is considerably increased and therewith also the quantity of atmospheric electricity capable of being collected.

(*c*) Such balloon collectors of light metal do not require to be of large size as they have to carry only their own moderate weight, and that of the conducting cable or wire.

(*d*) The entire system therefore offers little surface for the action of storm and wind and is resistant and stable.

(*e*) Each balloon can be easily raised and lowered by means of a winch so that all repairs, recharging and the like can be carried out without danger during the operation.

It is further proposed to use a collecting aerial network of several separate collectors spread out in the air above the earth, which collectors are interconnected by electrical conductors.

According to this invention charges of atmospheric electricity are not directly converted into mechanical energy, and this forms the main difference from previous inventions, but the static electricity which runs to earth through aerial conductors in the form of direct current of very high voltage and low current strength is converted into electro-dynamic energy in the form of high frequency vibrations. Many advantages are thereby obtained and all disadvantages avoided.

The very high voltage of static electricity of a low current strength can be converted by this invention to voltages more suitable for technical purposes and of greater current strength. By the use of closed oscillatory circuits it is possible to obtain electromagnetic waves of various amplitude and thereby to increase the degree of resonance of such current. Such resonance allows various values of inductance to be chosen whereby again the governing of the starting and stopping of machines driven thereby by simply tuning the resonance between coils of the machine and the transformer circuit forming the resonance can easily be obtained. Further, such currents have the property of being directly available for various uses, even without employing them for driving motors, of which there may be particularly mentioned, lighting, production of heat and use in electro-chemistry.

Further, with such currents a series of apparatus may be fed without direct current supply through conductors and also the electro-magnetic high frequency currents may be converted by means of special motors adapted for electro-magnetic oscillations into mechanical energy, or finally converted by special machines into alternating current of low frequency or even into direct current of high potential.

The invention is more particularly described with reference to the accompanying diagrams in which:—

Figure 1 is an explanatory figure.

Figure 2 is a diagrammatic view of the simplest form.

Figure 36 shows an incandescent collector with Nernst lamp.

Figure 37 shows a form with a gas flame.

Figure 1 illustrates a simple diagram for converting static electricity into dynamic energy of a high number of oscillations. For the sake of clearness in the drawings an influence machine is assumed to be employed and not an aerial antenna. 13 and 14 are combs for collecting the static electricity of the influence machine. 7 and 8 are spark discharging electrodes, 6 and 5 condensers, 9 an inductive primary coil, 10 secondary coil, 11 and 12 ends of conductors of the secondary coil 10. When the disc of the static influence machine is rotated by mechanical means, the combs collect the electric charges one the positive and the other the negative, and charge the condensers 5 and 6 until such a high potential is formed across the spark gap 7—8, that the spark gap is jumped. As the spark gap 7—8 forms a closed circuit with condensers 6 and 5, and inductive resistance 9, as is well known, waves of high frequency electromagnetic oscillations will pass in this circuit.

The high frequency of the oscillations produced in the primary circuit induces waves of the same periodicity in the secondary circuit. Thus in the primary circuit electromagnetic oscillations are formed by the passage of the spark over the spark gap and these waves are maintained by fresh charges of static electricity.

By suitably selecting the ratio between the number of the coils in the primary and secondary circuits with regard to a correct application of the co-efficients of resonance (capacity, inductance, and resistance) the high voltage of the primary circuit may be suitably converted into low voltage and high current strength.

When the oscillatory discharges in the primary circuit becomes weaker or entirely cease, the condensers are charged again by the static electricity until the accumulated charge again breaks down the spark gap. All this is repeated as long as electricity is produced by the static machine by employing mechanical energy.

An elementary form of the invention is shown in Figure 2 in which two spark gaps in parallel are used one of which may be termed the working gap 7 in Figure 2, whilst the second serves as a safety device for excess voltage and consists of a larger number of spark gaps than the working section, which gaps are arranged in series and are bridged by very small capacities as is illustrated in a_1, b_1, c_1, Figure 2 which allow of uniform sparking in the safety section.

In Figure 2 A is the aerial antenna for collecting charges of atmospheric electricity, 13 is the earth connection of the second part of the spark gap, 5 and 6 are condensers, 9 a primary coil. Now when through the aerial A the positive atmospheric electricity seeks to combine with the negative charge to earth, this is prevented by (the air gap between) the spark gaps. The resistance of the spark gap 7 is, as shown in the drawings, lower than that of the other safety section which consists of three spark gaps connected in

series, and consequently a three times greater air resistance is offered by the latter.

So long therefore, as the resistance of the spark gap 7 is not overloaded, so that the other spark gaps have an equal resistance with it the discharges take place only over spark gap 7. Should however the voltage be increased by any influences so that it might be dangerous for charging the condensers 5 and 6 or for the coil insulation 9 and 10 in consequence of break down, by a correct regulation of this spark gap the second spark gap can discharge free from inductive effects direct to earth without endangering the machine.

Without this second spark gap, arranged in parallel having a higher resistance than the working spark gap it is impossible to collect and render available large quantities of electrical energy.

The action of this closed oscillation circuit consisting of spark gap 7, two condensers 5 and 6, primary coil 9, and also secondary coil 10 is exactly the same as the one described in Figure 1 with the arrangement of the static induction machine with the only difference that here the second spark gap is provided. The electromagnetic high frequency alternating current obtained can be tapped off from the conductors 11 and 12 for lighting and heating purposes. Special kinds of motors adapted for working with these peculiar electrical charges may be connected at 14 and 15 which can work with static electricity charges or with high frequency oscillations.

In addition to the use of spark gaps in parallel a second measure of security is also necessary for taking off the current. This precaution consists according to this invention, in the introduction of and method of connecting certain protective electromagnets or choking coils in the aerial circuit as shown by S in Figure 3.

A single electromagnet only having a core of the thinnest possible separate laminations is connected with the aerial.

In the case of high voltages in the aerial network or at places where there are frequent thunder storms, several such magnets may however be connected in series.

In the case of large units or plants several electromagnets can be employed in parallel or in series parallel.

The windings of these electromagnets may be simply connected in series with the aerials. In this case the winding preferably consists of several thin parallel wires, which make up together, the necessary section.

The winding may be made of primary and secondary windings in the form of a transformer. The primary winding will be then connected in series with the aerial network, and the secondary winding more or less short-circuited over a regulating resistance or an induction coil. In the latter case it is possible to regulate to a certain extent the effect of the choking coils. In the further description of the connecting and constructional diagrams the aerial electromagnet choke coil is indicated by a simple ring S.

Figure 3 shows the simplest way of converting atmospheric electricity into electromagnetic wave energy by the use of special motors adapted for high oscillatory currents or static charges of electrical energy. Recent improvements in motors for working with static charges and motors working by resonance, that is to say, having groups of tuned electromagnetic cooperating circuits render this possible but such do not form part of the present invention.

A motor adapted to operate with static charges will for the sake of simplicity be diagrammatically indicated by two semicircles 1 and 2 and the rotor of the motor by a ring M. (Figure 3.) A is a vertical aerial or aerial network. S the safety choke or electromagnet with coil O as may be seen is connected with the aerial A. Adjacent the electromagnet S the aerial conductor is divided into three circuits, the circuit 8 giving the safety spark gap, the circuit 7 with the working spark gap, and then a circuit including the stator terminal 1, the rotor and stator terminal 2 at which a connection is made to the earth wire. The two spark gaps are also connected metallically with the earth wire. The method of working these diagrams is as follows:

The positive atmospheric electric charge collected tends to combine with the negative electricity (or earth electricity) connected with the earth wire. It travels along the aerial A through the electromagnet S without being checked as it flows in the same direction as the direct current. Further, its progress is arrested by two sparks gaps placed in the way and the stator condenser surfaces. The stator condenser surfaces are charged until the charge is greater than the resistance of the spark gap 7, whereupon a spark springs over the spark gap 7 and an oscillatory charge is obtained as by means of the motor M, stator surfaces 1 and 2, and spark gap 7, a closed oscillation circuit is obtained for producing the electromagnetic oscillations. The motor here forms the capacity and the necessary inductance and resistance, which, as is well known, are necessary for converting static electricity into electromagnetic wave energy.

The discharges formed are converted into mechanical energy in special motors and can not reach the aerial network by reason of the electromagnet or choke. If, however, when a spark springs over the spark gap 7 a greater quantity of atmospheric electricity tends to flow to earth, a counter voltage is

induced in the electromagnet, which is greater the more rapidly and strongly the flow of current direct to the earth is. By the formation of this opposing voltage a sufficiently high resistance is offered to the flow of atmospheric electricity direct to earth to prevent a short circuit with the earth.

The circuit containing spark gap 8 having a different wave length which is not in resonance with the natural frequency of the motor, does not endanger the motor and serves as security against excess voltage, which, as practical experiments have shown, may still arise in certain cases, but can be conducted direct to earth through this spark gap.

In the diagram illustrated in Figure 4 the spark gap 7 is shunted across condensers 5 and 6 from the motor M. This construction affords mainly a better insulation of the motor against excess voltage and a uniform excitation through the spark gap 7.

In Figure 5 a diagram is illustrated for transforming large current strengths which may be employed direct without motors, for example, for lighting or heating purposes. The main difference is that here the spark gap consists of a star shaped disc 7 which can rotate on its own axis and is rotated by a motor opposite similarly fitted electrodes 7^a. When separate points of stars face one another, discharges take place, thus forming an oscillation circuit over condensers 5 and 6 and inductance 9 for oscillatory discharges. It is evident that a motor may also be directly connected to the ends of the spiral 9.

The construction of the diagram shown in Figure 6 permits of the oscillation circuit of the motor being connected with an induction coil. Here a regulating inductive resistance is introduced for counter-acting excess voltages in the motor. By cutting the separate coils 9 (coupled inductively to the aerial) in or out the inductive action on the motor may be more or less increased or variable aerial action may be exerted on the oscillation circuit.

In Figure 7 the oscillation circuit is closed through the earth (E and E_1). The spark gap 7 may be prolonged or shortened by more or fewer spark gaps being successively connected by means of a contact arm 7^b.

Diagram 8 shows a unipolar connection of the motor with the aerial network. Here two oscillation circuits are closed through the same motor. The first oscillation circuit passes from aerial A through electromagnet S, point x, inductance 9^a to the earth condenser 6 and further, over spark gap 7 to the aerial condenser 5 and back to x. The second oscillation circuit starts from the aerial condenser 5 at the point x^1 over the inductance 9 to the earth condenser 6 at the point x^3 and through the condenser 6 over the spark gap 7 back to x^1. The motor itself is inserted between the two points of the spark gap 7. From this arrangement slightly damped oscillation wave currents are produced.

In the diagram illustrated in Figure 9 a loosely coupled system of connections is illustrated which is assumed to be for small motors for measuring purposes. A indicates the aerial conductor, S the electromagnet in the aerial conductor, 9 the inductance, 7 the spark gap, 5 and 6 condensers, E the earth, M the motor, and 1 and 2 stator connections of the motor. The motor is directly metallically connected with the oscillation circuit.

In Figure 10 a purely inductive coupling is employed for the motor circuit. The motor is connected with the secondary wire 10 as may be seen in Figure 11 in a somewhat modified diagram connection. The same applies to the diagram of Figure 12.

The diagrams hitherto described preferably allow of motors of small and medium strength to be operated. For large aggregates, however, they are too inconvenient as the construction of two or more oscillation circuits for large amounts of energy is difficult; the governing is still more difficult and the danger in switching on or off is greater.

A means of overcoming such difficulties is shown in Figure 13. The oscillation circuit here runs starting from the point x over condenser 5, variable inductance 9, spark gap 7 and the two segments (3^a and 4^a) forming arms of a Wheatstone bridge, back to x. If the motor is connected by brushes 3 and 4 transversely to the two arms of the bridge as shown in the drawings, electromagnetic oscillations of equal sign are induced in the stator surfaces 1 and 2 and the motor does not revolve. If however, the brushes 3 and 4 are moved in common with the conducting wires 1 and 2 which connect the brushes with the stator poles a certain alteration or displacement of the polarity is obtained and the motor commences to revolve.

The maximum action will result if one brush 3 comes on the central sparking contact 7 and the other brush 4 on the part x. They are however, usually in practice not brought on to the central contact 7 but only held in the path of the bridge segments 4^a and 3^a in order not to connect the spark gaps with the motor oscillation circuit.

As however, the entire oscillation energy can thereby not act on the motor it is better to carry out the same system according to the diagram 14. The diagram 14 differs from the foregoing only by the motor not being directly metallically connected with the segments of the commutator, but only a primary coil 9 which induces in a secondary coil 10, current which feeds the motor M and takes the place of the rotor. By this

arrangement a good transforming action is obtained, a loose coupling and also an oscillation circuit without a spark gap.

In Figure 15 the motor is not purely inductively as in 14, but directly metallically branched off from the primary coil (at x and x^1) after the principle of the auto-transformer.

In Figure 16 instead of an inductance a condenser 6 is in similar manner, and for the same object inserted between the segments 3^a and 4^a. This has the advantage that the segments 3^a and 4^a need not be made of solid metal but may consist of spiral coils whereby a more exact regulation is possible and further motors of high inductance may be employed.

The arrangements of Figures 17, 18 and 19 may be employed for use with resonance and particularly with induction condenser motors; between the large stator induction condenser surfaces, small reversing pole condensers are connected, which, as may be seen from Figures 17, 18 and 19 are led together to earth. Such reversing poles have the advantage that with large quantities of electrical energy the spark formation between the separate oscillation circuits ceases.

Figure 19 shows a further method which prevents electromagnetic oscillations of high number of alternations formed in the oscillation circuit striking back to the aerial conductor. It is based on the well known principle that a mercury lamp, one electrode of which is formed of mercury, the other of solid metal such as steel allows an electric charge to pass in only one direction from the mercury to the steel and not vice versa. The mercury electrode of the vacuum tube N is therefore connected with the aerial conductor and the steel electrode with the oscillation circuit. From this it results that charges can pass only from the aerial through the vacuum tube to the oscillation circuit, but not vice versa. Oscillations which are formed on being transformed in the oscillation circuit cannot pass to the aerial conductor.

In practice these vacuum tubes must be connected behind an electromagnet as the latter alone affords no protection against the danger of lightning.

As regards the use of spark gaps, all arrangements as used for wireless telegraphy may be used. Of course the spark gaps in large machines must have a sufficiently large surface. In very large stations they are cooled in liquid carbonic acid or better still in liquid nitrogen or hydrogen; in most cases the cooling may also take place by means of liquefied low homologues of the metal series or by means of hydrocarbons the freezing point of which lies at between −90° C. and −40° C. The spark gap casing must also be insulated and be of sufficient strength to be able to resist any pressure which may arise. Any undesirable excess super-pressure which may be formed must be automatically let off. I have employed with very good results mercury electrodes which were frozen in liquid carbonic acid, the cooling being maintained during the operation from the outside through the walls.

Figure 20 is one of the simplest forms of construction of an aerial network in combination with collectors, transformers and the like illustrated diagrammatically. E is here the earth wire, 8 the safety spark gap, 7 the working spark gap, 1 and 2 the stator surfaces of the motor, 5 a condenser battery, S the protective magnet which is connected with the coil in the aerial conductor, A^1 to A^{10} aerial antennæ with collecting balloons, N horizontal collecting or connecting wires from which, to the centre a number of connections run.

The actual collectors consist of metal sheaths preferably made of an aluminium magnesium alloy, and are filled with hydrogen or helium and are attached to copper plated steel wires. The size of the balloon is selected so that the actual weight of the balloon and the weight of the conducting wire is supported thereby. On the top of the balloon aluminium spikes, made and gilded in a special manner hereinafter described, are arranged in order to produce a conductor action. Small quantities of radium preparations, more particularly polonium-ionium or mesothorium preparations considerably increase the ionization, and therewith the action of these collectors.

In addition to metal balloons, fabric balloons which are superficially metal coated according to Schoop's metal spraying process, may however also be employed. A metallic surface may also be produced by lacquering with metallic bronzes, preferably according to Schoop's spraying process or lacquering with metallic bronze powders in two electrical series of widely different metals, because thereby the collecting effect is considerably increased.

Instead of the ordinary round balloons, elongated cigar shaped ones may be employed. In order also to utilize the frictional energy of the wind, patches or strips of non-conducting substances which produce electricity by friction, may be attached to the metallized balloon surfaces. The wind will impart a portion of its energy in the form of frictional electricity, to the balloon casing, and thereby the collecting effect is substantially increased.

In practice however, very high towers (up to 300 metres is fully admissible) may be employed as antennæ. In these towers copper tubes rise freely further above the top of the tower. A gas lamp secured

against the wind is then lit at the point of the copper tube and a netting is secured to the copper tube over the flame of this lamp to form a collector. The gas is conveyed through the interior of the tube up to the summit. The copper tube must be absolutely protected from moisture at the place at which it enters the tower and also rain must be prevented running down the walls of the tower which might lead to a bad catastrophe. This is done by bell shaped enlargements which expand downwards, being arranged in the tower in the form of high voltage insulators of Siamese pagodas.

Special attention must be devoted to the foundations of such towers. They must be well insulated from the ground, which may be obtained by first embedding a layer of concrete in a box form to a sufficient depth in the ground and inserting in this an asphalt lining and then glass bricks cast about 1 or 2 metres in thickness. Over this in turn there is a ferro-concrete layer in which alone the metal foot of the tube is secured. This concrete block must be at least 2 metres from the ground and be fully protected at the sides by a wooden covering, from moisture. In the lower part of the tower a wood or glass house for the large condenser batteries or for the motors may be constructed. In order to lead the earth connection to the ground water, a well insulated pit constructed of vitreous bricks, must be provided. Several such towers are erected at equal distances apart and connected with a horizontal conductor. The horizontal connecting wires may either run directly from tower to tower or be carried on bell shaped insulators similar to those in use for high voltage conductors. The width of the network may be of any suitable size and the connection of the motors can take place at any suitable places.

In order to collect large quantities of electricity with few aerials it is well to provide the aerial conductor with batteries of condensers as shown in two methods of construction in Figures 21 and 22. In Figure 21 the batteries of condensers 5 are connected on the one hand with the aerial electricity collectors Z by the aerial conductor A, and on the other hand interconnected in series with an annular conductor from which horizontal conductors run to the connecting points C to which the earth wire is connected.

Figure 22 shows a similar arrangement. Should two such series of antennæ rings be shown by a voltmeter to have a large difference of potential (for example, one in the mountains and one in the plain) or even of different polarity these differences may be compensated for by connecting sufficiently large condenser batteries (5, 5^a, 5^b) by means of Maji star conductors D and D^1. In Figure 23 a connection of three such rings of collectors to form a triangle with a central condenser battery is illustrated.

The condenser batteries of such large installations must be embedded in liquefied gases or in liquids freezing at very low temperatures. In such cases a portion of the atmospheric energy must be employed for liquefying these gases. It is also preferable to employ pressure. By this means the condenser surfaces may be diminished, and still allow for large quantities of energy to be stored, secure against breakdown. For smaller installations the immersing of the condensers in well insulated oil or the like, suffices. Solid substances on the other hand cannot be employed as insulators.

The arrangement in the diagrams hitherto described was always such that the condenser batteries were connected with both poles directly to the aerial conductors. An improved diagram of the connections for obtaining atmospheric electricity for the condenser batteries has however, been found to be very advantageous, this arrangement consists in that they are connected by only one pole (unipolar) to the collecting network. Such a method of arrangement is very important, as by means of it a constant current and an increase of the normal working pressure or voltage is obtained. If for example a collecting balloon aerial which is allowed to rise to a height of 300 metres, shows 40,000 volts above earth voltage, in practice it has been found that the working voltage (with a withdrawal of the power according to the method hereinbefore described by means of oscillating spark gaps and the like) is only about 400 volts. If however, the capacity of the condenser surfaces be increased, which capacity in the above mentioned case was equal to that of the collecting surface of the balloon aerials, to double the amount, by connecting the condenser batteries with only one pole, the voltage rises under an equal withdrawal of current up to and beyond 500 volts. This can only be ascribed to the favourable action of the connecting method.

In addition to this substantial improvement it has also been found preferable to insert double inductances with electromagnets and to place the capacities preferably between two such electromagnets. It has also been found that the useful action of such condensers can be further increased if an induction coil be connected as inductive resistance to the unconnected pole of the condenser, or still better if the condenser itself be made as an induction condenser. Such a condenser may be compared with a spring which when compressed carries in itself accumulated force, which it again gives off when released. In charging, a charge with reversed sign is formed at the

other free condenser pole, and if through the spark gap a short circuit results, the accumulated energy is again given back since now new quantities of energy are induced at the condenser pole connected with the conductor network, which in fact charges with opposite signs to that at the free condenser pole. The new induced charges have of course the same sign as the collector network. The whole voltage energy in the aerial is thereby however increased. In the same space of time larger quantities of energy are accumulated than is the case without such inserted condenser batteries.

In Figures 24 and 25 two different diagrams of connections are more exactly illustrated, Figure 24 shows a collecting balloon and the diagram of the connections to earth. Figure 25 four collecting balloons and the parallel connection of the condenser batteries belonging thereto.

A is the collecting balloon made of an aluminium magnesium alloy (electron metal, magnalium) of a specific gravity of 1.8 and a thickness of plate 0.1 to 0.2 mm. Inside there are eight strong vertical ribs of T shaped section about 10 to 20 mm. in height and about 3 mm. in thickness with the projecting part directed inwards (indicated by *a*, *b*, *c*, *d* and so forth); they are riveted together to form a firm skeleton and are stiffened in a horizontal direction by two cross ribs. The ribs are further connected with one another internally and transversely by means of thin steel wires, whereby the balloon obtains great power of resistance and elasticity. Rolled plates of 0.1 to 0.2 mm. in thickness made of magnalium alloy are then either soldered or riveted on this skeleton so that a fully metallic casing with smooth external surface is obtained. Well silvered or coppered aluminium plated steel wires run from each rib to the fastening ring 2. Further, the coppered steel hawser L preferably twisted out of separate thin wires (shown in dotted lines in Figure 24) and which must be long enough to allow the balloon to rise in the desired height, leads to a metal roller or pulley 3 and from thence to a winch W, well insulated from the earth. By means of this winch, the balloon, which is filled with hydrogen, or helium, can be allowed to rise to a suitable height (300 to 5,000 metres) and brought to the ground for recharging or repairs.

The actual current is taken directly through a friction contact from the metal roller 3 or from the wire, or even from the winch or simultaneously from all three by means of brushes (3, 3^a and 3^b). Beyond the brushes the conductor is divided, the paths being:—firstly over 12 to the safety spark gap 8, from thence to the earth conductor E^1, and secondly over electromagnet S^1, point 13, to a second loose electromagnet having an adjustable coil S^2, then to the spark gap 7 and to the second earth conductor E^2. The actual working circuit is formed through the spark gap 7, condensers 5 and 6, and through the primary coil 9; here the static electricity formed by oscillatory discharges is accumulated and converted into high frequency electromagnetic oscillations. Between the electromagnets S^1 and S^2 at the crossing point 13, four condenser batteries are introduced which are only indicated diagrammatically in the drawings each by one condenser. Two of these batteries (16 and 18) are made as plate condensers and prolonged by regulating induction coils or spirals 17 and 19 while the two others (21 and 23) are induction condensers. As may be seen from the drawings each of the four condenser batteries 16, 18, 21, 23 is connected only by one pole to the aerial or to the collector conductor. The second poles 17, 19, 22, 24 are open. In the case of plate condensers having no inductive resistance an induction coil is inserted. The object of such a spiral or coil is the displacement of phase of the induction current by ¼ periods, whilst the charging current of the condenser poles which lie free in the air, works back to the collector aerial. The consequence of this is that in discharges in the collector aerial the back inductive action of the free poles allows a higher voltage to be maintained in the aerial collecting conductor than would otherwise be the case. It has also been found that such a back action has an extremely favourable effect on the wear of the contacts. Of course the inductive effect may be regulated at will within the limits of the size of the induction coil, the length of the coil in action being adjustable by means of wire connection without induction (see Fig. 24, No. 20).

S^1 and S^2 may also be provided with such regulating devices in the case of S^2 (illustrated by 11). If excess voltage be formed it is conducted to earth through the wire 12 and spark gap 8 or through any other suitable apparatus, since this formation would be dangerous for the other apparatus.

The action of these condenser batteries has already been hereinbefore described.

The small circles on the collector balloon indicate places at which zinc amalgam or gold amalgam or other photoelectric acting metals in the form of small patches in extremely thin layers (.01 to .05 mm. in thickness) are applied to the balloon casing of light metal. Such metallic patches may also be applied to the entire balloon as well as in greater thickness to the conducting network. The capacity of the collector is thereby considerably strengthened at the surface. The greatest possible effect in collecting may be obtained by polonium amalgams and the like. On the surface of the

collector balloon metal points or spikes are also fixed along the ribs, which spikes serve particularly for collecting the collector charge. Since it is well known that the resistance of the spikes is less the sharper the spike is, for this purpose it is therefore extremely important to employ as sharp spikes as possible. Experiments made as regards these have shown that the formation of the body of the spike or point also plays a large part. for example, spikes made of bars or rollers with smooth surfaces, have a many times greater point resistance as collector accumulator spikes than those with rough surfaces. Various kinds of spike bodies have been experimented with for the collector balloons hereinbefore mentioned. The best results were given by spikes which were made in the following way. Fine points made of steel, copper, nickel, or copper and nickel alloys, were fastened together in bundles and then placed as anode with the points in a suitable electrolyte (preferably in hydrochloric acid or muriate of iron solutions) and so treated with weak current at 2 to 3 volts pressure. After 2 to 3 hours according to the thickness of the spikes or pins the points become extremely sharp and the bodies of the spikes have a rough surface. The bundle can then be removed and the acid washed off with water. The spikes are then placed as cathode in a bath consisting of solution of gold, platinum, iridium, paladium or wolfram salts or their compounds and coated at the cathode galvanically with a thin layer of precious metal, which must however be sufficiently firm to protect them from atmospheric oxidation.

Such spikes act at a 20 fold lower voltage almost as well as the best and finest points made by mechanical means. Still better results are obtained if polonium or radium salts are added to the galvanic bath when forming the protective layer or coating. Such pins have a low resistance at their points and even at one volt and still lower pressures have an excellent collector action.

In Figure 24 the three unconnected poles are not connected with one another in parallel. That is quite possible in practice without altering the principle of the free pole. It is also preferable to interconnect in parallel to a common collector network, a series of collecting aerials.

Figure 25 shows a diagram for such an installation. A^1, A^2, A^3, A^4 are four metal collector balloons with gold or platinum coated spikes which are electrolytically made in the presence of polonium emanations or radium salts, which spikes or needles are connected over four electro-magnets S^1, S^2, S^3, S^4, through an annular conductor R. From this annular conductor four wires run over four further electromagnets S^a, S^b, S^c, S^d, to the connecting point 13. There the conductor is divided, one branch passing over 12 and the safety spark gap 8 to the earth at E^1, the other over inductive resistance J and working spark gap 7 to the earth at E^2. The working circuit, consisting of the condenser 5 and 6 and a resonance motor or a condenser motor M, such as hereinbefore described, is connected in proximity round the sparking gap section 7.

Instead of directly connecting the condenser motor of course the primary circuit for high frequency oscillatory current may also be inserted.

The condenser batteries are connected by one pole to the annular conductor R and can be either inductionless (16 and 18) or made as induction condensers as shown by 21 and 23. The free poles of the inductionless condensers are indicated by 17 and 19, those of the induction condensers by 22 and 24. As may be seen from the drawings all these poles 17, 22, 19, 24 may be interconnected in parallel through a second annular conductor without any fear that thereby the principle of the free pole connection will be injured. In addition to the advantages already set forth the parallel connection also allows of an equalization of the working pressure in the entire collector network. Suitably constructed and calculated induction coils 25 and 26 may also be inserted in the annular conductor of the free poles, by means of which a circuit may be formed in the secondary coils 27 and 28 which allows current produced in this annular conductor by fluctuations of the charges or the like appearances to be measured or otherwise utilized.

According to what has been hereinbefore stated separate collector balloons may be connected at equidistant stations distributed over the entire country, either connected directly with one another metallically or by means of intermediate suitably connected condenser batteries through high voltage conductors insulated from earth. The static electricity is converted through a spark gap into dynamic energy of a high number of oscillations and may in such form be coupled as a source of energy by means of a suitable method of connecting, various precautions being observed and with special regulations. The wires leading from the collector balloons have hitherto been connected through an annular conductor without this endless connection, which can be regarded as an endless induction coil, being able to exert any action on the whole conductor system.

It has now been found that if the network conductor connecting the aerial collector balloons with one another is not made as a simple annular conductor, but preferably short circuited in the form of coils over a

condenser battery or spark gap or through thermionic tubes or valves or audions, then the total collecting network exhibits quite new properties. The collection of atmospheric electricity is thereby not only increased but an alternating field may be easily produced in the collector network. Further, the atmospheric electrical forces showing themselves in the higher regions may also be directly obtained by induction. In Figures 26 and 28 a form of construction is shown on the basis of which the further foundations of the method will be more particularly explained.

In Figure 26 1, 2, 3, 4 are metal collector balloons, 5, 6, 7, 8 their metallic aerial conductors and I the actual collector network. This consists of five coils and is mounted on high voltage insulators in the air, on high voltage masts (or with a suitable construction of cable embedded in the earth). One coil has a diameter of 1 to 100 km. or more. S and S^1 are two protective electromagnets, F the second safety section against excess voltage, E its earth conductor and E^1 the earth conductor of the working section. When an absorption of static atmospheric electricity is effected through the four balloon collectors, the current in order to reach the earth connection E^1 must flow spirally through the collector network over the electromagnet S, primary induction coil 9, conductor 14, anode A of the audion tube, incandescent cathode K, as the way over the electromagnet and safety spark gap F offers considerably greater resistance. Owing to the fact that the accumulated current flows in one direction, an electromagnetic alternating field is produced in the interior of the collector network coil, whereby the whole free electrons are directed more or less into the interior of the coil. An increased ionization of the atmosphere is therefore produced. In consequence of this the points mounted on the collector balloon show a considerably reduced resistance and therefore increased static charges between the points on the balloon and the surrounding atmosphere are produced. The result of this is a considerably increased collector effect.

A second effect which could not be obtained otherwise is obtained by the electromagnetic alternating field which running parallel to the earth surface, acts more or less with a diminishing or increasing effect on the earth magnetic field, whereby in the case of fluctuations in the current a return induction current of reversed sign is always produced in the collector coil by earth magnetism. Now if, however, a constantly pulsating continuous alternating field is produced as stated in the above collector network I, an alternating current of the same periodicity is produced also in the collecting network coil. As the same alternating field is further transmitted to the aerial balloon, the resistance of its points is thereby considerably reduced, whilst the collector action is considerably increased. A further advantage is that positive electrons which collect on the metal surfaces during the conversion into dynamic current produce a so-called drop of potential of the collector area. As an alternating field is present, the negative ions surrounding the collector surfaces, when discharge of the collector surfaces takes place produce by the law of induction, an induction of reversed sign on the collector surface and so forth (that is to say again a positive charge). In addition to the advantages hereinbefore set forth, the construction of connecting conductors in coil form when of sufficiently large diameter, allows of a utilization of energy arising in higher regions also in the simplest way. As is well known electric discharges frequently take place at very great elevations which may be observed, such as St. Elmo's fires or northern lights. These energy quantities have not been able to be utilized up to now. By this invention all these kinds of energy, as they are of an electromagnetic nature and the direction of the axis of the collector coils stands at right angles to the earth's surface, can be more or less absorbed in the same way as a receiver in wireless telegraphy absorbs waves coming from a far distance. With a large diameter of the spiral it is possible to connect large surfaces and thereby to take up also large quantities of energy.

It is well known that large wireless stations in the summer months, and also in the tropics are very frequently unable to receive the signals in consequence of interruptions which are caused by atmospheric electricity, and this takes place with vertical coils of only 40 to 100 m. diameter. If on the contrary horizontal coils of 1 to 100 km. diameter be employed very strong currents may be obtained through discharges which are constantly taking place in the atmosphere. Particularly in the tropics or still better in the polar regions where the northern lights are constantly present, large quantities of energy may probably be obtained in this way. A coil with several windings should act the best. In similar manner any alteration of the earth magnetism should act inductively on such a coil.

It is not at all unlikely that earthquakes and spots on the sun will also produce an induction in such collector coils of sufficient size. In similar manner this collector conductor will react on earth currents more particularly when they are near the surface of the earth or even embedded in the earth. By combining the previous kind of current collectors so far as they are adapted for

the improved system with the improved possibilities of obtaining current the quantities of free natural energy which are to be obtained in the form of electricity are considerably increased.

In order to produce in the improved collector coil uniform current oscillations of an undamped nature so-called audion high vacuum or thermionic tubes of suitable connection are employed instead of the previously known spark gaps (Fig. 26, Nos. 9–18). The main aerial current flows through electromagnet S (which in the case of a high number of alternations is not connected here but in the earth conductor E^1) and may be conveyed over the primary coils in the induction winding through wire 14 to the anode A of the high vacuum grid tube. Parallel with the induction resistance 9 a regulating capacity of suitable size, such as condenser 11 is inserted. In the lower part of the vacuum grid tube is arranged the incandescent filament or the cathode K which is fed through a battery B. From the battery B two branches run, one to the earth conductor E^1 and the other through battery B^1 and secondary coil 10 to the grid anode *g* in the vacuum tube. By the method of connections shown in dotted lines, a desired voltage at the grid electrode *g* may also be produced through the wire 17 which is branched off from the main current conductor through switches 16 and some small condensers (*a*, *b*, *c*, *d*) connected in series, and conductor 18, without the battery B^1 being required.

The action of the entire system is somewhat as follows:—

On the connecting conductor of the aerial collector network being short circuited to earth, the condenser pole 11 is charged and slightly damped oscillations are formed in the short circuited existing oscillation circuit formed of the condenser 11 and self inductance 9. In consequence of the coupling through coil 10, fluctuations of voltage take place in the grid circuit 15 with the same frequency, which, fluctuations in turn influence the strength of the electrode current passing through the high vacuum amplyfying tube and thus produce current fluctuations of the same frequency in the anode circuit. A permanent supply of energy to the oscillation circuits 9 and 10 consequently takes place, until a condition of balance is set up, in which the consumed oscillation energy is equal to that absorbed. Thereby constant undamped oscillations are now produced in the oscillation circuits 9–11.

For regular working of such oscillation producers high vacuum strengthening tubes are necessary and it is also necessary that the grid and anode voltages shall have a phase difference of 180° so that if the grid is negatively charged, then the anode is positively charged and vice versa. This necessary difference of phase may be obtained by most varied connections, for example, by placing the oscillation circuit in the grid circuit or by separating the oscillation circuit and inductive coupling from the anodes and the grid circuit and so forth.

A second important factor in this way of converting static atmospheric electricity into undamped oscillations is that care must be taken that the grid and anode voltages have a certain relation to one another; the latter may be obtained by altering the coupling and a suitable selection of the self induction in the grid circuit, or as shown by dotted lines 18, 17, 16 by means of a larger or smaller number of condensers of suitable size connected in series; in this case the battery B^1 may be omitted. With a suitable selection of the grid potential a glow discharge takes place between the grid *g* and the anode A, and accordingly at the grid there is a cathode drop and a dark space is formed. The size of this cathode drop is influenced by the ions which are emitted in the lower space in consequence of shock ionization of the incandescent cathodes K and pass through the grid in the upper space. On the other hand the number of the ions passing through the grid is dependent on the voltage between the grid and the cathode. Thus if the grid voltage undergos periodic fluctuations (as in the present case) the amount of the cathode drop at the grid fluctuates and consequently the internal resistance of the tube correspondingly fluctuates, so that when a back coupling of the feed circuit with the grid circuit takes place, the necessary means are afforded for producing undamped oscillations and of taking current, according to requirements from the collecting conductor.

The frequency of the undamped oscillations produced is with a suitably loose coupling equal to the self frequency of the oscillation circuits 9 and 10. By a suitable selection of the self induction of the coil 9 and capacity 11 it is possible to extend from frequencies which produce electromagnetic oscillations of only a few metres wave length down to the lowest practical alternating current frequency. For large installations a suitable number of frequency producing tubes in the form of the well known high vacuum transmission tubes of .5 to 2 kw. in size may be connected in parallel so that in this respect no difficulty exists.

The use of such tubes for producing undamped oscillations, and also the construction and method of inserting such transmission tubes in an accumulator or dynamo circuit is known and also that such oscillation producing tubes only work well at voltages of 1,000 up to 4,000 volts, so that on the contrary their use at lower voltages is

considerably more difficult. By the use of high voltage static electricity this method of producing undamped oscillations as compared with that through spark gaps must be regarded, as an ideal solution particularly for small installations of outputs of from 1 to 100 kw.

By the application of safety spark gaps, with interpolation of electro-magnets, not only is short circuiting avoided but also the taking up of current is regulated. Oscillation producers inserted in the above way form a constantly acting electromagnetic alternating field in the collector coil, whereby as already stated, a considerable accumulating effect takes place. The withdrawal wire or working wire is connected at 12 and 13, but current may be taken by means of a secondary coil which is firmly or movably mounted in any suitable way inside the large collector coil, i. e. in its electromagnetic alternating field, so long as the direction of its axis runs parallel with that of the main current collecting coil.

In producing undamped oscillations of a high frequency (50,000 per second and more) in the oscillation circuits 9 and 11, electromagnets S and S^1 must be inserted if the high frequency oscillations are not to penetrate the collector coil, between the oscillation producers and the collector coil. In all other cases they are connected shortly before the earthing (as in Figs. 27 and 28).

In Figure 27 a second method of construction of the connecting conductor of the balloon aerials is illustrated in the form of a coil. The main difference consists in that in addition to the connecting conductor I another annular conductor II is inserted parallel to the former on the high voltage masts in the air (or embedded as a cable in the earth) but both in the form of a coil. The connecting wire of the balloon aerials is indicated as a primary conductor and also as a current producing network; the other is the consumption network and is not in unipolar connection with the current producing network.

In Figure 27 the current producing network I is shown with three balloon collectors 1, 2, 3 and aerial conductors 4, 5, 6; it is short circuited through condenser 19 and inductance 9. The oscillation forming circuit consists in this diagram of spark gap *f*, inductance 10, and condenser 11; the earth wire E, is connected to earth over electromagnet S^1. F is the safety spark gap which is also connected to earth through a second electromagnet S at E. On connecting up the condenser circuit 11 this is charged over the spark gap *f* whereby an oscillatory discharge is formed. This discharging current acts through inductance 10 on the inductively coupled secondary 9, whereby in the producing network a modification of the potential of the condenser 19 is produced. The consequence of this is that oscillations arise in the coil shaped producer network. These oscillations induce a current in the secondary circuit II, which has a smaller number of windings and a less resistance, the voltage of which, according to the proportion of the number of windings and of the ohmic resistance, is considerably lower whilst the current strength is greater.

In order to convert the current thus obtained into current of an undamped character, and to tune its wave lengths, a sufficiently large regulatable capacity 20 is inserted between the ends 12 and 13 of the secondary conductor II. Here also current may be taken without an earth conductor, but it is advisable to insert a safety spark gap E^1 and to connect this with the earth over an electromagnet S^2.

The producer network may be connected with the working network II over an inductionless condenser 21 or over an induction condenser 22, 23. In this case the secondary conductor is unipolarly connected with the energy conductor.

In Figure 28 the connecting conductor between the separate accumulator balloons is carried out according to the autotransformer principle. The collecting coil connects four aerial balloons 1, 2, 3, 4, the windings of which are not made side by side but one above the other. In Figure 28 the collector coil I is shown with a thin line, the metallically connected prolongation coils II with a thick line. Between the ends I^1 and II^1 of the energy network I a regulating capacity 19 is inserted. The wire I^1 is connected with the output wire and with the spark gap F.

As transformer of the atmospheric electricity an arrangement is employed which consists in using rotary pairs of condensers in which the one stator surface B is connected with the main current, whilst the other A is connected with the earth pole. Between these pairs of short circuited condensers are caused to rotate from which the converted current can be taken by means of two collector rings and brushes, in the form of an alternating current, the frequency of which is dependent on the number of balloons and the revolutions of the rotor. As the alternating current formed in the rotor can act, in this improved method of connection described in this invention, through coils 10 on the inductance 9, an increase or diminution of the feed current in I can be obtained according to the direction of the current by back induction. Current oscillations of uniform rhythm thereby result in the coil shaped windings of the producer net-work.

As the ends of this conductor are short cir-

cuited through the regulatable condenser 19 these rhythms produce short circuited undamped oscillations in the energy conductor, the periodicity and wave lengths of which oscillations can be adjusted according to desire by altering the capacity 19 to a given wave length and therewith also to a given frequency. These currents may also be employed in this form directly as working current through the conductors II^1 and III. By inserting the condenser 20 a connection between these conductors may also be made, whereby harmonic oscillations of desired wave length are formed. By this means quite new effects as regards current distribution are obtained. The withdrawal of current can even take place without direct wire connection if, at a suitable point in the interior of the producing network (quite immaterially whether this has a diameter of 1 or 100 km.) a coil tuned to these wave lengths and of the desired capacity is firmly or movably mounted in the aerial conductor in such a way that its axial direction is in parallel with that of the collector coil. In this case a current is induced in the producing network, the size of which is dependent on the total capacity and resistance and also on the periodicity employed. A possibility is thereby afforded in future, of taking energy from the producer network by wireless means. As thereby in addition to atmospheric electricity also magnetic earth currents and the energy from the higher atmosphere (at least partially) may be simultaneously obtained, this last system for collecting the atmospheric energy is of particular importance for the future.

Of course everywhere instead of spark gaps suitable grid vacuum tubes may be employed as producers for undamped oscillations. The separate coils of the producer net-work with large diameters may be connected with one another through separate conductors all in parallel or all in series or in groups in series. By regulating the number of oscillations and also the extent of the voltage more or less large collector coils of this kind may be employed. The coils may also be divided spirally over the entire section. The coils may be carried out in annular form or also in triangular, quadrangular, hexagonal or octagonal form.

Of course wires may be carried from a suitable place to the centre or also laterally which serve the current waves as guides. This is necessary when the currents have to be conducted over mountains and valleys and so forth. In all these cases the current must be converted into a current of suitable periodicity.

As already hereinbefore mentioned separate collecting balloons may be directly metallically interconnected at equidistant stations distributed over the entire country or may be connected by interpolation of suitable condenser batteries by means of high voltage conductors. The static electricity is converted through a spark gap into dynamic energy of a high number of oscillations, and could then in such form, with a suitable arrangement of the connections, observing various measures of precaution, be employed as source of energy after separate or special regulation.

According to this invention in order to increase the collecting effect of the balloon in the aerial collector conductor or in the earth wire, radiating collectors are employed. These consist either of incandescent metal or oxide electrodes in the form of vacuum grid tubes, or electric arcs (mercury and the like electrodes) Nernst lamps, or finally flames of various kinds may be simply connected with the respective conductor.

It is well known that energy can be drawn off from a cathode consisting of an incandescent body opposite an anode charged with positive electricity (vacuum grid tube). Hitherto however, a cathode was always first directly placed opposite an anode, and secondly the system always consisted of a closed circuit.

Now if we dispense with the ordinary ideas in forming light or flame arcs in which a cathode must always stand directly opposite an anode, and if we place an incandescent cathode opposite an anode charged to a high potential or another body freely floating in the air, or regard the incandescent cathode only as a source of unipolar discharge (which represent group and point discharges in electro-static machines similar to unipolar discharges), it may be ascertained that incandescent cathodes and less perfectly all incandescent radiators, flames and the like admit of relatively large current densities and allow large quantities of electric energy to radiate into the open space in the form of electron streams as transmitters.

The object of this invention is as described below, if such incandescent oxide electrodes or other incandescent radiators or flames are not freely suspended in space but connected metallically with the earth so that they can be charged with negative terrestrial electricity, these radiators possess the property of absorbing the free positive electrical charges contained in the air space surrounding them (that is to say of collecting them and conducting them to earth). They can therefore, serve as collectors and have, in comparison to the action of the spikes, or points, a very large radius of action R; the effective capacity of these collector is much greater than the geometrical capacity (R_0-) calculated in an electro-static sense.

Now as our earth is surrounded as is well

known, with an electro-static field and the difference of potential

$$\frac{\delta V}{\delta h}$$

of the earth field according to the latest investigations, is in summer about 60 to 100 volts and in winter 300 to 500 volts per metre of difference in height (δh), a simple calculation gives the result that when such a radiation collector or flame collector is arranged for example on the ground, and a second one is mounted vertically over it at a distance of 2,000 metres and both are connected by a conducting cable, there is a difference of potential in summer of about 2,000,000 volts and in winter even of 6,000,000 volts and more.

According to Stefan Boltzmann's law of radiation, the quantity of energy which an incandescent surface (temperature T) of 1 sq. cm. radiates in a unit of time into the open air (temperature T_o) is expressed by the following formula:

$$S=\sigma\,(T^4-T^4{}_o)\ \text{watt/sq. cm.}$$

and the universal radiation constant σ is according to the latest researches of Ferry (Annales de Chimie et de physique 17 page 267 (1909)) equal to 6.30×10^{-12} watt/sq. cm.

Now if an incandescent surface of 1 sq. cm. shows, as compared with the surrounding space a periodic fall of potential δV it radiates (independent of the current direction, that is to say of the sign) in accordance with the above formula, for example at a temperature of 3725° C. an energy of 1.6 kw. per sq. cm. per second. As for the radiation the same value can be calculated for the collection of energy, but reversed. Now as carbon electrodes at the temperature of the electric arc support on the current basis a current density up to from 60 to 65 amperes per sq. cm. no difficulties will result in this direction in employing radiating collectors as accumulators.

If the earth be regarded as a cosmically insulated condenser in the sense of geometrical electro-statics *x* there results from the geometric (compare Ewald Rasch, "das elektrische Bogenlicht" (The electric arc light) page 169) capacity of the earth according to Chwolson:

For negative charging 1.3×10^6 Coulomb

For negative potential $V=10\times10^8$ volts.

From this there results however, $EJT\cong24.7\times10^{24}$ watt/Sec. Now if it is desired to make a theoretic short circuit through an earthed flame collector this would represent an electric total work of about 79,500 10^{10} kilowatt years. As the earth must be regarded as a rotating mechanism which is thermo-dynamically, electromagnetically, and also kinematically coupled with the sun and stars system by cosmic radiations and gravitation a diminution of the electric energy of the earth field is not to be feared. The energies which the incandescent collectors would withdraw from the earth field can only cause by the withdrawal of motor work a lowering of the earth temperature (temperature $T_E=300$) and reduce this to that of the world space ($T=O$) by using the entire energy. This is however not the case as the earth does not represent a cosmically entirely insulated system. On the contrary there is conveyed to the same according to the recent value corrected by Ferry for the solar constants through the radiation from the sun an energy of $18{,}500\times10^{10}$ kw. Accordingly any lowering of the earth temperature (T_E) without a simultaneous lowering of the sun's temperature (T_S) would contradict Stefan Boltzmann's law of radiation.

$$S=\sigma\,(T_S{}^4-T_E{}^4).$$

From this it must be concluded that if the earth temperature (T_E) sinks, the total radiation S absorbed by the earth increases, and further also that the secular speed of cooling of the earth is directly dependent on that of the sun and the other radiators cosmically coupled with the sun and is connected most closely with these.

The incandescent radiation collectors may, according to this invention, be employed for collecting atmospheric electricity if they (1) are charged with the negative earth electricity (that is to say when they are directly connected by means of a metallic conductor with the earth) and (2) if large capacities (metal surfaces) charged with electricity are mounted opposite them as positive poles in the air. This is regarded as the main feature of the present invention as without these inventive ideas it would not be possible to collect with an incandescent collector, sufficiently large quantities of the electrical charges contained in the atmosphere as technology requires; the radius of action of the flame collectors would also be too small, especially if it be considered that the very small surface density (energy density) (σ about$=2\times7\ .\ 10^9$ St. E. per sq. cm.) does not allow of large quantities of charge being absorbed from the atmosphere.

x) Calculated according to Poisson's calculation;

$\Delta V=-4\pi\delta$; as here the alteration of the potential or potential gradients only takes place in the direction of the normal, this calculation assumes the simple form

$$\delta=\frac{1}{4\pi}\times\frac{\delta^2V}{\delta n^2}$$

It has indeed already been proposed to employ flame collectors for collecting atmospheric electricity and it is known that

their collecting effect is substantially greater opposite the points. It is however, not known that the quantities of current which could hitherto be obtained are too small for technical purposes. According to my experiments the reason for this is to be found in the too small capacities of the collector conductor poles. If such flame or radiating collectors have no or only small positive surfaces, their radius of action for large technical purposes is too small. If the incandescent collectors be constantly kept in movement in the air they may collect more according to the speed of the movement, but this is again not capable of being carried out in practice.

By this invention the collector effect is considerably increased by a body charged with a positive potential and of the best possible capacity being also held floating (without direct earth connection) opposite such an incandescent collector which is held floating in the air at a desired height. If for example, a collecting balloon of sheet metal or of metalized balloon fabric be caused to mount to 300 up to 3,000 metres in the air and as positive pole it is brought opposite such a radiating collector connected by a conductor to earth, quite different results are obtained.

The metallic balloon shell (with a large surface) is charged to a high potential by the atmospheric electricity. This potential is greater the higher the collecting balloon is above the incandescent collector. The positive electricity acts concentratedly on the anode floating in the air as it is attracted through the radiation shock ionization, proceeding from the incandescent cathode. The consequence of this is that the radius of action of the incandescent cathode collector is considerably increased and thereby also the collecting effect of the collecting balloon surface. Further the large capacity of the anode floating in the air plays therefore an important part because it allows of the taking of large charges, and thereby a more uniform current is obtained even when there is a large consumption; this cannot be the case with small surfaces.

In the present case the metallic collecting balloon is a positive anode floating in the air and the end of the earth conductor of this balloon serves as positive pole surface opposite the surface of the radiating incandescent cathode, which in turn is charged with negative earth electricity being conductingly connected to earth.

The process may be carried out by two such contacts (negative incandescent cathode and anode end of a capacity floating in the air) a condenser and an inductive resistance being switched on in parallel, whereby simultaneously undamped oscillations may be formed.

In very large installations it is advisable to connect two such radiating collectors in series. Thus an arc light incandescent cathode may be placed below on the open ground and an incandescent cathode which is heated by special electro-magnetic currents be located high in the air. Of course for this the special vacuum Liebig tubes with or without grids may also be employed. An ordinary arc lamp with oxide electrodes may be introduced on the ground and the positive pole is not directly connected with the collecting balloon, but through the upper incandescent cathode or over a condenser. The method of connecting the incandescent cathode floating in the air may be seen in Figs. 29–33.

B is the air balloon, K a Cardan ring (connection with the hawser) C the balloon, L a good conducting cable, P a positive pole, N negative incandescent cathode, and E earth conductor.

Fig. 29 represents the simplest form of construction. If electric oscillations are produced below on the ground by means of a carbon arc lamp or in other suitable way a considerably greater electric resistance is opposed to that in the direct way by inserting an electrical inductive resistance 9. Consequently between P and N a voltage is formed, and as, over N and P only an inductionless ohmic resistance is present, a spark will spring over so long as the separate induction co-efficients and the like are correctly calculated. The consequence of this is that the oxide electrode (carbon or the like) is rendered incandescent and then shows as incandescent cathode an increased collecting effect. The positive poles must be substantially larger than the negative in order that they may not also become incandescent. As they are further connected with the large balloon area which has a large capacity and is charged at high voltage, an incandescent body which is held floating in the air and a positive pole which can collect large capacities is thereby obtained in the simplest way. The incandescent cathode is first caused to become incandescent by means of separate energy produced on the earth, and then maintained by the energy collected from the atmosphere.

Fig. 30 only shows the difference that instead of a round balloon a cigar shaped one (of metal or metalized fabric) may be employed and also a condenser 5 is inserted between the incandescent cathode and the earth conductor so that a short circuited oscillation circuit over P. N 5 and 9 is obtained. This has the advantage that quite small quantities of electricity cause the cathode to become incandescent and much larger cathode bodies may be rendered incandescent.

In this form of construction both the in-

candescent cathode and also the positive electrode may be enclosed in a vacuum chamber as may be seen in Fig. 32. A cable L is carried well insulated through the cover of a vessel and ends in a condenser disc 5. The cover is arched in order to keep off the rain. The vessel is entirely or partially made of magnetic metal and well insulated inside and outside. Opposite the disc 5 another disc 6 and on this again a metallic positive pole of the vacuum tube *g* with the incandescent cathode (oxide electrode) N is arranged. The negative electrode is on the one hand connected with the earth conductor E, and on the other hand with the inductive resistance 9 which is also connected with the cable L with the positive pole and wound round the vessel in coils. The action is exactly the same as that in Fig. 29 only instead of an open incandescent cathode one enclosed in vacuo is employed. As in such collectors only small bodies can be brought to incandescence in large installations a plurality of such vacuum tubes must be inserted in proximity to one another. According to the previous constructions Figs. 31 and 33 are quite self evident without further explanations.

Figs. 34–37 represent further diagrams of connections over radiating and flame collectors, and in fact, how they are to be arranged on the ground.

Fig. 34 shows an arc light collector with oxide electrodes for direct current and its connection; Fig. 35 a similar one for alternating current, Fig. 36 an incandescent collector with a Nernst lamp and Fig. 37 a similar one with a gas flame.

The positive pole 1 of the radiating collectors is always directly connected to the aerial collecting conductor A. In Fig. 34 this is further connected over the condenser battery 5 with a second positive electrode 3. The direct current dynamo *b* produces current which flows over between the electrodes 3 and 2 as an arc light. On the formation of an arc the negative incandescent electrode 2 absorbs electricity from the positive poles standing opposite it and highly charged with atmospheric electricity and conveys the same to the working circuit. The spark gap 7, inductive resistance 9 and induction coil 10 are like the ones previously described. The protective electromagnet S guards the installation against earth circuiting, the safety spark gap 8 from excess voltage or overcharging.

In Fig. 35 the connection is so far altered that the alternating current dynamo feeds the exciting coil 11 of the induction condenser. 12 is its negative and 13 its positive pole; if the coil 3 on the magnet core of the dynamo is correctly calculated and the periodicity of the alternating current is sufficiently high an arc light can be formed between the two poles 1 and 2. As the cathode 2 is connected with the negatively charged earth, and therefore always acts as a negative pole, a form of rectification of the alternating current produced by the dynamo 3 is obtained, the second half of the period is always suppressed. The working circuit may be carried out in the same way as in Fig. 34; the working spark gap 7 may however be dispensed with, and instead thereof between the points *n* and *m* a condenser 5 and an induction resistance 9 may be inserted from which the current is taken inductively.

Fig. 36 represents a form of construction similar to Fig. 34 only that here instead of an arc lamp a Nernst incandescent body is employed. The Nernst lamp is fed through the battery 3. The working section is connected with the negative pole, the safety spark gap with the + poles. The working spark gap 7 may also be dispensed with and the current for it taken at 12 over the oscillation circuit 5, 11 (shown in dotted lines).

Flame collectors (Fig. 37) may also be employed according to this invention. The wire network 1 is connected with the aerial collector conductor A and the burner with the earth. At the upper end of the latter, long points are provided which project into the flame. The positive electrode is connected with the negative over a condenser 5 and the induction coil 9 with the earth.

The novelty in this invention is firstly, the use of incandescent cathodes opposite positive poles which are connected with large metallic capacities as automatic collecting surfaces, (2) the connection of the incandescent cathodes with the earth whereby, in addition to the electricity conveyed to them from the battery or machine which causes the incandescing, also the negative charge of the earth potential is conveyed, and (3) the connection of the positive and negative poles of the radiating collectors over a condenser circuit alone or with the introduction of a suitable inductive resistance, whereby simultaneously an oscillatory oscillation circuit may be obtained. The collecting effect is by these methods quite considerably increased.

I declare that what I claim is:—

1. An electrical energy generating system, comprising a conducting surface for static charges, means to support same at a distance above the earth, a conductor leading to the earth level, a spark gap associated with said conductor to convert electrostatic charges into electromagnetic high frequency oscillations means to supply said electromagnetic energy to a net work, and a spark gap of greatly increased relative resistance in parallel therewith.

2. An electrical energy generating system

comprising a conductor, means to support same above the earth level, an inductance therein, a spark gap associated with said conductor, a second spark gap of much higher relative resistance in parallel therewith and an energy receiving circuit coupled with the spark gap of lesser resistance.

3. An electrical energy generating system comprising a collecting surface, means to support same above the earth level, a conductor connecting said collecting surface with the earth level, a choke in said conductor, an electromagnetic resistance converting electrostatic energy to electromagnetic energy, a safety higher resistance in parallel therewith and a net work coupled with the conversion resistance of lesser value.

4. An electrical energy generating system comprising electric conductors spaced above the earth to form electromagnetic oscillating circuits, conductors connecting to earth level, electrostatic to electromagnetic energy conversion means therein, a safety high electrostatic resistance in parallel therewith and means to alter the electromagnetic characteristic of the circuits.

5. An electrical energy generating system comprising in combination a static collecting surface arranged above the earth, conductors connecting to earth level, a pair of spark gaps in parallel of different electrostatic resistance, a utilization net work shunted across the spark gap of lesser resistance and an electromagnetic choke in said conductors.

6. An electrical energy generating system comprising an open circuit energy collecting aerial, a pair of sparking gaps in parallel of widely different resistance, connected thereto and a closed electric oscillation circuit in shunt across the gap of lesser resistance.

7. An electrical energy generating system comprising an open circuit energy collecting aerial, a pair of sparking gaps in parallel of widely different resistance connected thereto, a closed electric oscillation circuit in shunt across the gap of lesser resistance, a plurality of electrostatic collecting surfaces, means to connect said collecting surfaces in parallel in groups and means to connect said groups symmetrically with said aerial.

In witness whereof, I have hereunto signed my name this 30 day of Dec., 1920, in the presence of two subscribing witnesses.

HERMANN PLAUSON.

POWERING ELECTRICAL DEVICES WITH ENERGY ABSTRACTED FROM THE ATMOSPHERE

Lloyd R. Crump, Silver Spring, Md.

Application March 12, 1954, Serial No. 415,986

1 Claim. (Cl. 321—2)

(Granted under Title 35, U. S. Code (1952), sec. 266)

The invention described herein may be manufactured and used by or for the Government for governmental purposes without payment to me of any royalty thereon.

This invention relates to the convenient and economical provision of power for the operation of electronic circuits and devices using transistors, and of other electrical devices having modest power requirements.

A great advantage of transistors, and a major reason for their enthusiastic reception since their introduction a few years ago, is the fact that they will operate satisfactorily with very low supply voltages and currents. One milliwatt or even less is sufficient to power a transistor in many applications. Various batteries have been developed to provide, in a minimum of space, the relatively minute amounts of power needed by transistors.

My invention provides methods and means that permit transistor circuits, and also other low-powered electrical devices, to be economically and conveniently operated without any batteries whatever, and indeed without any power supply whatever as power supplies are ordinarily conceived.

The invention centers around my discovery that it is practicable to construct operative transistor circuits that are able to abstract from the atmosphere sufficient electromagnetic energy to provide all necessary supply voltages and currents for their own operation. Circuits and devices powered according to my invention will operate indefinitely without any local power source whatever.

I have successfully constructed and demonstrated such circuits. For example, I have constructed a batteryless transistor radio receiver on which I have listened to either nearby or distant broadcast stations as desired, using either headphones or a loudspeaker; this receiver has been powered entirely by electromagnetic energy abstracted from the atmosphere.

From the successful operation of this receiver, and from other experimental work, it becomes clear that, by the methods and means of the invention, a great variety of practical and useful transistor circuits can be powered entirely by energy abstracted from the atmosphere.

Furthermore, as will become apparent below, my invention is applicable to the powering of other electrical devices requiring relatively small amounts of power.

An object of the present invention is to provide methods and means for powering transistor circuits entirely from radiofrequency energy abstracted from the atmosphere.

Another object is to provide methods and means for powering remote radio receivers, low-powered radio transmitters, and other low-powered electrical devices, with energy received by radio from a master station, so that no local power supplies are needed by the devices and so that the powering or non-powering of the remote device is under the control of the master station.

A further object is to provide methods and means for powering transistor circuits and other low-powered electrical devices with radiofrequency energy received from one or more remote radio transmitters.

Other objects, aspects, uses, and advantages of the invention will become apparent from the following description and from the drawing.

Figure 1 is a schematic diagram of a transistor radio receiver in which all necessary power is supplied by energy abstracted from the atmosphere in accordance with the invention.

Figure 2 is a schematic diagram showing a general application of the invention to provide direct-current power to a load.

Figure 3 is a schematic diagram of a system for obtaining a high energy D.-C. source at a high voltage level using energy abstracted from the atmosphere.

Referring to Figure 1, a receiving antenna **1** is connected to antenna coupling coils **2** and **3**, the other ends of which are connected to ground. A parallel resonant circuit consisting of coil **5** and capacitor **6** is coupled to coil **2**. A second parallel resonant circuit consisting of coil **7** and capacitor **10** is coupled to coil **3**. A third parallel resonant circuit consisting of coil **11** and capacitor **12** is also coupled to coil **3**.

Coil **5** and capacitor **6** are tuned to the frequency of a radio transmitter from which it is desired to receive information—for instance, an amplitude-modulated standard broadcast station. The signal received from this transmitter need not be strong. The signal is detected by diode **15** to obtain an audio-frequency information signal. This audio signal is coupled through a capacitor **16** and is amplified by a circuit that includes a transistor **17** having a base **20**, an emitter **21**, and a collector **22**. The amplified audio output of the transistor is coupled through an audio transformer **23** to an electroacoustical transducer, preferably a permanent-magnet dynamic loudspeaker **25** as shown.

The novelty of the invention lies largely in the method and means by which the necessary direct-current power is supplied to the emitter and collector circuits of transistor **17**. This method and means will now be described.

Coil **7** and capacitor **10**, and also coil **11** and capacitor **12**, are tuned to receive radio signals of relatively high strength. It does not matter whether these signals contain information. These power signals are rectified by diodes **26** and **27** to provide direct-current power that is filtered by capacitors **30** and **31**. The D.-C. power thus obtained is utilized to power the transistor **17**.

In the circuit shown, two tuned circuits (coil **7** and capacitor **10**, and coil **11** and capacitor **12**) are tuned to power signals and the D.-C. voltages obtained from each are connected in series. The tuned power circuits may be tuned to the same or different power signals. Under certain circumstances it may be desirable to use more than two tuned power circuits and to tune them to more than two power signals; in this way power can be obtained from several signals and combined. On the other hand, if a strong power signal is available, a single tuned power circuit may suffice to give the needed D.-C. power.

Even weak information signals can be received successfully. A plurality of transistor amplifier stages can be used if desired, or other circuits such as superheterodyne circuits can be used. It is merely necessary that a sufficiently strong power signal or signals be available to provide the small amount of D.-C. needed to power the transistors.

If the information signal happens to be strong, it can be used as the power signal; all of the tuned circuits (coil **5** and capacitor **6**, coil **7** and capacitor **10**, coil **11** and capacitor **12**) are tuned to the information signal.

Engineers who have observed my invention in operation have been surprised at the unexpectedly good results obtained, even with readily available power signals of quite moderate strength. For instance, sufficient power for satisfactory operation of a loudspeaker at low volumes is

readily obtained from a 5-kilowatt standard broadcast station 5 miles away, using only an indoor antenna to pick up the power signal as well as information signals. In typical operation under these conditions a D.-C. voltage of about 2.5 to 3 volts is obtained between the emitter and the collector, at a current of about 250 microamperes; D.-C. power input to the transistor is thus of the order of 0.5 to 1 milliwatt. So far as I am aware, no one has ever before discovered and demonstrated the practicability of this method of powering a radio receiver.

Because existing broadcast stations within a radius of a number of miles provide adequate power signals, the invention is readily practicable with existing power signals in almost any location in or near any city in the United States.

Although I have described a transistor radio receiver powered by my invention, it will be readily apparent that the invention is applicable to the powering of any transistor circuit using one or a number of transistors, and to the powering of other devices requiring relatively small amounts of power. For instance, sensitive electromechanical, electrochemical, or electrothermal devices can be operated by the method of the invention.

Referring to Figure 2, which shows a more general embodiment of my invention, an antenna **35** picks up radiofrequency energy from the atmosphere. This energy flows through coil **36**, which is coupled to a tuned circuit consisting of coil **37** and capacitor **40**. The radiofrequency voltage across capacitor **40** is rectified by diode **41** and filtered by a low-pass filter **46** consisting of capacitors **42** and **44** and choke coil **43**. The resulting D.-C. voltage is applied to a load **45**.

In the practice of my invention, larger amounts of power can be obtained for short periods of time by storing received energy in a suitable energy storage device. Stored energy may then be withdrawn at intervals at a more rapid rate than that at which it was received and put into the storage device. In this way the invention can be used to provide short pulses of relatively very high electrical energy. This result can be readily obtained by charging a relatively large capacitor with direct current and then discharging the capacitor rapidly into a load when desired. This rapid discharge can be initiated automatically when the voltage across the capacitor reaches a certain level, or it can be initiated when a transistor radio receiver receives a certain information signal.

Higher voltages can be obtained with the invention by means of well known devices for raising D.-C. voltages as shown in Figure 3. The D.-C. voltage output from the capacitor **44** can be used to power a low frequency transistor oscillator **52** whose A.-C. output is raised to a higher voltage level by the transformer **55**. This relatively high A.-C. voltage can then be rectified by a diode **61** and fed to a capacitor **64** to provide a high energy D.-C. source at a relatively high voltage level at the terminals **69** and **70**. If desired, energy can now be withdrawn from the capacitor **64** at intervals in short pulses of high energy at a high voltage level. Pulsed radio transmission is one of the possible uses for this form of the invention. Other uses would be to provide a single relatively powerful pulse needed to actuate an electrothermal or electromechanical device.

As has been indicated above, in many locations and particularly anywhere in or near most American cities, power signals normally present in the atmosphere are readily available for the easy and convenient practice of the invention. However, the invention also has important applications in systems in which the necessary power signal is generated and transmitted specifically for the operation of the particular system. Such systems can, for example, comprise a master station transmitting all the power that is needed for hundreds or thousands of fixed or mobile transistor receivers or other remote devices over a range of many miles. This eliminates the need for hundreds or thousands, as the case may be, of local power supplies. At the same time, such a system has the advantage that all of the remote devices can be simultaneously activated or deactivated at the will of the master station, simply by starting or stopping the transmission of the power signal. In such systems it will often be advantageous to use power signals of frequencies sufficiently high to permit the use of resonant receiving antennas of small physical dimensions for signal pickup at the remote devices. In addition to the power signal, the master station may transmit an information signal on the same or a different carrier.

Certain types of devices powered entirely by received radio waves are of course well known. The well-known "crystal set" of the early days of radio, which used a diode rectifier to demodulate an amplitude-modulated radiofrequency signal, is an outstanding example of such a device. My invention is readily distinguishable from such prior devices, however. In typical prior devices a modulated radiofrequency signal is applied to a diode to obtain unidirectional half-wave pulses whose amplitudes vary with modulation. These pulses are integrated by means of a capacitor to obtain a unidirectional signal the amplitude of which follows the audiofrequency modulation envelope. If the radiofrequency signal is received with sufficient strength the audio signal may have sufficient power to operate headphones or similar utilization device without power amplification; but the signal is utilized for its information content, rather than to supply non-information-containing power.

My invention, on the other hand, entails the utilization of received radiofrequency energy to supply power to at least one pair of circuit points (across capacitor **31** in Fig. 1, for example), such circuit points requiring power solely for its power content and not for any information or modulation it may contain. In other words, my invention entails the utilization of radiofrequency energy to supply power that would otherwise have to be supplied by batteries, generator, or other local power source.

It will be apparent that the embodiments shown are only exemplary and that various modifications can be made in construction and arrangement within the scope of the invention as defined in the appended claim.

I claim:

An electrical device for obtaining a high energy D.-C. source at a high voltage level using energy abstracted from the atmosphere, said device comprising in combination: resonant means for receiving radio waves, first rectifier means for converting said radio waves into first direct current energy, first capacitor means for storing said first direct current energy, an oscillator powered by said direct current energy, said oscillator producing an A.-C. output, transformer means for raising said A.-C. output to an increased voltage level, second rectifier means for converting the A.-C. output of increased voltage level from said transformer into second direct current energy, and second capacitor means for storing said second direct current energy.

Preface

How to Have Fun with This Book

Everyone uses electronic devices, but most of us don't really know what goes on inside them.

Of course, you may feel that you don't need to know. If you can drive a car without understanding the workings of an internal combustion engine, presumably you can use an iPod without knowing anything about integrated circuits. However, understanding some basics about electricity and electronics can be worthwhile for three reasons:

- By learning how technology works, you become better able to control your world instead of being controlled by it. When you run into problems, you can solve them instead of feeling frustrated by them.
- Learning about electronics can be fun—so long as you approach the process in the right way. The tools are relatively cheap, you can do all the work on a tabletop, and it doesn't consume a lot of time (unless you want it to).
- Knowledge of electronics can enhance your value as an employee or perhaps even lead to a whole new career.

Learning by Discovery

Most introductory guides begin with definitions and facts, and gradually get to the point where you can follow instructions to build a simple circuit.

This book works the other way around. I want you to start putting components together right away. After you see what happens, you'll figure out what's going on. I believe this process of *learning by discovery* creates a more powerful and lasting experience.

Stay Within the Limits!

Although I believe that everything suggested in this book is safe, I'm assuming that you will stay within the limits that I suggest. Please always follow the instructions and pay attention to the warnings, denoted by the icon you see here. If you go beyond the limits, you will expose yourself to unnecessary risks.

Learning by discovery occurs in serious research, when scientists notice an unusual phenomenon that cannot be explained by current theory, and they start to investigate it in an effort to explain it. This may ultimately lead to a better understanding of the world.

We're going to be doing the same thing, although obviously on a much less ambitious level.

Along the way, you will make some mistakes. This is good. Mistakes are the best of all learning processes. I want you to burn things out and mess things up, because this is how you learn the limits of components and materials. Since we'll be using low voltages, there'll be no chance of electrocution, and so long as you limit the flow of current in the ways I'll describe, there will be no risk of burning your fingers or starting fires.

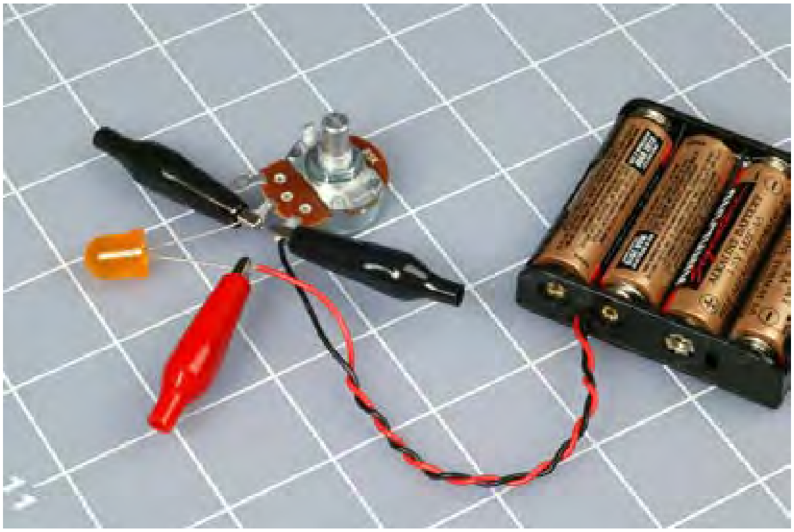

Figure P-1. *Learning by discovery allows you to start building simple circuits right away, using a handful of cheap components, a few batteries, and some alligator clips.*

How Hard Will It Be?

I assume that you're beginning with no prior knowledge of electronics. So, the first few experiments will be ultra-simple, and you won't even use solder or prototyping boards to build a circuit. You'll be holding wires together with alligator clips.

Very quickly, though, you'll be experimenting with transistors, and by the end of Chapter 2, you will have a working circuit that has useful applications.

I don't believe that hobby electronics has to be difficult to understand. Of course, if you want to study electronics more formally and do your own circuit design, this can be challenging. But in this book, the tools and supplies will be inexpensive, the objectives will be clearly defined, and the only math you'll need will be addition, subtraction, multiplication, division, and the ability to move decimal points from one position to another.

Moving Through This Book

Basically there are two ways to present information in a book of this kind: in tutorials and in reference sections. I'm going to use both of these methods. You'll find the tutorials in sections headed as follows:

- Shopping Lists
- Using Tools
- Experiments

You'll find reference sections under the following headings:

- Fundamentals
- Theory
- Background

How you use the sections is up to you. You can skip many of the reference sections and come back to them later. But if you skip many of the tutorials, this book won't be of much use to you. Learning by discovery means that you absolutely, positively have to do some hands-on work, and this in turn means that you have to buy some basic components and play with them. You will gain very little by merely imagining that you are doing this.

It's easy and inexpensive to buy what you need. In almost any urban or suburban area in the United States, chances are you live near a store that sells electronic components and some basic tools to work with them. I am referring, of course, to RadioShack franchises. Some Shacks have more components than others, but almost all of them have the basics that you'll need.

You can also visit auto supply stores such as AutoZone and Pep Boys for basics such as hookup wire, fuses, and switches, while stores such as Ace Hardware, Home Depot, and Lowe's will sell you tools.

If you prefer to buy via mail order, you can easily find everything you need by searching online. In each section of the book, I'll include the URLs of the most popular supply sources, and you'll find a complete list of URLs in the appendix.

Fundamentals

Mail-ordering components and tools

Here are the primary mail-order sources that I use myself online:

http://www.radioshack.com
RadioShack, a.k.a. The Shack. For tools and components. Not always the cheapest, but the site is easy and convenient, and some of the tools are exactly what you need.

http://www.mouser.com
Mouser Electronics.

http://www.digikey.com
Digi-Key Corporation.

http://www.newark.com
Newark.

Mouser, Digi-Key, and Newark are all good sources for components, usually requiring no minimum quantities.

http://www.allelectronics.com
All Electronics Corporation. A narrower range of components, but specifically aimed at the hobbyist, with kits available.

http://www.ebay.com
You can find surplus parts and bargains here, but you may have to try several eBay Stores to get what you want. Those based in Hong Kong are often very cheap, and I've found that they are reliable.

http://www.mcmaster.com
McMaster-Carr. Especially useful for high-quality tools.

Lowe's and Home Depot also allow you to shop online.

McMASTER-CARR
Soldering Irons & Guns
MOUSER ELECTRONICS
RobotShop
Robotics at your service!
Shop With Confidence
Contact the Experts
SERVO
Digi-Key
Mr. Clock Radio
LITTER-ROBOT
No more litter box cleaning!
ALL ELECTRONICS CORPORATION
3 1/2 DIGIT LCD MULTIMETER W/ BACK

Figure P-2. *You'll find no shortage of parts, tools, kits, and gadgets online.*

Companion Kits

Maker Shed (*www.makershed.com*) offers a number of *Make: Electronics* companion kits, both toolkits and bundles of the various components used in the book's experiments. This is a simple, convenient, and cost-effective way of getting all the tools and materials you need to do the projects in this book.

Comments and Questions

Safari Books Online is an on-demand digital library that lets you easily search over 7,500 technology and creative reference books and videos to find the answers you need quickly.

With a subscription, you can read any page and watch any video from our library online. Read books on your cell phone and mobile devices. Access new titles before they are available for print, and get exclusive access to manuscripts in development and post feedback for the authors. Copy and paste code samples, organize your favorites, download chapters, bookmark key sections, create notes, print out pages, and benefit from tons of other time-saving features.

O'Reilly Media has uploaded this book to the Safari Books Online service. To have full digital access to this book and others on similar topics from O'Reilly and other publishers, sign up for free at *http://my.safaribooksonline.com*.

1

Experiencing Electricity

I want you to get a taste for electricity—literally!—in the first experiment. This first chapter of the book will show you:

- How to understand and measure electricity and resistance
- How to handle and connect components without overloading, damaging, or destroying them

Even if you have some prior knowledge of electronics, you should try these experiments before you venture on to the rest of the book.

IN THIS CHAPTER

Shopping List: Experiments 1 Through 5
Experiment 1: Taste the Power!
Experiment 2: Let's Abuse a Battery!
Experiment 3: Your First Circuit
Experiment 4: Varying the Voltage
Experiment 5: Let's Make a Battery

*Maker Shed (*www.makershed.com*) has put together a series of* Make: Electronics *companion kits. These include all of the tools and components used in book's experiments. This is a quick, simple, and cost-effective way of getting everything you need to complete the projects in this book.*

Shopping List: Experiments 1 Through 5

If you want to limit your number of shopping trips or online purchases, look ahead in the book for additional shopping lists, and combine them to make one bulk purchase.

In this first chapter, I will give you part numbers and sources for every tool and component that we'll be using. Subsequently, I won't expect you to need such specific information, because you will have gained experience searching for items on your own.

Tools

Small pliers

RadioShack Kronus 4.5-inch, part number 64-2953 or Xcelite 4-inch mini long-nose pliers, model L4G.

Or similar. See Figures 1-1 through 1-3. Look for these tools in hardware stores and the sources listed in the preface. The brand is unimportant. After you use them for a while, you'll develop your own preferences. In particular, you have to decide whether you like spring-loaded handles. If you decide you don't, you'll need a second pair of pliers to pull the springs out of the first.

Wire cutters

RadioShack Kronus 4.5-inch, part number 64-2951, or Stanley 7-inch model 84-108.

Or similar. Use them for cutting copper wire, not harder metals (Figure 1-4).

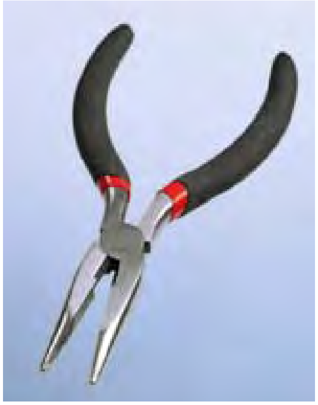

Figure 1-1. *Generic long-nosed pliers are your most fundamental tool for gripping, bending, and picking things up after you drop them.*

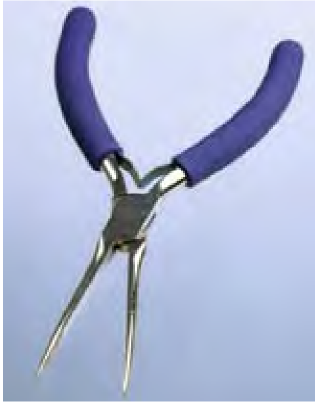

Figure 1-2. *Longer-nosed pliers: these are useful for reaching into tiny spaces.*

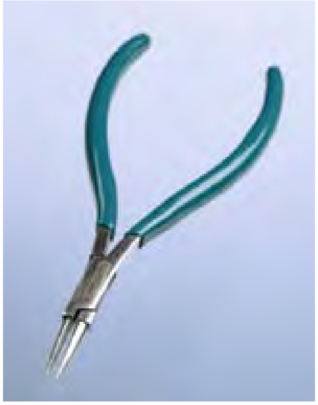

Figure 1-3. *Sharp-pointed pliers are designed for making jewelry, but are also useful for grabbing tiny components.*

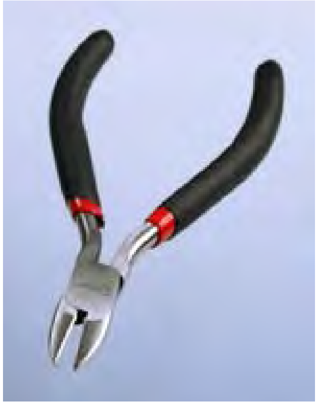

Figure 1-4. *Wire cutters, sometimes known as side cutters, are essential.*

Multimeter

Extech model EX410 or BK Precision model 2704-B or Amprobe model 5XP-A.

Or similar. Because electricity is invisible, we need a tool to visualize the pressure and flow, and a meter is the only way. A cheap meter will be sufficient for your initial experiments. If you buy online, try to check customer reviews, because reliability may be a problem for cheap meters. You can shop around for retailers offering the best price. Don't forget to search on eBay.

The meter must be digital—don't get the old-fashioned analog kind with a needle that moves across a set of printed scales. This book assumes that you are looking at a digital display.

I suggest that you do not buy an autoranging meter. "Autoranging" sounds useful—for example, when you want to check a 9-volt battery, the meter figures out for itself that you are not trying to measure hundreds of volts, nor fractions of a volt. The trouble is that this can trick you into making errors. What if the battery is almost dead? Then you may be measuring a fraction of a volt without realizing it. The only indication will be an easily overlooked "m" for "millivolts" beside the large numerals of the meter display.

On a manual-ranging meter, you select the range, and if the source that you are measuring is outside of that range, the meter tells you that you made an error. I prefer this. I also get impatient with the time it takes for the autoranging feature to figure out the appropriate range each time I make a measurement. But it's a matter of personal preference. See Figures 1-5 through 1-7 for some examples of multimeters.

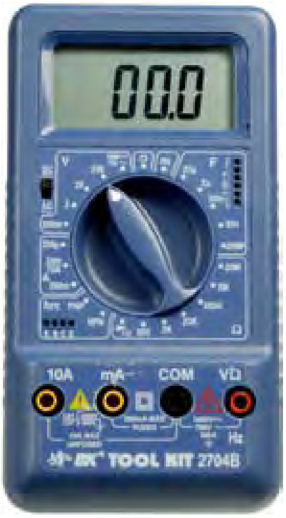

Figure 1-5. *You can see by the wear and tear that this is my own favorite meter. It has all the necessary basic features and can also measure capacitance (the F section, for Farads). It can also check transistors. You have to choose the ranges manually.*

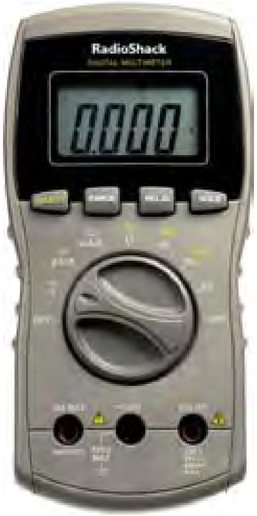

Figure 1-6. *Mid-priced RadioShack meter, which has the basic features; however, the dual purpose for each dial position, selected with the SELECT button, may be confusing. This is an autoranging meter.*

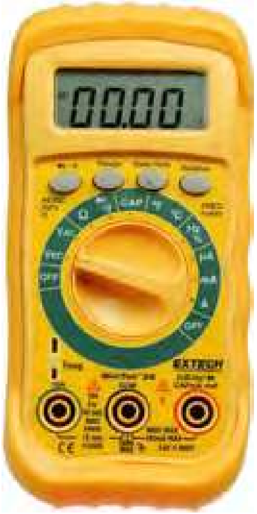

Figure 1-7. *An autoranging meter from Extech offers basic functions, plus a temperature probe, which may be useful to check whether components such as power supplies are running unduly hot.*

Supplies

Batteries

9-volt battery. Quantity: 1.

AA batteries, 1.5 volts each. Quantity: 6.

The batteries should be disposable alkaline, the cheapest available, because we may destroy some of them. You should *absolutely not* use rechargeable batteries in Experiments 1 and 2.

Battery holders and connectors

Snap connector for 9-volt battery, with wires attached (Figure 1-8). Quantity: 1. RadioShack part number 270-325 or similar. Any snap connector that has wires attached will do.

Battery holder for single AA cell, with wires attached (Figure 1-9). Quantity: 1. RadioShack part number 270-401 or Mouser.com catalog number 12BH410-GR, or similar; any single-battery holder that has thin wires attached will do.

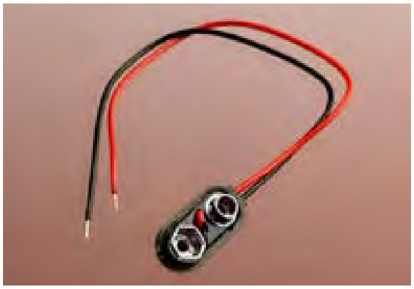

Figure 1-8. *Snap connector for a 9-volt battery.*

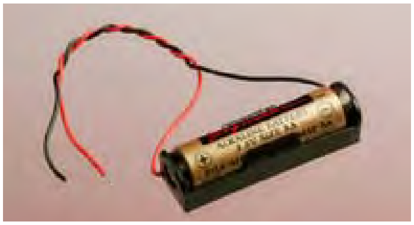

Figure 1-9. *Single AA-sized battery carrier with wires.*

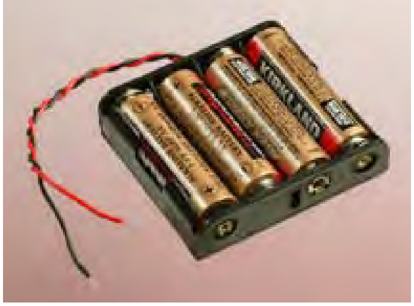

Figure 1-10. *Battery carrier for four AA cells, to be installed in series, delivering 6 volts.*

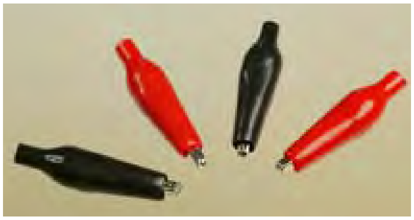

Figure 1-11. *Alligator clips inside vinyl sheaths, which reduce the chance of accidental short circuits.*

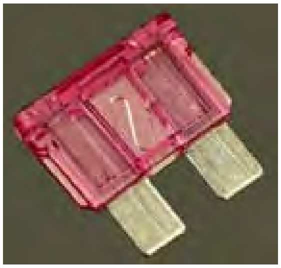

Figure 1-12. *A 3-amp fuse intended primarily for automotive use, shown here larger than actual size.*

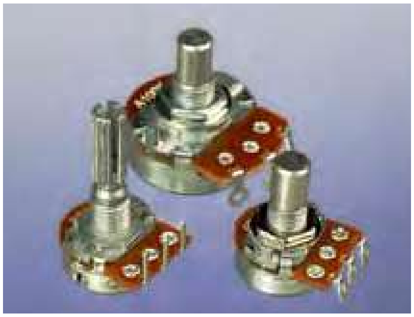

Figure 1-13. *Potentiometers come in many shapes and sizes, with different lengths of shafts intended for different types of knobs. For our purposes, any style will do, but the larger-sized ones are easier to play with.*

Battery holder for four AA cells, with wires attached (Figure 1-10). Quantity: 1. All Electronics catalog number BH-342 or RadioShack part 270-391 or similar.

Alligator clips

Vinyl-insulated. Quantity: at least 6. All Electronics catalog number ALG-28 or RadioShack part number 270-1545 or similar (Figure 1-11).

Components

You may not know what some of these items are, or what they do. Just look for the part numbers and descriptions, and match them with the photographs shown here. Very quickly, in the learning by discovery process, all will be revealed.

Fuses

Automotive-style, mini-blade type, 3 amps. Quantity: 3. RadioShack part number 270-1089, or Bussmann part ATM-3, available from automotive parts suppliers such as AutoZone (Figure 1-12).

Or similar. A blade-type fuse is easier to grip with alligator clips than a round cartridge fuse.

Potentiometers

Panel-mount, single-turn, 2K linear, 0.1 watt minimum. Quantity: 2. Alpha part RV170F-10-15R1-B23 or BI Technologies part P160KNPD-2QC25B2K, from Mouser.com or other component suppliers (Figure 1-13).

Or similar. The "watt" rating tells you how much power this component can handle. You don't need more than 0.5 watts.

Resistors

Assortment 1/4-watt minimum, various values but must include 470 ohms, 1K, and 2K or 2.2K. Quantity: at least 100. RadioShack part number 271-312.

Or search eBay for "resistor assorted."

Light-emitting diodes (LEDs)

Any size or color (Figures 1-14 and 1-15). Quantity: 10. RadioShack part number 276-1622 or All Spectrum Electronics part K/LED1 from Mouser.com.

Or similar. Just about any LEDs will do for these first experiments.

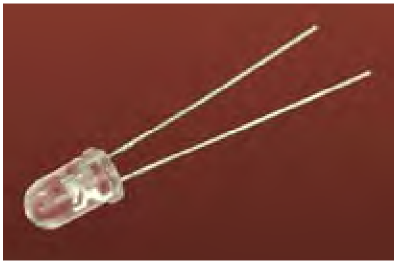

Figure 1-14. *Typical 5-mm diameter light-emitting diode (LED).*

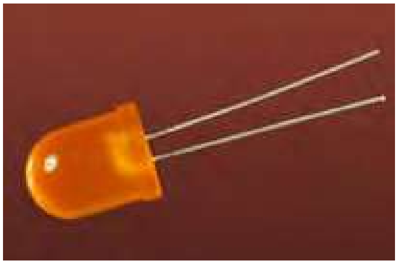

Figure 1-15. *Jumbo-sized LED (1 cm diameter) is not necessarily brighter or more expensive. For most of the experiments in this book, buy whatever LEDs you like the look of.*

Experiment 1: Taste the Power!

Can you taste electricity? Maybe not, but it feels as if you can.

You will need:

- 9-volt battery
- Snap connector for battery terminals
- Multimeter

No More Than 9 Volts

A 9-volt battery won't hurt you. But do not try this experiment with a higher-voltage battery or a larger battery that can deliver more current. Also, if you have metal braces on your teeth, be very careful not to touch them with the battery.

Procedure

Moisten your tongue and touch the tip of it to the metal terminals of a 9-volt battery. The sudden sharp tingle that you feel is caused by electricity flowing from one terminal of the battery (Figure 1-16), through the moisture on and in your tongue, to the other terminal. Because the skin of your tongue is very thin (it's actually a mucus membrane) and the nerves are close to the surface, you can feel the electricity very easily.

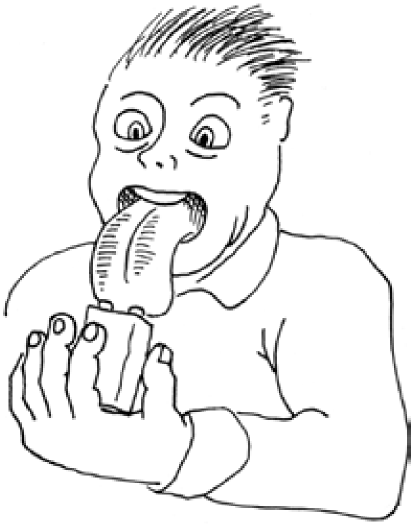

Figure 1-16. *Step 1 in the process of learning by discovery: the 9-volt tongue test.*

Now stick out your tongue, dry the tip of it very thoroughly with a tissue, and repeat the experiment without allowing your tongue to become moist again. You should feel less of a tingle.

What's happening here? We're going to need a meter to find out.

Tools

Setting up your meter

Check the instructions that came with the meter to find out whether you have to install a battery in it, or whether a battery is preinstalled.

Most meters have removable wires, known as *leads* (pronounced "leeds"). Most meters also have three sockets on the front, the leftmost one usually being reserved to measure high electrical currents (flows of electricity). We can ignore that one for now.

The leads will probably be black and red. The black wire plugs into a socket labeled "COM" or "Common." Plug the red one into the socket labeled "V" or "volts." See Figures 1-17 through 1-20.

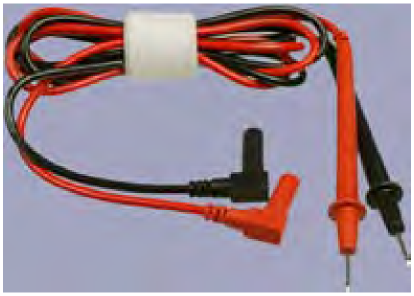

Figure 1-17. *The black lead plugs into the Common (COM) socket, and the red lead plugs into the red socket that's almost always on the righthand side of a multimeter.*

The other ends of the leads terminate in metal spikes known as *probes*, which you will be touching to components when you want to make electrical measurements. The probes detect electricity; they don't emit it in significant quantities. Therefore, they cannot hurt you unless you poke yourself with their sharp ends.

If your meter doesn't do autoranging, each position on the dial will have a number beside it. This number means "no higher than." For instance if you want to check a 6-volt battery, and one position on the voltage section of the dial is numbered 2 and the next position is numbered 20, position 2 means "no higher than 2 volts." You have to go to the next position, which means "no higher than 20 volts."

If you make a mistake and try to measure something inappropriate, the meter will show you an error message such as "E" or "L." Turn the dial and try again.

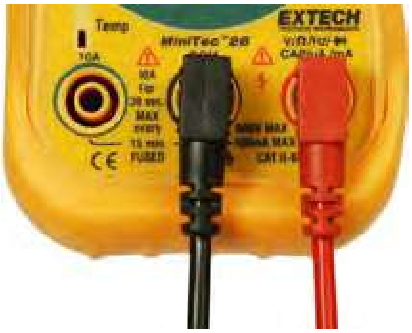

Figure 1-18

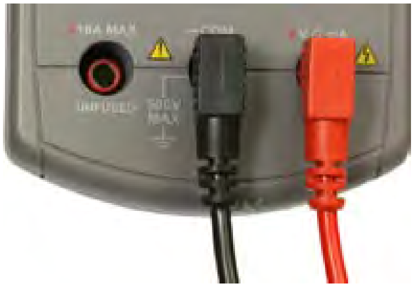

Figure 1-19

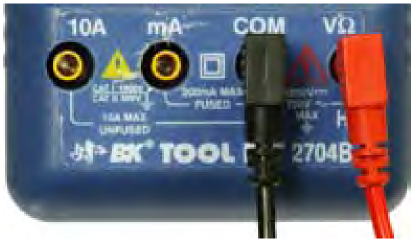

Figure 1-20. *To measure resistance and voltage, plug the black lead into the Common socket and the red lead into the Volts socket. Almost all meters have a separate socket where you must plug the red lead when you measure large currents in amps, but we'll be dealing with this later.*

FUNDAMENTALS

Ohms

We measure distance in miles or kilometers, weight in pounds or kilograms, temperature in Fahrenheit or Centigrade—and electrical resistance in ohms. The ohm is an international unit.

The Greek omega symbol (Ω) is used to indicate ohms, as shown in Figures 1-21 and 1-22. Letter K (or alternatively, KΩ) means a kilohm, which is 1,000 ohms. Letter M (or MΩ) means a megohm, which is 1,000,000 ohms.

Number of ohms	Usually expressed as	Abbreviated as
1,000 ohms	1 kilohm	1KΩ or 1K
10,000 ohms	10 kilohms	10KΩ or 10K
100,000 ohms	100 kilohms	100KΩ or 100K
1,000,000 ohms	1 megohm	1MΩ or 1M
10,000,000 ohms	10 megohms	10MΩ or 10M

A material that has very high resistance to electricity is known as an *insulator*. Most plastics, including the colored sheaths around wires, are insulators.

A material with very low resistance is a *conductor*. Metals such as copper, aluminum, silver, and gold are excellent conductors.

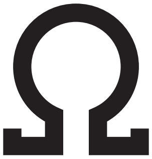

Figure 1-21. *The omega symbol is used internationally to indicate resistance on ohms.*

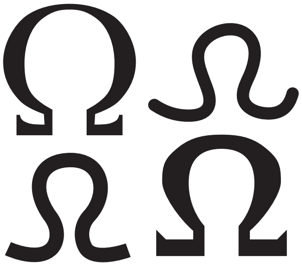

Figure 1-22. *You'll find it printed or written in a wide variety of styles.*

Procedure

We're going to use the meter to discover the electrical resistance of your tongue. First, set your meter to measure resistance. If it has autoranging, look to see whether it is displaying a K, meaning kilohms, or M, meaning megohms. If you have to set the range manually, begin with no less than 100,000 ohms (100K). See Figures 1-23 through 1-25.

Touch the probes to your tongue, about an inch apart. Note the reading, which should be around 50K. Now put aside the probes, stick out your tongue, and use a tissue to dry it very carefully and thoroughly. Without allowing your tongue to become moist again, repeat the test, and the reading should be higher. Finally, press the probes against the skin of your hand or arm: you may get no reading at all, until you moisten your skin.

When your skin is moist (for instance, if you perspire), its electrical resistance decreases. This principle is used in lie detectors, because someone who knowingly tells a lie, under conditions of stress, tends to perspire.

A 9-volt battery contains chemicals that liberate electrons (particles of electricity), which want to flow from one terminal to the other as a result of a chemical reaction inside it. Think of the cells inside a battery as being like two water tanks—one of them full, the other empty. If they are connected with a pipe, water flows between them until their levels are equal. Figure 1-26 may help you visualize this. Similarly, when you open up an electrical pathway between the two sides of a battery, electrons flow between them, even if the pathway consists only of the moisture on your tongue.

Electrons flow more easily through some substances (such as a moist tongue) than others (such as a dry tongue).

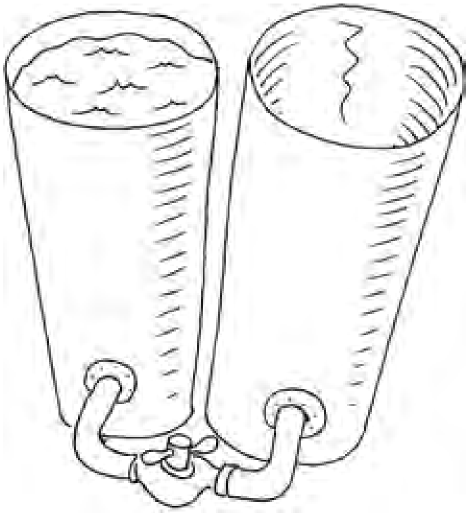

Figure 1-26. *Think of the cells in a battery as being like two cylinders: one full of water, the other empty. Open a connection between the cylinders, and the water will flow until the levels are equal on both sides. The less resistance in the connection, the faster the flow will be.*

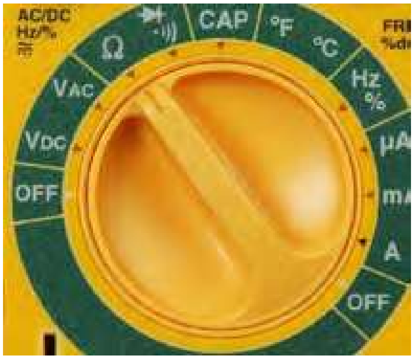

Figure 1-23

Figure 1-24

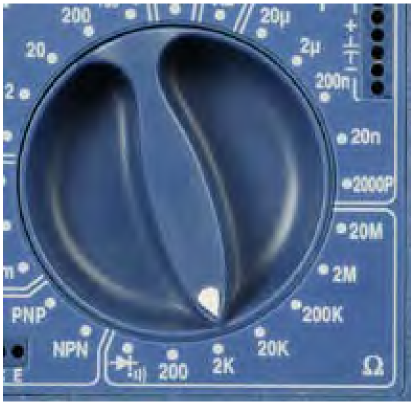

Figure 1-25. *To measure ohms, turn the dial to the ohm (omega) symbol. On an autoranging meter, you can then press the Range button repeatedly to display different ranges of resistance, or simply touch the probes to a resistance and wait for the meter to choose a range automatically. A manual meter requires you to select the range with the dial (you should set it to 100K or higher, to measure skin resistance). If you don't get a meaningful reading, try a different range.*

BACKGROUND

The man who discovered resistance

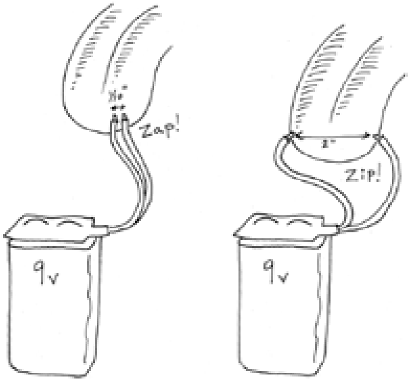
Georg Simon Ohm, pictured in Figure 1-27, was born in Bavaria in 1787 and worked in obscurity for much of his life, studying the nature of electricity using metal wire that he had to make for himself (you couldn't truck on down to Home Depot for a spool of hookup wire back in the early 1800s).

Despite his limited resources and inadequate mathematical abilities, Ohm was able to demonstrate in 1827 that the electrical resistance of a conductor such as copper varied in proportion with its area of cross-section, and the current flowing through it is proportional to the voltage applied to it, as long as temperature is held constant. Fourteen years later, the Royal Society in London finally recognized the significance of his contribution and awarded him the Copley Medal. Today, his discovery is known as Ohm's Law.

Figure 1-27. *Georg Simon Ohm, after being honored for his pioneering work, most of which he pursued in relative obscurity.*

Further Investigation

Attach the snap-on terminal cap (shown earlier in Figure 1-8) to the 9-volt battery. Take the two wires that are attached to the cap and hold them so that the bare ends are just a few millimeters apart. Touch them to your tongue. Now separate the ends of the wires by a couple of inches, and touch them to your tongue again. (See Figure 1-28.) Notice any difference?



Zap!
9v
Zip!
9v

Figure 1-28. *Modifying the tongue test to show that a shorter distance, with lower resistance, allows greater flow of electricity, and a bigger zap.*

Use your meter to measure the electrical resistance of your tongue, this time varying the distance between the two probes. When electricity travels through a shorter distance, it encounters less total resistance. As a result, the current (the flow of electricity per second) increases. You can try a similar experiment on your arm, as shown in Figure 1-29.

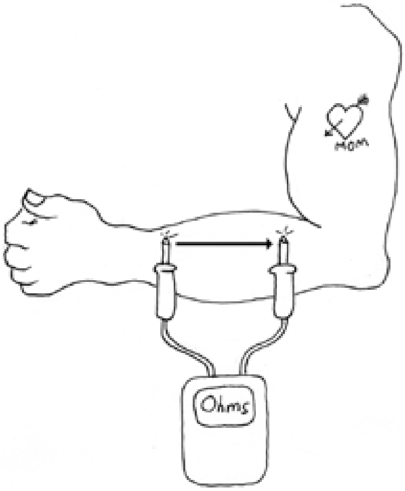


Figure 1-29. *Moisten your skin before trying to measure its resistance. You should find that the resistance goes up as you move the meter probes farther apart. The resistance is proportional to the distance.*

Use your meter to test the electrical resistance of water. Dissolve some salt in the water, and test it again. Now try measuring the resistance of distilled water (in a clean glass).

The world around you is full of materials that conduct electricity with varying amounts of resistance.

Cleanup and Recycling

Your battery should not have been damaged or significantly discharged by this experiment. You'll be able to use it again.

Remember to switch off your meter before putting it away.

Experiment 2: Let's Abuse a Battery!

To get a better feeling for electrical power, you're going to do what most books tell you not to do. You're going to short out a battery. A short circuit is a direct connection between the two sides of a power source.

Short Circuits

Short circuits can be dangerous. Do not short out a power outlet in your home: there'll be a loud bang, a bright flash, and the wire or tool that you use will be partially melted, while flying particles of melted metal can burn you or blind you.

If you short out a car battery, the flow of current is so huge that the battery might even explode, drenching you in acid (Figure 1-30).

Lithium batteries are also dangerous. Never short-circuit a lithium battery: it can catch fire and burn you (Figure 1-31).

Use only an alkaline battery in this experiment, and only a single AA cell (Figure 1-32). You should also wear safety glasses in case you happen to have a defective battery.

You will need:

- 1.5-volt AA battery
- Single-battery carrier
- 3-amp fuse
- Safety glasses (regular eyeglasses or sunglasses will do)

Procedure

Use an alkaline battery. Do not use any kind of rechargeable battery.

Put the battery into a battery holder that's designed for a single battery and has two thin insulated wires emerging from it, as shown in Figure 1-32. Do not use any other kind of battery holder.

Use an alligator clip to connect the bare ends of the wires, as shown in Figure 1-32. There will be no spark, because you are using only 1.5 volts. Wait one minute, and you'll find that the wires are getting hot. Wait another minute, and the battery, too, will be hot.

Figure 1-30. *Anyone who has dropped an adjustable wrench across the bare terminals of a car battery will tell you that short circuits can be dramatic at a "mere" 12 volts, if the battery is big enough.*

Figure 1-31. *The low internal resistance of lithium batteries (which are often used in laptop computers) allows high currents to flow, with unexpected results. Never fool around with lithium batteries!*

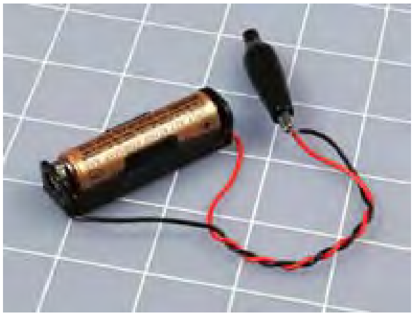

Figure 1-32. *Shorting out an alkaline battery can be safe if you follow the directions precisely. Even so, the battery is liable to become too hot to touch comfortably. Don't try this with any type of rechargeable battery.*

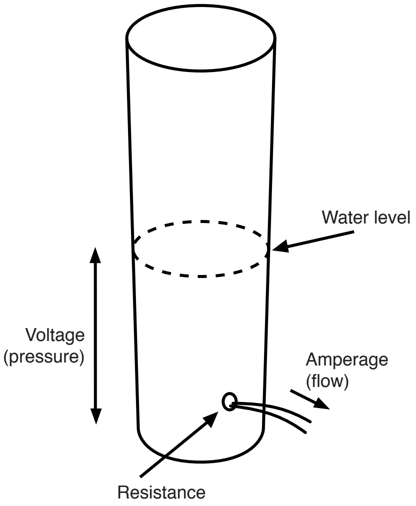

Figure 1-33. *Think of voltage as pressure, and amperes as flow.*

The heat is caused by electricity flowing through the wires and through the electrolyte (the conductive fluid) inside the battery. If you've ever used a hand pump to force air into a bicycle tire, you know that the pump gets warm. Electricity behaves in much the same way. You can imagine the electricity being composed of particles (electrons) that make the wire hot as they push through it. This isn't a perfect analogy, but it's close enough for our purposes.

Chemical reactions inside the battery create electrical pressure. The correct name for this pressure is *voltage*, which is measured in volts and is named after Alessandro Volta, an electrical pioneer.

Going back to the water analogy: the height of the water in a tank is proportionate to the pressure of the water, and comparable to voltage. Figure 1-33 may help you to visualize this.

But volts are only half of the story. When electrons flow through a wire, the flow is known as *amperage*, named after yet another electrical pioneer, André-Marie Ampère. The flow is also generally known as current. It's the current—the amperage—that generates the heat.

BACKGROUND

Why didn't your tongue get hot?

When you touched the 9-volt battery to your tongue, you felt a tingle, but no perceptible heat. When you shorted out a battery, you generated a noticeable amount of heat, even though you used a lower voltage. How can we explain this?

The electrical resistance of your tongue is very high, which reduces the flow of electrons. The resistance of a wire is very low, so if there's only a wire connecting the two terminals of the battery, more current will pass through it, creating more heat. If all other factors remain constant:

- Lower resistance allows more current to flow (Figure 1-34).
- The heat generated by electricity is proportional to the amount of electricity (the current) that flows.

Here are some other basic concepts:

- The flow of electricity per second is measured in amperes, or amps.
- The pressure of electricity causes the flow, measured in volts.
- The resistance to the flow is measured in ohms.
- A higher resistance restricts the current.
- A higher voltage overcomes resistance and increases the current.

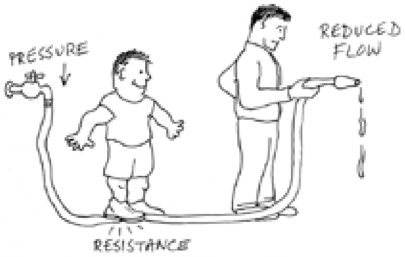

Figure 1-34. *Larger resistance results in smaller flow—but if you increase the pressure, it may overcome the resistance and increase the flow.*

If you're wondering exactly how much current flows between the terminals of a battery when you short it out, that's a difficult question to answer. If you try to use your multimeter to measure it, you're liable to blow the fuse inside the meter. Still, you can use your very own 3-amp fuse, which we can sacrifice because it didn't cost very much.

First inspect the fuse very carefully, using a magnifying glass if you have one. You should see a tiny S-shape in the transparent window at the center of the fuse. That S is a thin section of metal that melts easily.

Remove the battery that you short-circuited. It is no longer useful for anything, and should be recycled if possible. Put a fresh battery into the battery carrier, connect the fuse as shown in Figure 1-35, and take another look. You should see a break in the center of the S shape, where the metal melted almost instantly. Figure 1-36 shows the fuse before you connected it, and Figure 1-37 depicts a blown fuse. This is how a fuse works: it melts to protect the rest of the circuit. That tiny break inside the fuse stops any more current from flowing.

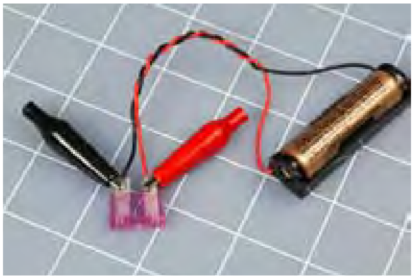

Figure 1-35. *When you attach both wires to the fuse, the little S-shaped element inside will melt almost instantly.*

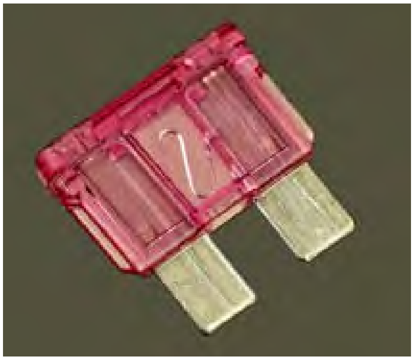

Figure 1-36. *A 3-amp fuse, before its element was melted by a single 1.5-volt battery.*

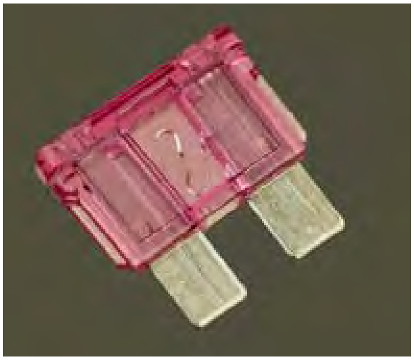

Figure 1-37. *The same fuse after being melted by electric current.*

FUNDAMENTALS

Volt basics

Electrical pressure is measured in volts. The volt is an international unit. A millivolt is 1/1,000 of a volt.

Number of volts	Usually expressed as	Abbreviated as
0.001 volts	1 millivolt	1 mV
0.01 volts	10 millivolts	10 mV
0.1 volts	100 millivolts	100 mV
1 volt	1,000 millivolts	1V

Ampere basics

We measure electrical flow in amperes, or amps. The ampere is an international unit, often referred to as an "amp." A milliamp is 1/1,000 of an ampere.

Number of amperes	Usually expressed as	Abbreviated as
0.001 amps	1 milliamp	1 mA
0.01 amps	10 milliamps	10 mA
0.1 amps	100 milliamps	100 mA
1 amp	1,000 milliamps	1A

BACKGROUND

Inventor of the battery

Alessandro Volta (Figure 1-38) was born in Italy in 1745, long before science was broken up into specialties. After studying chemistry (he discovered methane in 1776), he became a professor of physics and became interested in the so-called galvanic response, whereby a frog's leg will twitch in response to a jolt of static electricity.

Using a wine glass full of salt water, Volta demonstrated that the chemical reaction between two electrodes, one made of copper, the other of zinc, will generate a steady electric current. In 1800, he refined his apparatus by stacking plates of copper and zinc, separated by cardboard soaked in salt and water. This "voltaic pile" was the first electric battery.

Figure 1-38. *Alessandro Volta discovered that chemical reactions can create electricity.*

FUNDAMENTALS

Direct and alternating current

The flow of current that you get from a battery is known as *direct current*, or DC. Like the flow of water from a faucet, it is a steady stream, in one direction.

The flow of current that you get from the "hot" wire in a power outlet in your home is very different. It changes from positive to negative 50 times each second (in Great Britain and some other nations, 60 times per second). This is known as *alternating current*, or AC, which is more like the pulsatile flow you get from a power washer.

Alternating current is essential for some purposes, such as cranking up voltage so that electricity can be distributed over long distances. AC is also useful in motors and domestic appliances. The parts of an American power outlet are shown in Figure 1-39. A few other nations, such as Japan, also use American-style outlets.

For most of this book I'm going to be talking about DC, for two reasons: first, most simple electronic circuits are powered with DC, and second, the way it behaves is much easier to understand.

I won't bother to mention repeatedly that I'm dealing with DC. Just assume that everything is DC unless otherwise noted.

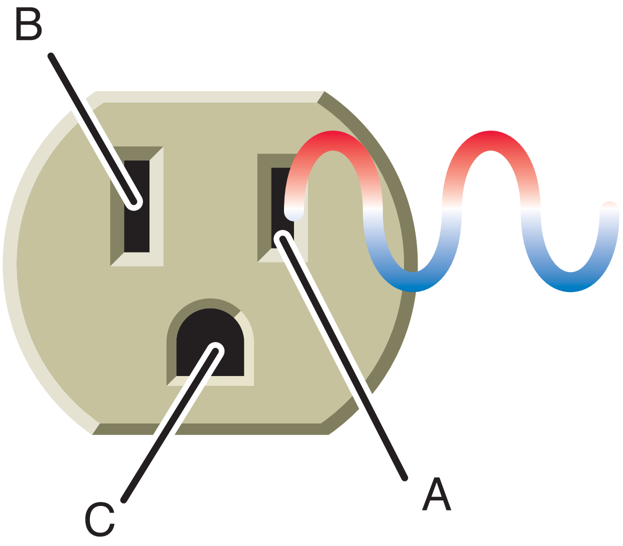

Figure 1-39. *This style of power outlet is found in North America, South America, Japan, and some other nations. European outlets look different, but the principle remains the same. Socket A is the "live" side of the outlet, supplying voltage that alternates between positive and negative, relative to socket B, which is called the "neutral" side. If an appliance develops a fault such as an internal loose wire, it should protect you by sinking the voltage through socket C, the ground.*

Cleanup and Recycling

The first AA battery that you shorted out is probably damaged beyond repair. You should dispose of it. Putting batteries in the trash is not a great idea, because they contain heavy metals that should be kept out of the ecosystem. Your state or town may include batteries in a local recycling scheme. (California requires that almost all batteries be recycled.) You'll have to check your local regulations for details.

The blown fuse is of no further use, and can be thrown away.

The second battery, which was protected by the fuse, should still be OK. The battery holder also can be reused later.

Experiment 3: Your First Circuit

Now it's time to make electricity do something that's at least slightly useful. For this purpose, you'll use components known as resistors, and a light-emitting diode, or LED.

You will need:

- 1.5-volt AA batteries. Quantity: 4.
- Four-battery holder. Quantity: 1.
- Resistors: 470Ω, 1K, and either 2K or 2.2K (the 2.2K value happens to be more common than 2K, but either will do in this experiment). Quantity: 1 of each resistor.
- An LED, any type. Quantity: 1.
- Alligator clips. Quantity: 3.

Setup

It's time to get acquainted with the most fundamental component we'll be using in electronic circuits: the humble resistor. As its name implies, it resists the flow of electricity. As you might expect, the value is measured in ohms.

If you bought a bargain-basement assortment package of resistors, you may find nothing that tells you their values. That's OK; we can find out easily enough. In fact, even if they are clearly labeled, I want you to check their values yourself. You can do it in two ways:

- Use your multimeter. This is excellent practice in learning to interpret the numbers that it displays.
- Learn the color codes that are printed on most resistors. See the following section, "Fundamentals: Decoding resistors," for instructions.

After you check them, it's a good idea to sort them into labeled compartments in a little plastic parts box. Personally, I like the boxes sold at the Michaels chain of crafts stores, but you can find them from many sources.

BACKGROUND

Father of electromagnetism

Born in 1775 in France, André-Marie Ampère (Figure 1-40) was a mathematical prodigy who became a science teacher, despite being largely self-educated in his father's library. His best-known work was to derive a theory of electromagnetism in 1820, describing the way that an electric current generates a magnetic field. He also built the first instrument to measure the flow of electricity (now known as a *galvanometer*), and discovered the element fluorine.

Figure 1-40. *Andre-Marie Ampere found that an electric current running through a wire creates a magnetic field around it. He used this principle to make the first reliable measurements of what came to be known as amperage.*

FUNDAMENTALS

Decoding resistors

Some resistors have their value clearly stated on them in microscopic print that you can read with a magnifying glass. Most, however, are color-coded with stripes. The code works like this: first, ignore the color of the body of the resistor. Second, look for a silver or gold stripe. If you find it, turn the resistor so that the stripe is on the righthand side. Silver means that the value of the resistor is accurate within 10%, while gold means that the value is accurate within 5%. If you don't find a silver or gold stripe, turn the resistor so that the stripes are clustered at the left end. You should now find yourself looking at three colored stripes on the left. Some resistors have more stripes, but we'll deal with those in a moment. See Figures 1-41 and 1-42.

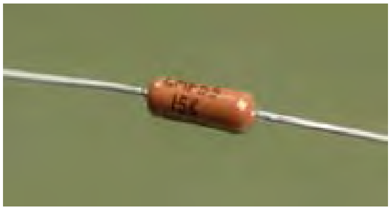

Figure 1-41. *Some modern resistors have their values printed on them, although you may need a magnifier to read them. This 15K resistor is less than half an inch long.*

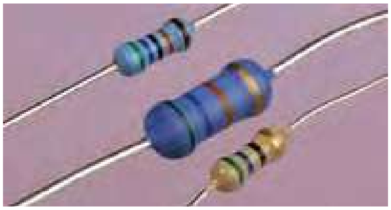

Figure 1-42. *From top to bottom, these resistor values are 56,000 ohms (56K), 5,600 ohms (5.6K), and 560 ohms. The size tells you how much power the resistor can handle; it has nothing to do with the resistance. The smaller components are rated at 1/4 watt; the larger one in the center can handle 1 watt of power.*

Starting from the left, the first and second stripes are coded according to this table:

Black	0
Brown	1
Red	2
Orange	3
Yellow	4
Green	5
Blue	6
Violet	7
Gray	8
White	9

The third stripe has a different meaning: It tells you how many zeros to add, like this:

Black	-	No zeros
Brown	0	1 zero
Red	00	2 zeros
Orange	000	3 zeros
Yellow	0000	4 zeros
Green	00000	5 zeros
Blue	000000	6 zeros
Violet	0000000	7 zeros
Gray	00000000	8 zeros
White	000000000	9 zeros

FUNDAMENTALS

Decoding resistors (continued)

Note that the color-coding is consistent, so that green, for instance, means either a value of 5 (for the first two stripes) or 5 zeros (for the third stripe). Also, the sequence of colors is the same as their sequence in a rainbow.

So, a resistor colored brown-red-green would have a value of 1-2 and five zeros, making 1,200,000 ohms, or 1.2MΩ. A resistor colored orange-orange-orange would have a value of 3-3 and three zeros, making 33,000 ohms, or 33KΩ. A resistor colored brown-black-red would have a value of 1-0 and two additional zeros, or 1KΩ. Figure 1-43 shows some other examples.

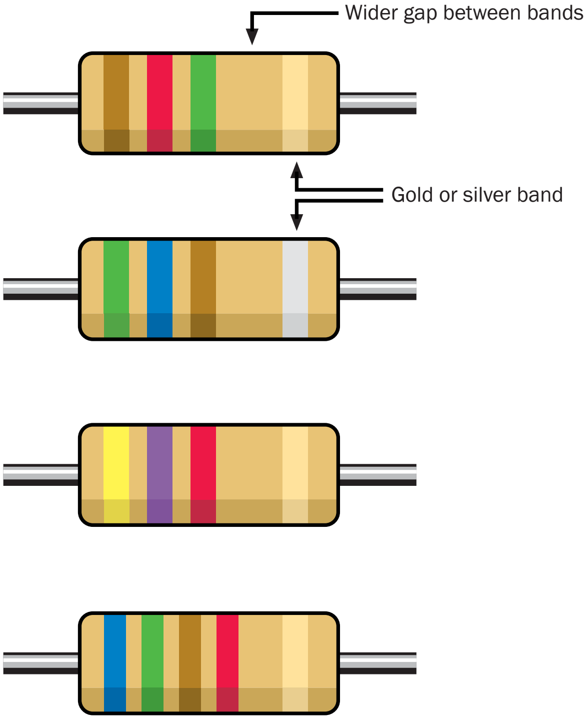

Figure 1-43. *To read the value of a resistor, first turn it so that the silver or gold stripe is on the right, or the other stripes are clustered on the left. From top to bottom: The first resistor has a value of 1-2 and five zeros, or 1,200,000, which is 1.2MΩ. The second is 5-6 and one zero, or 560Ω. The third is 4-7 and two zeros, or 4,700, which is 4.7KΩ. The last is 6-5-1 and two zeros, or 65,100Ω, which is 65.1KΩ.*

If you run across a resistor with four stripes instead of three, the first *three* stripes are digits and the *fourth* stripe is the number of zeros. The third numeric stripe allows the resistor to be calibrated to a finer tolerance.

Confusing? Absolutely. That's why it's easier to use your meter to check the values. Just be aware that the meter reading may be slightly different from the claimed value of the resistor. This can happen because your meter isn't absolutely accurate, or because the resistor is not absolutely accurate, or both. As long as you're within 5% of the claimed value, it doesn't matter for our purposes.

Lighting an LED

Now take a look at one of your LEDs. An old-fashioned lightbulb wastes a lot of power by converting it into heat. LEDs are much smarter: they convert almost all their power into light, and they last almost indefinitely—as long as you treat them right!

An LED is quite fussy about the amount of power it gets, and the way it gets it. Always follow these rules:

- The *longer* wire protruding from the LED must receive a *more positive* voltage than the shorter wire.
- The voltage difference between the long wire and the short wire must not exceed the limit stated by the manufacturer.
- The current passing through the LED must not exceed the limit stated by the manufacturer.

What happens if you break these rules? Well, we're going to find out!

Make sure you are using fresh batteries. You can check by setting your multimeter to measure volts DC, and touching the probes to the terminals of each battery. You should find that each of them generates a pressure of at least 1.5 volts. If they read slightly higher than this, it's normal. A battery starts out above its rated voltage, and delivers progressively less as you use it. Batteries also lose some voltage while they are sitting on the shelf doing nothing.

Load your battery holder (taking care that the batteries are the right way around, with the negative ends pressing against the springs in the carrier). Use your meter to check the voltage on the wires coming out of the battery carrier. You should have at least 6 volts.

Now select a 2KΩ resistor. Remember, "2KΩ" means "2,000 ohms." If it has colored stripes, they should be red-black-red, meaning 2-0 and two more zeros. Because 2.2K resistors are more common than 2K resistors, you can substitute one of them if necessary. It will be colored red-red-red.

Wire it into the circuit as shown in Figures 1-44 and 1-45, making the connections with alligator clips. You should see the LED glow very dimly.

Now swap out your 2K resistor and substitute a 1K resistor, which will have brown-black-red stripes, meaning 1-0 and two more zeros. The LED should glow more brightly.

Swap out the 1K resistor and substitute a 470Ω resistor, which will have yellow-violet-brown stripes, meaning 4-7 and one more zero. The LED should be brighter still.

This may seem very elementary, but it makes an important point. The resistor blocks a percentage of the voltage in the circuit. Think of it as being like a kink or constriction in a flexible hose. A higher-value resistor blocks more voltage, leaving less for the LED.

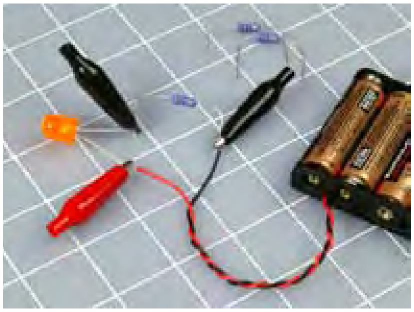

Figure 1-44. *The setup for Experiment 3, showing resistors of 470Ω, 1KΩ, and 2KΩ. Apply alligator clips where shown, to make a secure contact, and try each of the resistors one at a time at the same point in the circuit, while watching the LED.*

6v Battery Pack

Figure 1-45. *Here's how it actually looks, using a large LED. If you start with the highest value resistor, the LED will glow very dimly as you complete the circuit. The resistor drops most of the voltage, leaving the LED with insufficient current to make it shine brightly.*

Cleanup and Recycling

We'll use the batteries and the LED in the next experiment. The resistors can be reused in the future.

Experiment 4: Varying the Voltage

Potentiometers come in various shapes and sizes, but they all do the same thing: they allow you to vary voltage and current by varying resistance. This experiment will enable you to learn more about voltage, amperage, and the relationship between them. You'll also learn how to read a manufacturer's data sheet.

You will need the same batteries, battery carrier, alligator clips, and LED from the last experiment, plus:

- Potentiometer, 2KΩ linear. Quantity: 2. (See Figure 1-46.) Full-sized potentiometers that look like this are becoming less common, as miniature versions are taking their place. I'd like you to use a large one, though, because it's so much easier to work with.
- One extra LED.
- Multimeter.

Look Inside Your Potentiometer

The first thing I want you to do is find out how a potentiometer works. This means you'll have to open it, which is why your shopping list required you to buy two of them, in case you can't put the first one back together again.

Most potentiometers are held together with little metal tabs. You should be able to grab hold of the tabs with your wire cutters or pliers, and bend them up and outward. If you do this, the potentiometer should open up as shown in Figures 1-47 and 1-48.

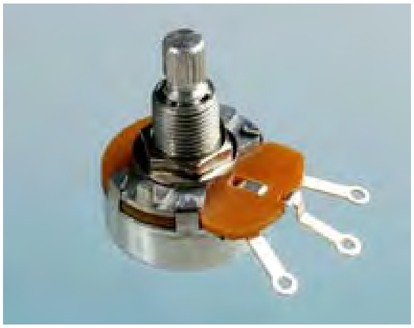

Figure 1-46

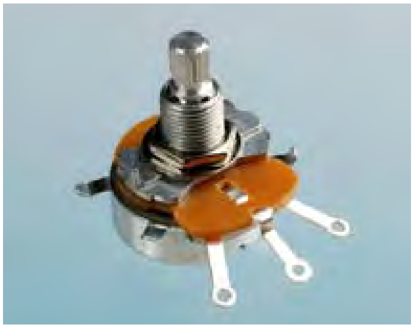

Figure 1-47

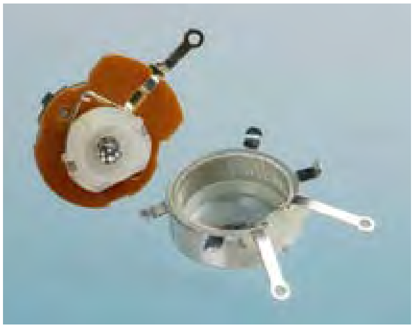

Figure 1-48. *To open the potentiometer, first pry up the four little metal tabs around the edge (you can see one sticking out at the left and another one sticking out at the right in Figure 1-47). Inside is a coil of wire around a flat plastic band, and a pair of springy contacts (the wiper), which conduct electricity to or from any point in the coil when you turn the shaft.*

Depending whether you have a really cheap potentiometer or a slightly more high-class version, you may find a circular track of conductive plastic or a loop of coiled wire. Either way, the principle is the same. The wire or the plastic possesses some resistance (a total of 2K in this instance), and as you turn the shaft of the potentiometer, a wiper rubs against the resistance, giving you a shortcut to any point from the center terminal.

You can try to put it back together, but if it doesn't work, use your backup potentiometer instead.

To test your potentiometer, set your meter to measure resistance (ohms) and touch the probes while turning the potentiometer shaft to and fro, as shown in Figure 1-49.

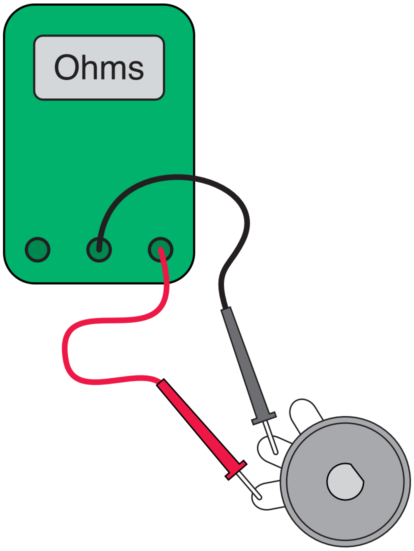

Figure 1-49. *Measure the resistance between these two terminals of the potentiometer while you turn its shaft to and fro.*

Dimming Your LED

Begin with the potentiometer turned all the way counterclockwise, otherwise you'll burn out the LED before we even get started. (A very, very small number of potentiometers increase and decrease resistance in the opposite way to which I'm describing here, but as long as your potentiometer looks like the one in Figure 1-48 after you open it up, my description should be accurate.)

Now connect everything as shown in Figures 1-50 and 1-51, taking care that you don't allow the metal parts of any of the alligator clips to touch each other. Now turn up the potentiometer *very* slowly. You'll notice the LED glowing brighter, and brighter, and brighter—until, oops, it goes dark. You see how easy it is to destroy modern electronics? Throw away that LED. It will never glow again. Substitute a new LED, and we'll be more careful this time.

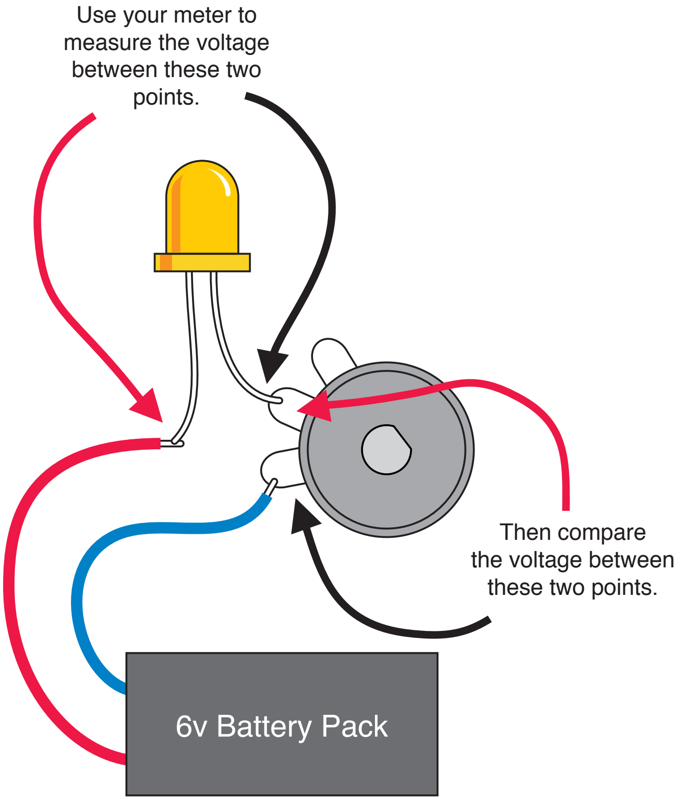
Figure 1-54. *Each meter has a different way to measure volts DC. The manually adjusted meter (top) requires you to move a slider switch to "DC" and then choose the highest voltage you want to measure: In this case, the selected voltage is 20 (because 2 would be too low). Using the autoranging RadioShack meter, you set it to "V" and the meter will figure out which range to use.*

While the batteries are connected to the circuit, set your meter to measure *volts DC* as shown in Figures 1-52 through 1-54. Now touch the probes either side of the LED. Try to hold the probes in place while you turn the potentiometer up a little, and down a little. You should see the voltage pressure around the LED changing accordingly. We call this the *potential difference* between the two wires of the LED.

If you were using a miniature old-fashioned lightbulb instead of an LED, you'd see the potential difference varying much more, because a lightbulb behaves like a "pure" resistor, whereas an LED self-adjusts to some extent, modifying its resistance as the voltage pressure changes.

Now touch the probes to the two terminals of the potentiometer that we're using, so that you can measure the potential difference between them. The potentiometer and the LED share the total available voltage, so when the potential difference (the voltage drop) around the potentiometer goes up, the potential difference around the LED goes down, and vice versa. See Figures 1-55 through 1-57. A few things to keep in mind:

- If you add the voltage drops across the devices in the circuit, the total is the same as the voltage supplied by the batteries.
- You measure voltage relatively, between two points in a circuit.
- Apply your meter like a stethoscope, without disturbing or breaking the connections in the circuit.



Use your meter to measure the voltage between these two points.
Then compare the voltage between these two points.
6v Battery Pack

Figure 1-55. *How to measure voltage in a simple circuit.*

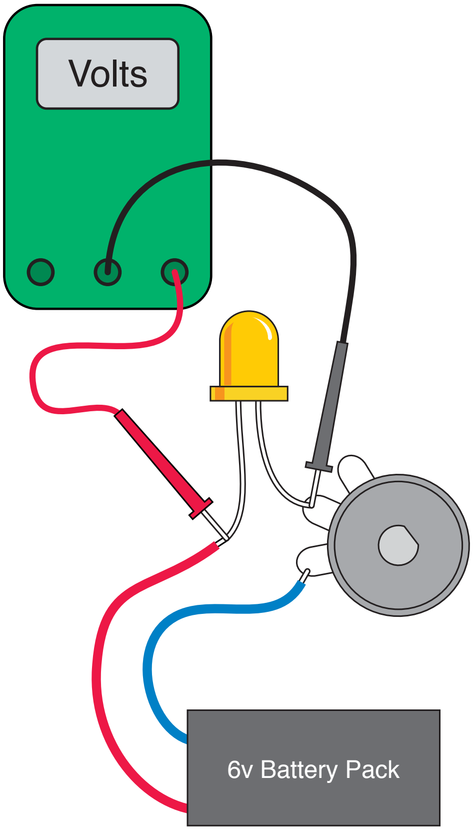


Figure 1-56. *The meter shows how much voltage the LED takes.*

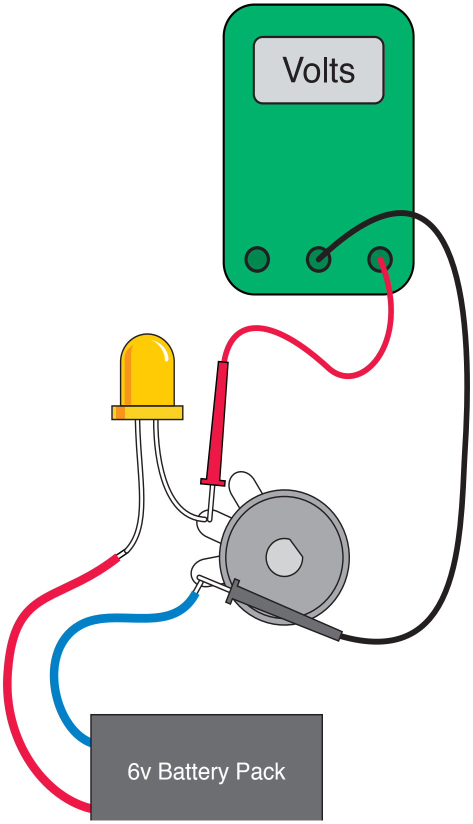

Figure 1-57. *The meter shows how much voltage the potentiometer takes.*

Checking the Flow

Now I want you to make a different measurement. I want you to measure the flow, or current, in the circuit, using your meter set to mA (milliamps). Remember, to measure current:

- You can only measure current when it passes *through* the meter.
- You have to insert your meter into the circuit.
- Too much current will blow the fuse inside your meter.

Make sure you set your meter to measure mA, not volts, before you try this. Some meters require you to move one of your leads to a different socket on the meter, to measure mA. See Figures 1-58 through 1-61.

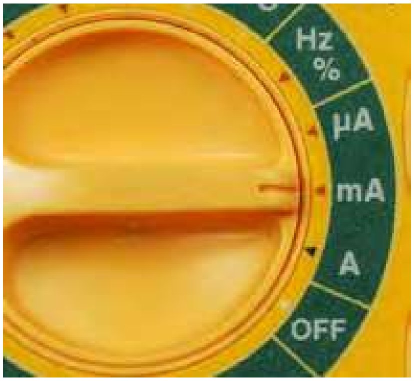

Figure 1-58. *Any meter will blow its internal fuse if you try to make it measure too high an amperage. In our circuit, this is not a risk as long as you keep the potentiometer in the middle of its range. Choose "mA" for milliamps and remember that the meter displays numbers that mean thousandths of an amp.*

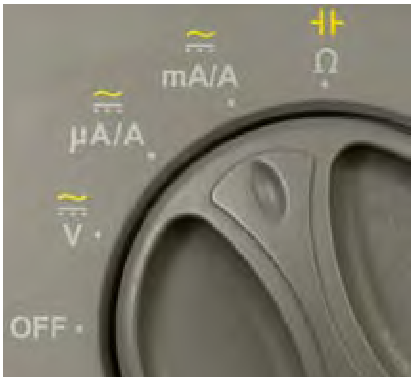

Figure 1-59

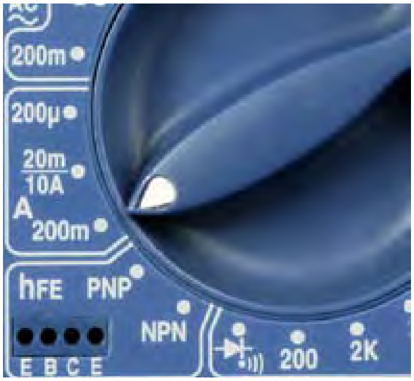

Figure 1-60

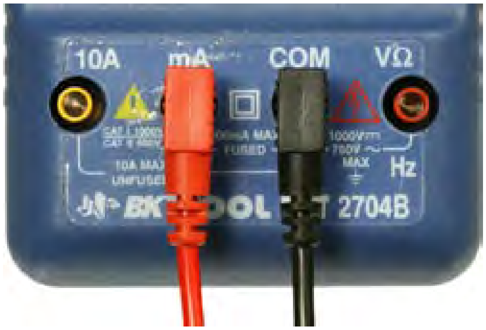

Figure 1-61. *A manual meter such as the one here may require you to shift the red lead to a different socket, to measure milliamps. Most modern meters don't require this until you are measuring higher currents.*

Insert your meter into the circuit, as shown in Figure 1-62. Don't turn the potentiometer more than halfway up. The resistance in the potentiometer will protect your meter, as well as the LED. If the meter gets too much current, you'll find yourself replacing its internal fuse.

As you adjust the potentiometer up and down a little, you should find that the varying resistance in the circuit changes the flow of current—the amperage. This is why the LED burned out in the previous experiment: too much current made it hot, and the heat melts it inside, just like the fuse in the previous experiment. *A higher resistance limits the flow of current, or amperage*.

Now insert the meter in another part of the circuit, as shown in Figure 1-63. As you turn the potentiometer up and down, you should get exactly the same results as with the configuration in Figure 1-64. This is because the current is the same at all points in a similar circuit. *It has to be, because the flow of electrons has no place else to go*.

It's time now to nail this down with some numbers. Here's one last thing to try. Set aside the LED and substitute a 1KΩ resistor, as shown in Figure 1-64. The total resistance in the circuit is now 1KΩ plus whatever the resistance the potentiometer provides, depending how you set it. (The meter also has some resistance, but it's so low, we can ignore it.)

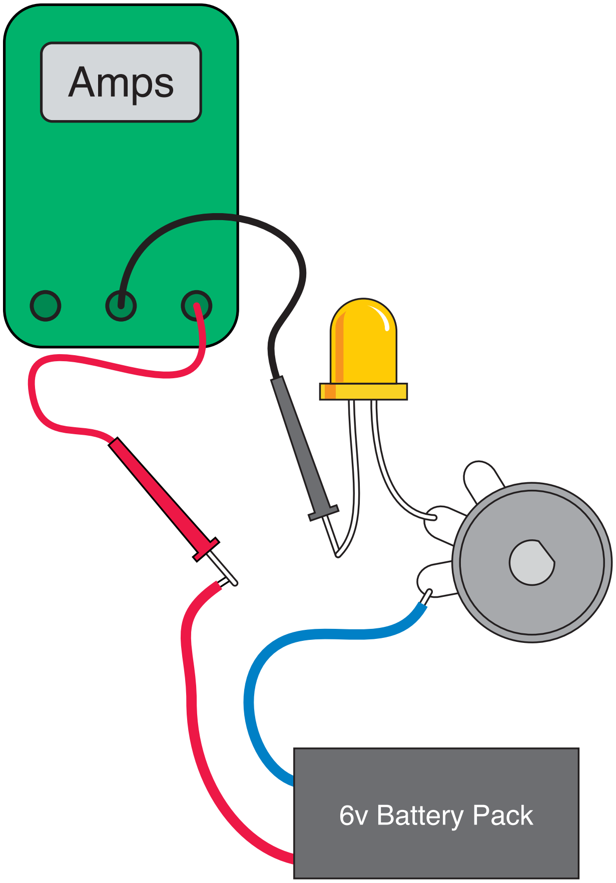

Figure 1-62. *To measure amps, as illustrated here and in Figure 1-63, the current has to pass through the meter. When you increase the resistance, you restrict the current flow, and the lower flow makes the LED glow less brightly.*

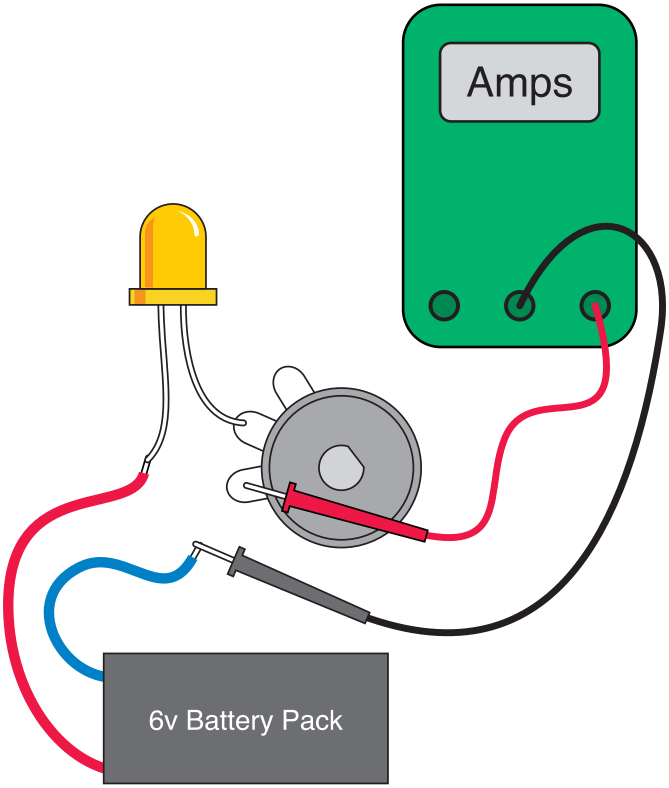

Figure 1-63

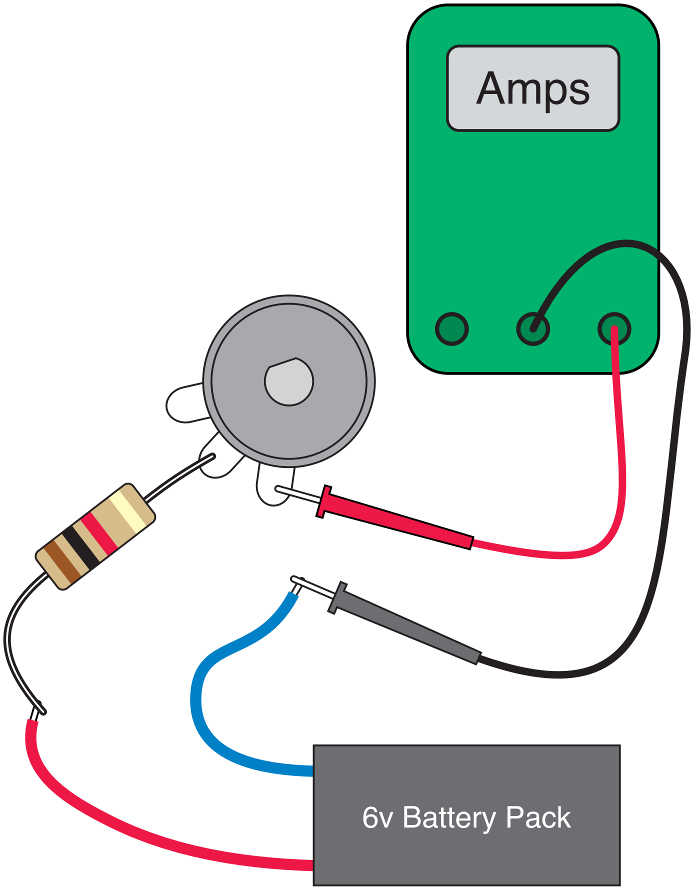

Figure 1-64. *If you substitute a resistor instead of the LED, you can confirm that the current flowing through the circuit varies with the total resistance in the circuit, if the voltage stays the same.*

Turn the potentiometer all the way counterclockwise, and you have a total of 3K resistance in the circuit. Your meter should show about 2 mA flowing. Now turn the potentiometer halfway, and you have about 2K total resistance. You should see about 3 mA flowing. Turn the potentiometer all the way clockwise, so there's a total of 1K, and you should see 6 mA flowing. You may notice that if we multiply the resistance by the amperage, we get 6 each time—which just happens to be the voltage being applied to the circuit. See the following table.

Total resistance	**Current**	**Voltage**
(KΩ)	(mA)	(Volts)
3	2	6
2	3	6
1	6	6

In fact, we could say:

voltage = kilohms × milliamps

But wait a minute: 1K is 1,000 ohms, and 1mA is 1/1,000 of an amp. Therefore, our formula should really look like this:

voltage = (ohms × 1,000) × (amps/1,000)

The two factors of 1,000 cancel out, so we get this:

volts = ohms × amps

This is known as Ohm's Law. See the section, "Fundamentals: Ohm's Law," on the following page.

FUNDAMENTALS

Series and parallel

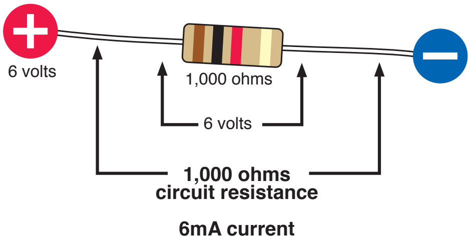
Before we go any further, you should know how resistance in a circuit increases when you put resistors in series or in parallel. Figures 1-65 through 1-67 illustrate this. Remember:

- Resistors in series are oriented so that one follows the other.
- Resistors in parallel are oriented side by side.

When you put two equal-valued resistors in series, you double the total resistance, because electricity has to pass through two barriers in succession.

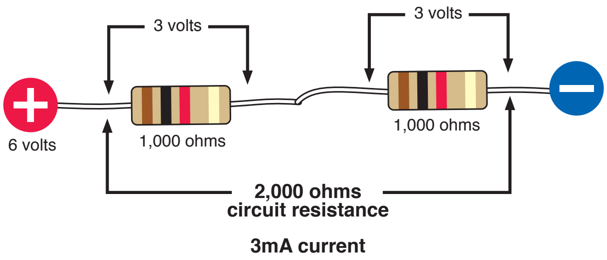
When you put two equal-valued resistors in parallel, you divide the total resistance by two, because you're giving the electricity two paths which it can take, instead of one.

In reality we don't normally need to put resistors in parallel, but we often put other types of components in parallel. Lightbulbs in your house, for instance, are all wired that way. So, it's useful to understand that resistance in a circuit goes down if you keep adding components in parallel.



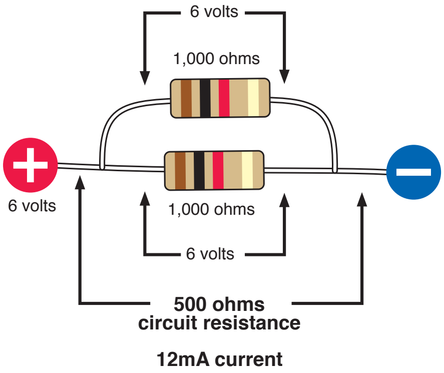
6 volts
1,000 ohms
6 volts
1,000 ohms
circuit resistance
6mA current

Figure 1-65. *One resistor takes the entire voltage, and according to Ohm's Law, it draws v/R = 6/1,000 = 0.006 amps = 6mA of current.*



3 volts
3 volts
6 volts
1,000 ohms
1,000 ohms
2,000 ohms
circuit resistance
3mA current

Figure 1-66. *When two resistors are in series, the electricity has to pass through one to reach the other, and therefore each of them takes half the voltage. Total resistance is now 2,000 ohms, and according to Ohm's Law, the circuit draws v/R = 6/2,000 = 0.003 amps = 3mA of current.*



6 volts
1,000 ohms
6 volts
1,000 ohms
6 volts
500 ohms
circuit resistance
12mA current

Figure 1-67. *When two resistors are in parallel, each is exposed to the full voltage, so each of them takes 6 volts. The electricity can now flow through both at once, so the total resistance of the circuit is half as much as before. According to Ohm's Law, the circuit draws v/R = 6/500 = 0.012 amps = 12mA of current.*

FUNDAMENTALS

Ohm's Law

For reasons I'll explain in a moment, amps are normally abbreviated with the letter I. V stands for volts and R stands for resistance in ohms (because the omega symbol, Ω, is not easily generated from most keyboards). Using these symbols, you can write Ohm's Law in three different ways:

$V = I \times R$

$I = V/R$

$R = V/I$

Remember, V is a *difference* in voltage between two points in a simple circuit, R is the resistance in ohms *between* the same two points, and I is the current in amps flowing *through* the circuit between the two points.

Letter I is used because originally current was measured by its *inductance*, meaning the ability to induce magnetic effects. It would be much less confusing to use A for amps, but unfortunately it's too late for that to happen.

Using Ohm's Law

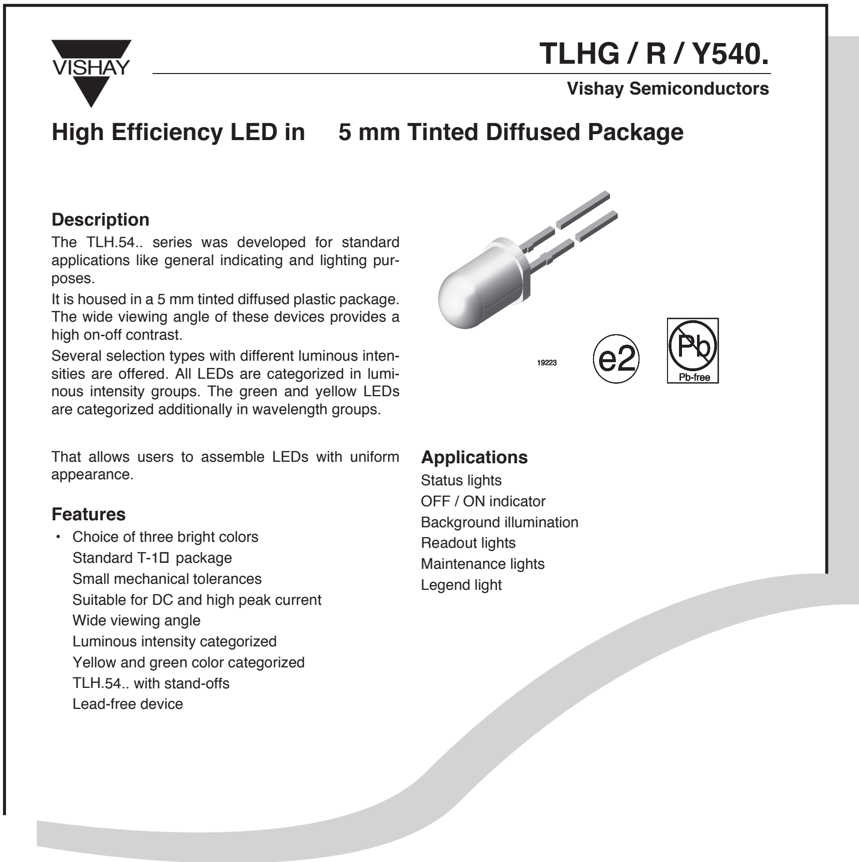
Ohm's Law is extremely useful. For example, it helps us to figure out whether a component can be used safely in a circuit. Instead of stressing the component until we burn it out, we can predict whether it will work.

For instance, the first time you turned the potentiometer, you didn't really know how far you could go until the LED burned out. Wouldn't it be useful to know precisely what resistance to put in series with an LED, to protect it adequately while providing as much light as possible?

How to Read a Data Sheet

Like most information, the answer to this question is available online.

Here's how you find a manufacturer's data sheet (Figure 1-68). First, find the component that you're interested in from a mail-order source. Next, Google the part number and manufacturer's name. Usually the data sheet will pop up as the first hit. A source such as *Mouser.com* makes it even easier by giving you a direct link to manufacturers' data sheets for many products.



VISHAY

TLHG / R / Y540.

Vishay Semiconductors

High Efficiency LED in 5 mm Tinted Diffused Package

Description

The TLH.54.. series was developed for standard applications like general indicating and lighting purposes.

It is housed in a 5 mm tinted diffused plastic package. The wide viewing angle of these devices provides a high on-off contrast.

Several selection types with different luminous intensities are offered. All LEDs are categorized in luminous intensity groups. The green and yellow LEDs are categorized additionally in wavelength groups.

That allows users to assemble LEDs with uniform appearance.

Features

- Choice of three bright colors
- Standard T-1□ package
- Small mechanical tolerances
- Suitable for DC and high peak current
- Wide viewing angle
- Luminous intensity categorized
- Yellow and green color categorized
- TLH.54.. with stand-offs
- Lead-free device

Applications

Status lights
OFF / ON indicator
Background illumination
Readout lights
Maintenance lights
Legend light

Figure 1-68. *The beginning of a typical data sheet, which includes all relevant specifications for the product, freely available online.*

BACKGROUND

How much voltage does a wire consume?

Normally, we can ignore the resistance in electric wires, such as the little leads of wire that stick out of resistors, because it's trivial. However, if you try to force large amounts of current through long lengths of thin wire, the resistance of the wire can become important.

How important? Once again, we can use Ohm's Law to find out.

Suppose that a very long piece of wire has a resistance of 0.2Ω. And we want to run 15 amps through it. How much voltage will the wire steal from the circuit, because of its resistance?

Once again, you begin by writing down what you know:

$R = 0.2$

$I = 15$

We want to know V, the potential difference, for the wire, so we use the version of Ohm's Law that places V on the left side:

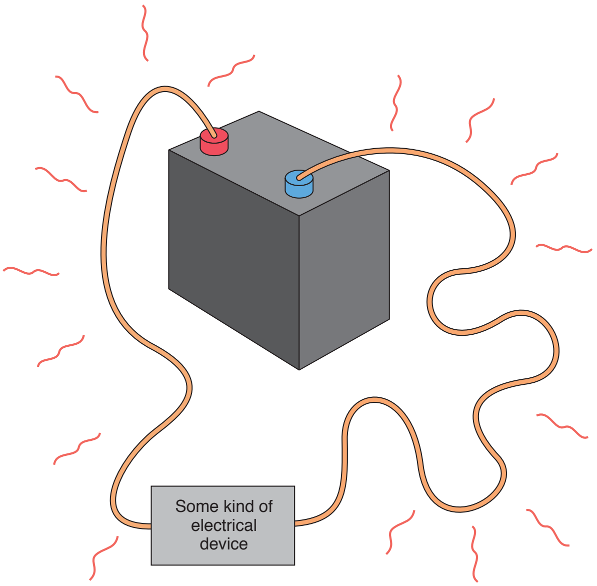
$V = I \times R$

Now plug in the values:

$V = 15 \times 0.2 = 3$ volts

Three volts is not a big deal if you have a high-voltage power supply, but if you are using a 12-volt car battery, this length of wire will take one-quarter of the available voltage.

Now you know why the wiring in automobiles is relatively thick—to reduce its resistance well below 0.2Ω. See Figure 1-69.



Some kind of electrical device

Figure 1-69. *When a 12-volt car battery runs some kind of electrical device through a long piece of thin wire, the resistance of the wire steals some of the voltage and dissipates it as heat.*

BACKGROUND

The origins of wattage

James Watt (Figure 1-70) is known as the inventor of the steam engine. Born in 1736 in Scotland, he set up a small workshop in the University of Glasgow, where he struggled to perfect an efficient design for using steam to move a piston in a cylinder. Financial problems and the primitive state of the art of metal working delayed practical applications until 1776.

Despite difficulties in obtaining patents (which could only be granted by an act of parliament in those times), Watt and his business partner eventually made a lot of money from his innovations. Although he predated the pioneers in electricity, in 1889 (70 years after his death), his name was assigned to the basic unit of electric power that can be defined by multiplying amperes by volts. See the Fundamentals section, "Watt Basics," on page 31.

Figure 1-70. *James Watt's development of steam power enabled the industrial revolution. After his death, he was honored by having his name applied to the basic unit of power in electricity.*

Here's an example. Suppose I want a red LED, such as the Vishay part TLHR5400, which has become such a common item that I can buy them individually for 9 cents apiece. I click the link to the data sheet maintained by the manufacturer, Vishay Semiconductor. Almost immediately I have a PDF page on my screen. This data sheet is for TLHR, TLHG, and TLHY types of LED, which are red, green, and yellow respectively, as suggested by the R, G, and Y in the product codes. I scroll down and look at the "Optical and Electrical Characteristics" section. It tells me that under conditions of drawing a current of 20 mA, the LED will enjoy a "Typ," meaning, typical, "forward voltage" of 2 volts. The "Max," meaning maximum, is 3 volts.

Let's look at one other data sheet, as not all of them are written the same way. I'll choose a different LED, the Kingbright part WP7113SGC. Click on the link to the manufacturer's site, and I find on the second page of the data sheet a typical forward voltage of 2.2, maximum 2.5, and a maximum forward current of 25 mA. I also find some additional information: a maximum reverse voltage of 5 and maximum reverse current of 10 uA (that's microamps, which are 1,000 times smaller than milliamps). This tells us that you should avoid applying excessive voltage to the LED the wrong way around. If you exceed the reverse voltage, you risk burning out the LED. Always observe polarity!

Kingbright also warns us how much heat the LED can stand: 260° C (500° F) for a few seconds. This is useful information, as we'll be putting aside our alligator clips and using hot molten solder to connect electrical parts in the near future. Because we have already destroyed a battery, a fuse, and an LED in just four experiments, maybe you won't be surprised when I tell you that we will destroy at least a couple more components as we test their limits with a soldering iron.

Anyway, now we know what an LED wants, we can figure out how to supply it. If you have any difficulties dealing with decimals, check the Fundamentals section "Decimals," on the next page, before continuing.

How Big a Resistor Does an LED Need?

Suppose that we're use the Vishay LED. Remember its requirements from the data sheet? Maximum of 3 volts, and a safe current of 20mA.

I'm going to limit it to 2.5 volts, to be on the safe side. We have 6 volts of battery power. Subtract 2.5 from 6 and we get 3.5. So we need a resistor that will take 3.5 volts from the circuit, leaving 2.5 for the LED.

The current flow is the same at all places in a simple circuit. If we want a maximum of 20mA to flow through the LED, the same amount of current will be flowing through the resistor.

Now we can write down what we know about the resistor in the circuit. Note that we have to convert all units to volts, amps, and ohms, so that 20mA should be written as 0.02 amps:

V = 3.5 (the potential drop across the resistor)
I = 0.02 (the current flowing through the resistor)

We want to know R, the resistance. So, we use the version of Ohm's Law that puts R on the left side:

$$R = V/I$$

Now plug in the values:

$$R = 3.5/0.02$$

Run this through your pocket calculator if you find decimals confusing. The answer is:

$$R = 175\Omega$$

It so happens that 175Ω isn't a standard value. You may have to settle for 180 or 220Ω, but that's close enough.

Evidently the 470Ω resistor that you used in Experiment 3 was a very conservative choice. I suggested it because I said originally that you could use any LED at all. I figured that no matter which one you picked, it should be safe with 470Ω to protect it.

Cleanup and Recycling

The dead LED can be thrown away. Everything else is reusable.

FUNDAMENTALS

Decimals

Legendary British politician Sir Winston Churchill is famous for complaining about "those damned dots." He was referring to decimal points. Because Churchill was Chancellor of the Exchequer at the time, and thus in charge of all government expenditures, his difficulty with decimals was a bit of a problem. Still, he muddled through in time-honored British fashion, and so can you.

You can also use a pocket calculator—or follow two basic rules.

Doing multiplication: combine the zeros

Suppose you need to multiply 0.04 by 0.005:

1. Count the total number of zeros following both of the decimal points. In this case, three zeros.
2. Multiply the numbers which follow the zeros. In this case, $4 \times 5 = 20$.
3. Write down the result as 0 followed by a decimal point, followed by the number of zeros, followed by the multiplication result. Like this: 0.00020, which is the same as 0.0002.

Doing division: cancel the zeros

Suppose you need to divide 0.006 by 0.0002:

1. Shift the decimal points to the right, in both the numbers, by the same number of steps, until both the numbers are greater than 1. In this case, shift the point four steps in each number, so you get 60 divided by 2.
2. Do the division. The result in this case is 30.

THEORY

Doing the math on your tongue

I'm going to go back to the question I asked in the previous experiment: why didn't your tongue get hot?

Now that you know Ohm's Law, you can figure out the answer in numbers. Let's suppose the battery delivered its rated 9 volts, and your tongue had a resistance of 50K, which is 50,000 ohms. Write down what you know:

$V = 9$

$R = 50{,}000$

We want to know the current, I, so we use the version of Ohm's Law that puts this on the left:

$I = V/R$

Plug in the numbers:

$I = 9/50{,}000 = 0.00018$ amps

Move the decimal point three places to convert to milliamps:

$I = 0.18$ mA

That's a tiny current that will not produce much heat at 9 volts.

What about when you shorted out the battery? How much current made the wires get hot? Well, suppose the wires had a resistance of 0.1 ohms (probably it's less, but I'll start with 0.1 as a guess). Write down what we know:

$V = 1.5$

$R = 0.1$

Once again we're trying to find I, the current, so we use:

$I = V/R$

Plug in the numbers:

$I = 1.5/0.1 = 15$ amps

That's 100,000 times the current that may have passed through your tongue, which would have generated much more heat, even though the voltage was lower.

Could that tiny little battery really pump out 15 amps? Remember that the battery got hot, as well as the wire. This tells us that the electrons may have met some resistance inside the battery, as well as in the wire. (Otherwise, where else did the heat come from?) Normally we can forget about the internal resistance of a battery, because it's so low. But at high currents, it becomes a factor.

I was reluctant to short-circuit the battery through a meter, to try to measure the current. My meter will fry if the current is greater than 10A. However I did try putting other fuses into the circuit, to see whether they would blow. When I tried a 10A fuse, it did not melt. Therefore, for the brand of battery I used, I'm fairly sure that the current in the short circuit was under 10A, but I know it was over 3A, because the 3A fuse blew right away.

The internal resistance of the 1.5-volt battery prevented the current in the short circuit from getting too high. This is why I cautioned against using a larger battery (especially a car battery). Larger batteries have a much lower internal resistance, allowing dangerously high currents which generate explosive amounts of heat. A car battery is designed to deliver literally hundreds of amps when it turns a starter motor. That's quite enough current to melt wires and cause nasty burns. In fact, you can weld metal using a car battery.

Lithium batteries also have low internal resistance, making them very dangerous when they're shorted out. High current can be just as dangerous as high voltage.

FUNDAMENTALS

Watt basics

So far I haven't mentioned a unit that everyone is familiar with: watts.

A watt is a unit of work. Engineers have their own definition of work—they say that work is done when a person, an animal, or a machine pushes something to overcome mechanical resistance. Examples would be a steam engine pulling a train on a level track (overcoming friction and air resistance) or a person walking upstairs (overcoming the force of gravity).

When electrons push their way through a circuit, they are overcoming a kind of resistance, and so they are doing work, which can be measured in watts. The definition is easy:

watts = volts × amps

Or, using the symbols customarily assigned, these three formulas all mean the same thing:

$W = V \times I$

$V = W/I$

$I = W/V$

Watts can be preceded with an "m," for "milli," just like volts:

Number of watts	Usually expressed as	Abbreviated as
0.001 watts	1 milliwatt	1mW
0.01 watts	10 milliwatts	10 mW
0.1 watts	100 milliwatts	100 mW
1 watt	1,000 milliwatts	1W

Because power stations, solar installations, and wind farms deal with much larger numbers, you may also see references to kilowatts (using letter K) and megawatts (with a capital M, not to be confused with the lowercase m used to define milliwatts):

Number of watts	Usually expressed as	Abbreviated as
1,000 watts	1 kilowatt	1 KW
1,000,000 watts	1 megawatt	1 MW

Lightbulbs are calibrated in watts. So are stereo systems. The watt is named after James Watt, inventor of the steam engine. Incidentally, watts can be converted to horsepower, and vice versa.

THEORY

Power assessments

I mentioned earlier than resistors are commonly rated as being capable of dealing with 1/4 watt, 1/2 watt, 1 watt, and so on. I suggested that you should buy resistors of 1/4 watt or higher. How did I know this?

Go back to the LED circuit. Remember we wanted the resistor to drop the voltage by 3.5 volts, at a current of 20 mA. How many watts of power would this impose on the resistor?

Write down what you know:

$V = 3.5$ (the voltage drop imposed by the resistor)

$I = 20mA = 0.02$ amps (the current flowing through the resistor)

We want to know W, so we use this version of the formula:

$W = V \times I$

Plug in the values:

$W = 3.5 \times 0.02 = 0.07$ watts (the power being dissipated by the resistor)

Because 1/4 watt is 0.25 watts, obviously a 1/4 watt resistor will have about four times the necessary capacity. In fact you could have used a 1/8 watt resistor, but in future experiments we may need resistors that can handle 1/4 watt, and there's no penalty for using a resistor that is rated for more watts than will actually pass through it.

Experiment 5: Let's Make a Battery

Long ago, before web surfing, file sharing, or cell phones, kids were so horribly deprived that they tried to amuse themselves with kitchen-table experiments such as making a primitive battery by pushing a nail and a penny into a lemon. Hard to believe, perhaps, but true!

This is seriously old-school—but I want you to try it anyway, because anyone who wants to get a feel for electricity should see how easy it is to extract it from everyday objects around us. Plus, if you use enough lemons, you just *might* generate enough voltage to power an LED.

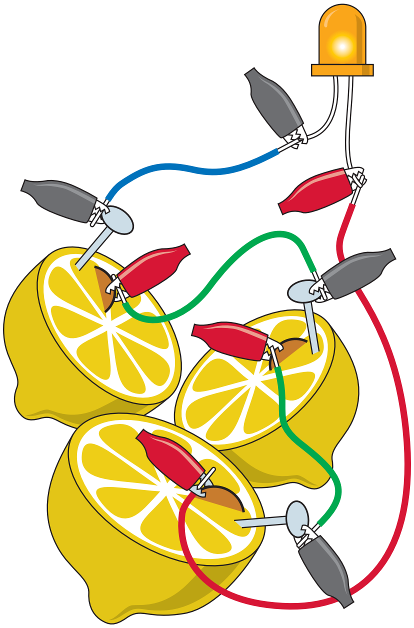


Figure 1-71. *A three-lemon battery. Don't be too disappointed if the LED fails to light up. The lemons have a high electrical resistance, so they can't deliver much current, especially through the relatively small surface area of the nails and the pennies. However, the lemon battery does generate voltage that you can measure with your meter.*

The basic components of a battery are two metal electrodes immersed in an electrolyte. I won't define these terms here (they're explained in the following section "Theory: The nature of electricity"). Right now all you need to know is that lemon juice will be your electrolyte, and copper and zinc will be your electrodes. A penny provides the necessary copper, as long as it is fairly new and shiny. Pennies aren't solid copper anymore, but they are still copper-plated, which is good enough.

To find some metallic zinc, you will have to make a trip to a hardware store, where you should ask for roofing nails. The nails are zinc-plated to prevent them from rusting. Small metal brackets or mending plates also are usually zinc-plated. They should have a slightly dull, silvery look. If they have a mirror-bright finish, they're more likely to be nickel-plated.

Cut a lemon in half, set your multimeter so that it can measure up to 2 volts DC, and hold one probe against a penny while you hold the other probe against a roofing nail (or other zinc-plated object). Now force the penny and the nail into the exposed juicy interior of the lemon, as close to each other as possible, but not actually touching. You should find that your meter detects between 0.8 volts and 1 volt.

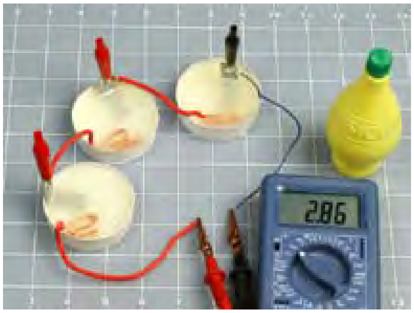

Figure 1-72. *Bottled lemon juice seems to work just as well as fresh lemon juice. I cut the bottoms off three paper cups, inserted a galvanized bracket into each, and used heavyweight stranded copper wire to make the positive electrodes*

You can experiment with different items and liquids to see which works best. Immersing your nail and penny in lemon juice that you have squeezed into a shot glass or egg cup may enhance the efficiency of your battery, although you'll have a harder time holding everything in place. Grapefruit juice and vinegar will work as substitutes for lemon juice.

To drive a typical LED, you need more than 1 volt. How to generate the extra electrical pressure? By putting batteries in series, of course. In other words, more lemons! (Or more shot glasses or egg cups.) You'll also need lengths of wire to connect multiple electrodes, and this may entail skipping ahead to Chapter 2, where I describe how to strip insulation from hookup wire. Figures 1-71 and 1-72 show the configuration.

If you set things up carefully, making sure than none of the electrodes are touching, you may be able to illuminate your LED with two or three lemon-juice batteries in series. (Some LEDs are more sensitive to very low currents than others. Later in the book I'll be talking about very-low-current LEDs. If you want your lemon-juice battery to have the best chance of working, you can search online for low-current LEDs and buy a couple.)

THEORY

The nature of electricity

To understand electricity, you have to start with some basic information about atoms. Each atom consists of a nucleus at the center, containing protons, which have a positive charge. The nucleus is surrounded by electrons, which carry a negative charge.

Breaking up the nucleus of an atom requires a lot of energy, and can also liberate a lot of energy—as happens in a nuclear explosion. But persuading a couple of electrons to leave an atom (or join an atom) takes very little energy. For instance, when zinc reacts chemically with an acid, it can liberate electrons. This is what happens at the zinc electrode of the chemical battery in Experiment 5.

The reaction soon stops, as electrons accumulate on the zinc electrode. They feel a mutual force of repulsion, yet they have nowhere to go. You can imagine them like a crowd of hostile people, each one wanting the others to leave, and refusing to allow new ones to join them, as shown in Figure 1-73.

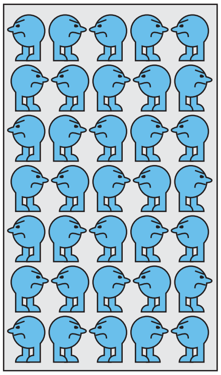

Figure 1-73. *Electrons on an electrode have a bad attitude known as mutual repulsion.*

Now consider what happens when a wire connects the zinc electrode, which has a surplus of electronics, to another electrode, made from a different material, that has a shortage of electrons. The electrons can pass through the wire very easily by jumping from one atom to the next, so they escape from the zinc electrode and run through the wire, propelled by their great desire to get away from each other. See Figure 1-74. This mutual force of propulsion is what creates an electrical current.

Now that the population of electrons on the zinc electrode has been reduced, the zinc-acid reaction can continue, replacing the missing electrodes with new ones—which promptly imitate their predecessors and try to get away from each other by running away down the wire. The process continues until the zinc-acid reaction grinds to a halt, usually because it creates a layer of a compound such as zinc oxide, which won't react with acid and prevents the acid from reacting with the zinc underneath. (This is why your zinc electrode may have looked sooty when you pulled it out of the acidic electrolyte.)

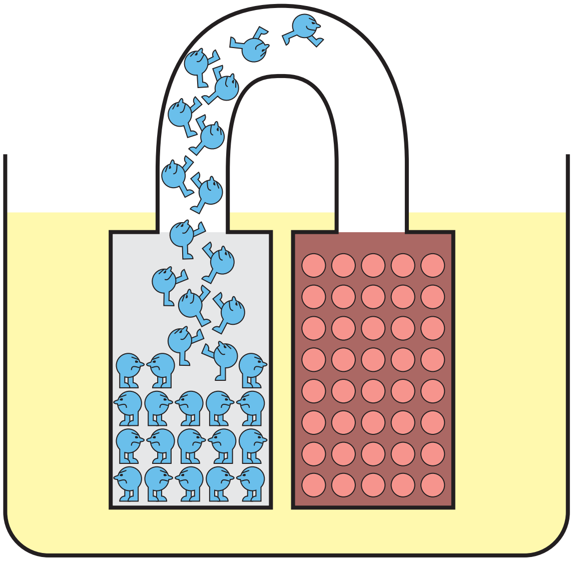

Figure 1-74. *As soon as we open up a pathway from a zinc electrode crowded with electrons to a copper electrode, which contains "holes" for the electrons, their mutual repulsion makes them try to escape from each other to their new home as quickly as possible.*

This description applies to a "primary battery," meaning one that is ready to generate electricity as soon as a connection between its terminals allows electrons to transfer from one electrode to the other. The amount of current that a primary battery can generate is determined by the speed at which chemical reactions inside the battery can liberate electrons. When the raw metal in the electrodes has all been used up in chemical reactions, the battery can't generate any more electricity and is dead. It cannot easily be recharged, because the chemical reactions are not easily reversible, and the electrodes may have oxidized.

In a rechargeable battery, also known as a secondary battery, a smarter choice of electrodes and electrolyte does allow the chemical reactions to be reversed.

How much current is being generated in your lemon battery? Set your meter to measure milliamps, and connect it between the nail and the penny. I measured about 2mA, but got 10mA when I used some #10 stranded copper wire instead of a penny and a large mending plate instead of a roofing nail, immersed in a cup of grapefruit juice. When a larger surface area of metal makes better contact with the electrolyte, you get a greater flow of current. (Don't ever connect your meter to measure amps directly between the terminals of a real battery. The current will be too high, and can blow the fuse inside your meter.)

What's the internal resistance of your lemon? Put aside the copper and zinc electrodes and insert your nickel-plated meter probes into the juice. I got a reading of around 30K when both probes were in the same segment of the lemon, but 40K or higher if the probes were in different segments. Is the resistance lower when you test liquid in a cup?

Here are a couple more questions that you may wish to investigate. For how long will your lemon battery generate electricity? And why do you think your zinc-plated electrode becomes discolored after it has been used for a while?

Electricity is generated in a battery by an exchange of ions, or free electrons, between metals. If you want to know more about this, check the section "Theory: The nature of electricity" on the previous page.

Cleanup and Recycling

The hardware that you immersed in lemons or lemon juice may be discolored, but it is reusable. Whether you eat the lemons is up to you.

BACKGROUND

Positive and negative

If electricity is a flow of electrons, which have a negative charge, why do people talk as if electricity flows from the positive terminal to the negative terminal of a battery?

The answer lies in a fundamental embarrassment in the history of research into electricity. For various reasons, when Benjamin Franklin was trying to understand the nature of electric current by studying phenomena such as lightning during thunderstorms, he believed he observed a flow of "electrical fluid" from positive to negative. He proposed this concept in 1747.

In fact, Franklin had made an unfortunate error that remained uncorrected until after physicist J. J. Thomson announced his discovery of the electron in 1897, 150 years later. Electricity actually flows from an area of greater negative charge, to some other location that is "less negative"—that is, "more positive." In other words, electricity is a flow of negatively charged particles. In a battery, they originate from the negative terminal and flow to the positive terminal.

You might think that when this fact was established, everyone should have discarded Franklin's idea of a flow from positive to negative. But when an electron moves through a wire, you can still think of an equal positive charge flowing in the opposite direction. When the electron leaves home, it takes a small negative charge with it; therefore, its home becomes a bit more positive. When the electron arrives at its destination, its negative charge makes the destination a bit less positive. This is pretty much what would happen if an imaginary positive particle traveled in the opposite direction. Moreover, all of the mathematics describing electrical behavior are still valid if you apply them to the imaginary flow of positive charges.

As a matter of tradition and convenience we still retain Ben Franklin's erroneous concept of flow from positive to negative, because it really makes no difference. In the symbols that represent components such as diodes and transistors, you will actually find arrows reminding you which way these components should be placed—and the arrows all point from positive to negative, even though that's not the way things really work at all! Ben Franklin would have been surprised to learn that although most lightning strikes occur when a negative charge in clouds discharges to neutralize a positive charge on the ground, some forms of lightning are actually a flow of electrons from the negatively charged surface of the earth, up to a positive charge in the clouds. That's right: someone who is "struck by lightning" may be hurt by *emitting* electrons rather than by receiving them, as shown in Figure 1-75.

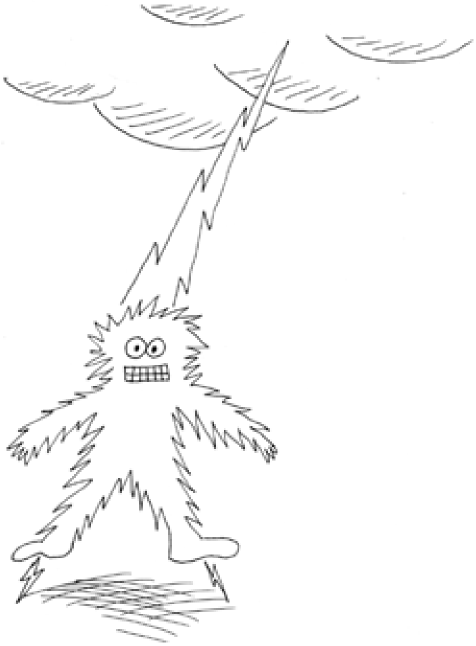

Figure 1-75. *In some weather conditions, the flow of electrons during a lightning strike can be from the ground, through your feet, out of the top of your head, and up to the clouds. Benjamin Franklin would have been surprised.*

THEORY

Basic measurements

Electrical potential is measured by adding up the charges on individual electrons. The basic unit is the *coulomb*, equal to the total charge on about 6,250,000,000,000,000,000 electrons.

If you know how many electrons pass through a piece of wire each second, this establishes the flow of electricity, which can be expressed in amperes. In fact 1 ampere can be defined as 1 coulomb per second. Thus:

1 ampere = 1 coulomb/second
= about 6.25 quintillion electrons/second

There's no way to "see" the number of electrons running through a conductor (Figure 1-76), but there are indirect ways of getting at this information. For instance, when an electron goes running through a wire, it creates a wave of electromagnetic force around it. This force can be measured, and we can calculate the amperage from that. The electric meter installed at your home by the utility company functions on this principle.

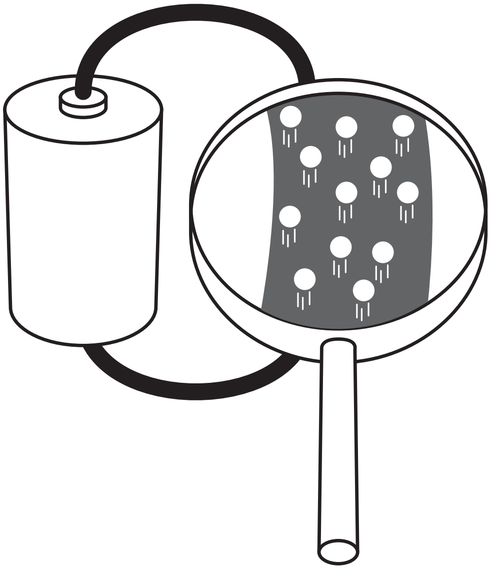

Figure 1-76. *If you could look inside an electric wire with a sufficiently powerful magnifying device, and the wire happened to be carrying 1 ampere of electron flow at the time, you might hope to see about 6.25 quintillion electrons speeding past each second.*

If electrons are just moving freely, they aren't doing any work. If you had a loop of wire of zero resistance, and you kick-started a flow of electrons somehow, they could just go buzzing around forever. (This is what happens inside a superconductor—almost.)

Under everyday conditions, even a copper wire has some resistance. The force that we need to push electrons through it is known as "voltage," and creates a flow that can create heat, as you saw when you shorted out a battery. (If the wire that you used had zero resistance, the electricity running through it would not have created any heat.) We can use the heat directly, as in an electric stove, or we can use the electrical energy in other ways—to run a motor, for instance. Either way, we are taking energy out of the electrons, to do some work.

One volt can be defined as the amount of pressure that you need to create a flow of 1 ampere, which does 1 watt of work. As previously defined, 1 watt = 1 volt × 1 ampere, but the definition actually originated the other way around:

1 volt = 1 watt/1 ampere

It's more meaningful this way, because a watt can be defined in nonelectrical terms. Just in case you're interested, we can work backward through the units of the metric system like this:

1 watt = 1 joule/second
1 joule = a force of 1 newton acting through 1 meter
1 newton = the force required to accelerate 1 kilogram by 1 meter per second, each second

On this basis, the electrical units can all be anchored with observations of mass, time, and the charge on electrons.

Practically Speaking

For practical purposes, an intuitive understanding of electricity can be more useful than the theory. Personally I like the water analogies that have been used for decades in guides to electricity. Figure 1-77 shows a tall tank half full of water, with a hole punched in it near the bottom. Think of the tank as being like a battery. The height of the water is comparable to voltage. The volume of flow through the hole, per second, is comparable to amperage. The smallness of the hole is comparable to resistance. See Figure 1-79 on the next page.

Where's the wattage in this picture? Suppose we place a little water wheel where it is hit by the flow from the hole. We can attach some machinery to the water wheel. Now the flow is doing some work. (Remember, wattage is a measurement of work.)

Maybe this looks as if we're getting something for nothing, extracting work from the water wheel without putting any energy back into the system. But remember, the water level in the tank is falling. As soon as I include some helpers hauling the waste water back up to the top of the tank (in Figure 1-78), you see that we have to put work in to get work out.

Similarly, a battery may seem to be giving power out without taking anything in, but the chemical reactions inside it are changing pure metals into metallic compounds, and the power we get out of a battery is enabled by this change of state. If it's a rechargeable battery, we have to push power back into it to reverse the chemical reactions.

Going back to the tank of water, suppose we can't get enough power out of it to turn the wheel. One answer could be to add more water. The height of the water will create more force. This would be the same as putting two batteries end to end, positive to negative, in series, to double the voltage. See Figure 1-80. As long as the resistance in the circuit remains the same, greater voltage will create more amperage, because amperage = voltage/resistance.

What if we want to run two wheels instead of one? We can punch a second hole in the tank, and the force (voltage) will be the same at each of them. However, the water level in the tank will drop twice as fast. Really, we'd do better to build a second tank, and here again the analogy with a battery is good. If you wire two batteries side by side, in parallel, you get the same voltage, but for twice as long. The two batteries may also be able to deliver more current than if you just used one. See Figure 1-81.

Summing up:

- Two batteries in series deliver twice the voltage.
- Two batteries in parallel can deliver twice the current.

All right, that's more than enough theory for now. In the next chapter, we'll continue with some experiments that will build on the foundations of knowledge about electricity, to take us gradually toward gadgets that can be fun and useful.

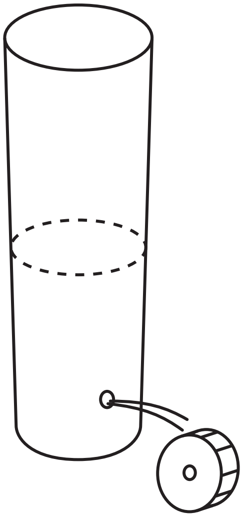

Figure 1-77. *If you want to get work out of a system...*

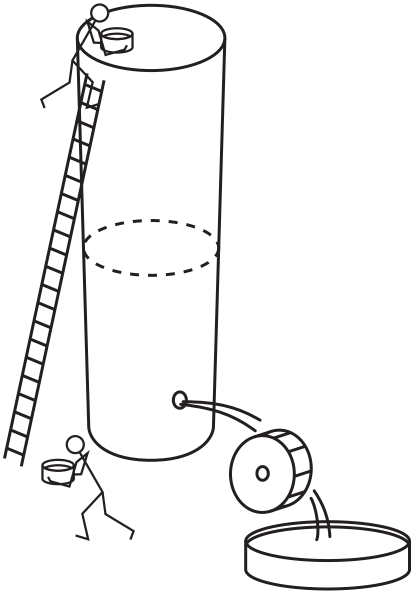

Figure 1-78. *. . . somehow or other you have to put work back into it.*

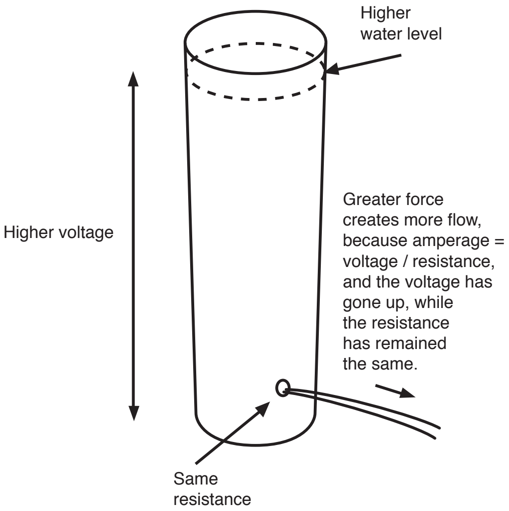

Higher water level
Higher voltage
Greater force creates more flow, because amperage = voltage / resistance, and the voltage has gone up, while the resistance has remained the same.
Same resistance

1.5 volts
for twice as long

Figure 1-81. *Two equal batteries that are wired in parallel will deliver the same voltage for twice as long as one.*

Switching Basics and More

2

The concept of switching is fundamental in electronics, and I'm not just talking about power switches. By "switching," I mean using one flow of electricity to switch, or control, another. This is such an important principle that no digital device can exist without it.

Today, switching is mostly done with semiconductors. Before I deal with them, I'll back up and illustrate the concept by introducing you to relays, which are easier to understand, because you can see what's going on inside them. And before I get to relays, I'll deal with everyday on/off switches, which may seem very simple—but we have to nail down the basics.

Also in this chapter, I'll deal with capacitance, because capacitance and resistance are fundamental to electronic circuits. By the end of the chapter, you should have a basic grounding in electronics and be able to build the noise-making section of a simple intrusion alarm. This will be your first circuit that does something genuinely useful!

IN THIS CHAPTER

Shopping List: Experiments 6 Through 11
Experiment 6: Very Simple Switching
Experiment 7: Relay-Driven LEDs
Experiment 8: A Relay Oscillator
Experiment 9: Time and Capacitors
Experiment 10: Transistor Switching
Experiment 11: A Modular Project

Shopping List: Experiments 6 Through 11

As in the previous shopping list, you should visit the various online suppliers for availability and pricing of components and devices. Manufacturers seldom sell small numbers of parts directly. Check the appendix for a complete list of URLs for all the companies mentioned here.

Devices

- Power supply/universal AC adapter, 3 to 12 volts at 1A (1,000 mA). See Figure 2-1. Part number 273-029 from RadioShack, part PH-62092 by Philips, or similar.
- Breadboard suitable for integrated circuits. Quantity: 1. See Figures 2-2 and 2-3. Part 276-002 from RadioShack, model 383-X1000 made by PSP, part 923252-I by 3M, or similar. A breadboard that has screw terminals mounted beside it will be a little easier to use but more expensive than one that does not have terminals.

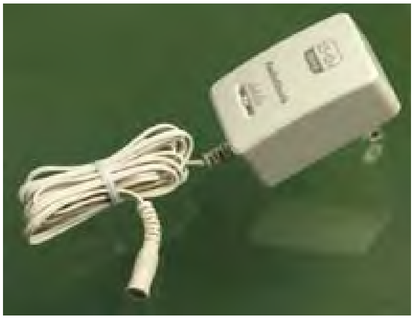

Figure 2-1. *This AC adapter delivers DC from 3 to 12 volts, and is ideal for electronics projects.*

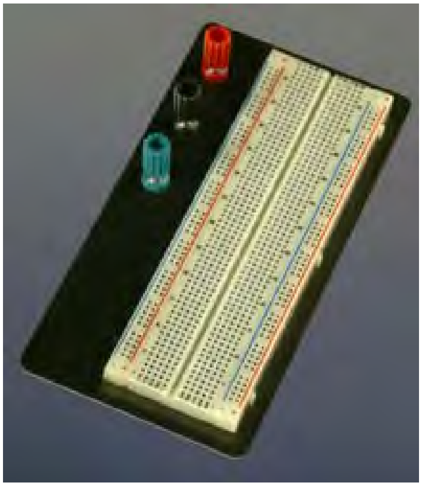

Figure 2-2. *This "breadboard" for quickly constructing electronic circuits has a metal base, and screw terminals for attaching wires from a power supply.*

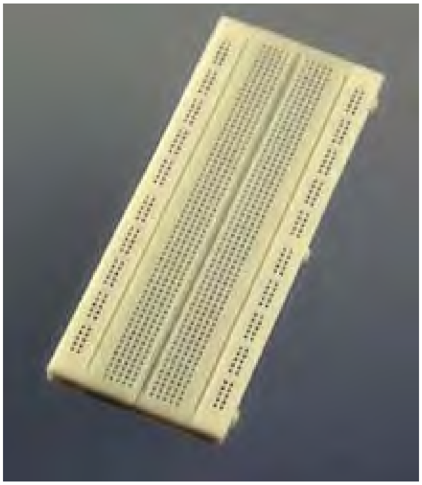

Figure 2-3. *A breadboard without screw terminals is almost as convenient, and is cheaper.*

Tools

Wire strippers

Ideal model 45-121 wire strippers for 16- to 26-gauge wire, or similar. See Figure 2-4. (The "gauge" of the wire tells you how thick it is. A higher gauge means a thinner wire. In this book, we will mainly be using thin wire of 20- to 24-gauge.)

You may also consider the Kronus Automatic Wire Strippers, part 64-2981 from RadioShack, or GB Automatic Wire Strippers, part SE-92 from Amazon.com. See Figure 2-5.

The Kronus and GB wire strippers are functionally identical. The advantage of their design is that it enables you to strip insulation from a wire with one hand. But they do not work well on really thin wire.

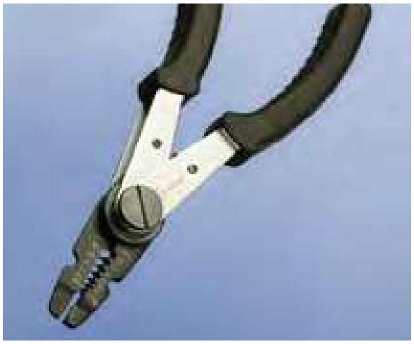

Figure 2-4. *To use these wire strippers, insert a piece of insulated wire in the appropriate-sized hole between the jaws, grip the handles, and pull a section of insulation away. See page 45.*

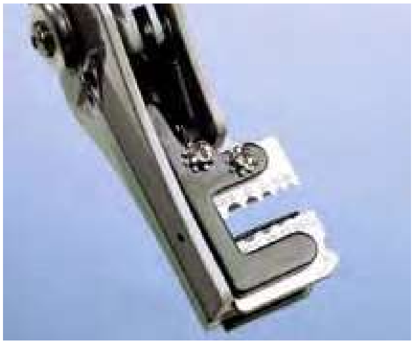

Figure 2-5. *These automatic wire strippers enable one-handed operation, but are not suitable for very small wire diameters. See page 44.*

Supplies

Hookup wire

Solid-conductor, 22-gauge, minimum 25 feet of each color. See Figure 2-6. Part 278-1222 from RadioShack, catalog item 9948T17 from McMaster-Carr, or check eBay for deals.

It's easy to buy the wrong kind of wire. You need solid-core wire, which has a single conductor inside the plastic insulation, not stranded, which has multiple, thinner conductors. See Figures 2-7 and 2-8. You're going to be pushing wires into little holes in a "breadboard," and stranded wire won't let you do this. You will also have problems if you buy wire thicker than 22-gauge. Remember: the lower the gauge number, the thicker the wire.

For a little extra money, you can buy an assortment of precut sections of wire, with ends stripped and ready for use. Try catalog item JW-140 (jumper wire assortment) from All Electronics or search eBay for "breadboard wire." See Figure 2-9.

Patch cords

Patch cords are not strictly necessary but very convenient. You don't want audio or video patch cords, which have a plug on each end; you want wires with alligator clips on each end, also sometimes referred to as "test leads." Try catalog item 461-1176-ND from Digi-Key or catalog item MTL-10 from All Electronics. See Figure 2-10.

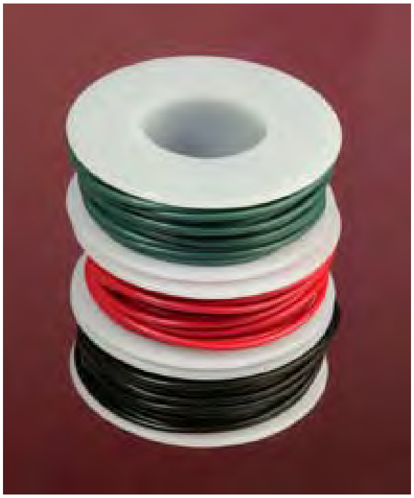

Figure 2-6. *Using hookup wire with different colors of plastic insulation will help you to distinguish one wire from another in your circuits.*

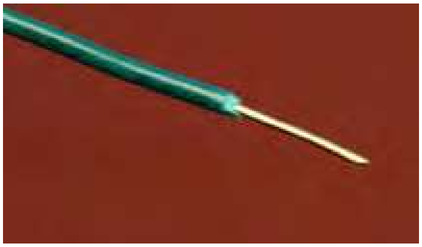

Figure 2-7. *Solid-conductor wire of 22 or 24 gauge is suitable for most of the experiments in this chapter.*

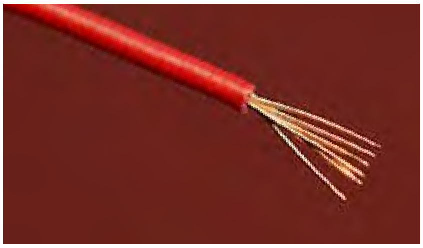

Figure 2-8. *Stranded is more flexible, but cannot be used easily with breadboards.*

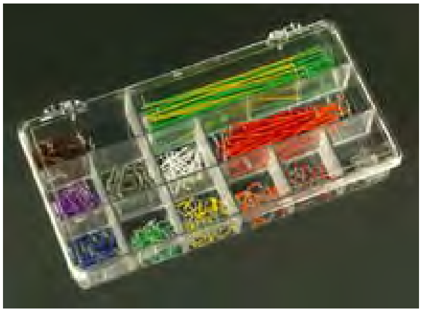

Figure 2-9. *Precut wires with stripped ends can save a lot of time and trouble—if you don't mind paying a little extra.*

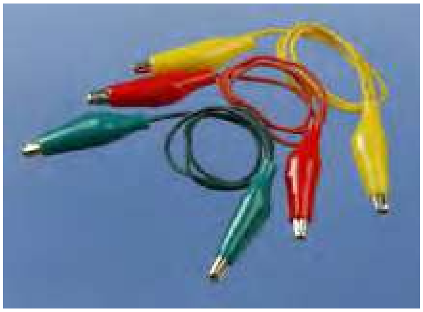

Figure 2-10. *Patch cords, sometimes known as test leads, consist of wires preattached to alligator clips. This is another of those little luxuries that reduces the hassle factor in hobby electronics.*

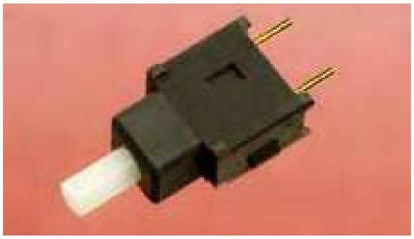

Figure 2-11. *The terminals protruding from this tiny pushbutton are spaced 0.2 inches apart, making it ideal for the "breadboard" that you'll be using.*

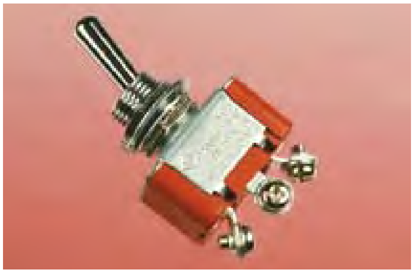

Figure 2-12. *This relatively large toggle switch made by NKK has screw terminals, which will reduce the inconvenience of attaching it to hookup wire.*

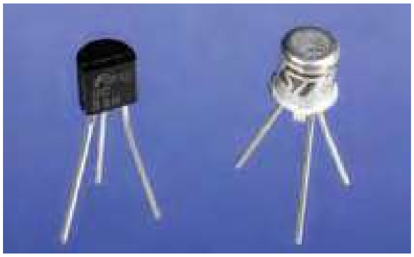

Figure 2-13. *Transistors are commonly sold either in little metal cans or sealed into little lumps of plastic. For our purposes, the packaging makes no difference.*

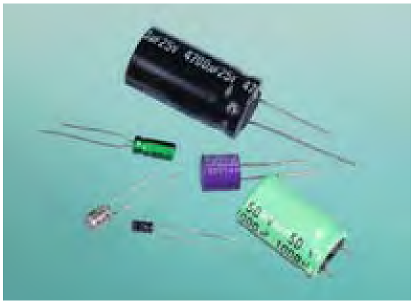

Figure 2-14. *An assortment of electrolytic capacitors.*

Components

Pushbutton

Momentary-on, SPST, sometimes referred to as OFF-(ON) or (ON)-OFF type. Must be PCB- or PC-mount, meaning is extremely small with thin spiky contacts on the bottom. Quantity: 1. See Figure 2-11.

Examples are part number AB11AP by NKK, part MPA103B04 by Alcoswitch, or part EP11SD1CBE by C&K. If you have a choice, buy the cheapest, as we're going to switch very low current.

Switches

Toggle switch, single-pole, double-throw (SPDT), sometimes referred to as ON-ON type. Quantity: 2. See Figure 2-12.

Model S302T-RO by NKK is ideal; it has screw terminals that will eliminate the need for alligator clips. Other options are catalog item MTS-4PC from All Electronics or part 275-603 from RadioShack.

We won't be switching large currents or high voltages, so the exact type of switch is unimportant. However, the terminals on larger-size switches are spaced wider apart, which makes them easier to deal with.

Relays

DPDT, nonlatching, 12v DC. Quantity: 2.

It's important to get the right kind of relay—one whose configuration matches the pictures I'll be using. Look for parts FTR-F1CA012V or FTR-F1CD012V by Fujitsu, G2RL-24-DC12 by Omron, or OMI-SH-212D by Tyco. Avoid substitutions.

Potentiometer

1 megohm linear potentiometer, Part number 271-211 from RadioShack, part number 24N-1M-15R-R from Jameco, or similar.

Transistors

NPN transistor, general-purpose, such as 2N2222 by STMicroelectronics, part PN2222 by Fairchild, or part 2N2222 from RadioShack. Quantity: 4. See Figure 2-13.

2N6027 programmable unijunction transistor manufactured by On Semiconductor or Motorola. Quantity: 4.

Capacitors

Electrolytic capacitors, assorted. Must be rated for a minimum of 25 volts and include at least one capacitor of 1,000 µF (microfarads). If you search on eBay, make sure you find *electrolytic* capacitors. If they're rated for higher voltages, that's OK, although they will be physically larger than you need. See Figure 2-14.

Ceramic capacitors, assorted. Make sure you get at least one rated at 0.0047 µF (which can also be written as 47 nF). See Figure 2-15.

Resistors

If you bought only a minimal selection for experiments 1 through 5, now's the time to buy a larger assortment, so that you won't be stuck needing the one value that you don't have. 1/4-watt minimum.

Loudspeaker

Any 8Ω, 1-inch miniature loudspeaker such as part 273-092 from RadioShack. See Figure 2-16.

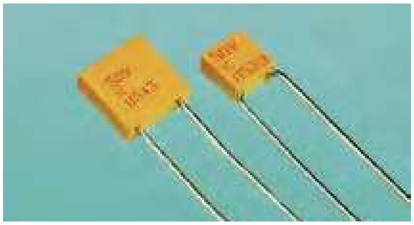

Figure 2-15. *Ceramic capacitors mostly look like this, although many of them are round or bead-shaped instead of square. The packaging shape is unimportant to us.*

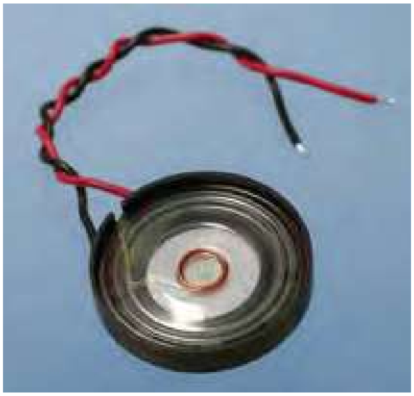

Figure 2-16. *This miniature loudspeaker, just over 1 inch in diameter, is useful for verifying audio output direct from transistor circuits.*

Experiment 6: Very Simple Switching

You will need:

- AA batteries. Quantity: 4.
- Battery carrier for 4 AA batteries. Quantity: 1.
- LED. Quantity: 1.
- Toggle switches, SPDT. Quantity: 2. See Figure 2-12.
- 220Ω or similar value resistor, 1/4-watt minimum. Quantity: 1.
- Alligator clips. Quantity: 8.
- Wire or patch cords. See Figure 2-10, shown previously.
- Wire cutters and wire strippers if you don't use patch cords. See Figure 2-4, shown previously.

In Experiment 3, you illuminated an LED by attaching a battery, and switched it off by removing the battery. For greater convenience our circuits should have proper switches to control power, and while I'm dealing with the general topic of switches, I'm going to explore all the varieties, using a circuit to suggest some possibilities.

Assemble the parts as shown in Figures 2-17 and 2-18. The long lead on the LED must connect with the resistor, because that is the more positive side of the circuit.

You'll notice that you have to include a couple lengths of wire. I suggest green wire to remind you that these sections are not connected directly to positive or to negative power. But you can use any color you like. You can also substitute patch cords, if you have them. However, learning to strip insulation from pieces of wire is a necessary skill, so let's deal with that now.

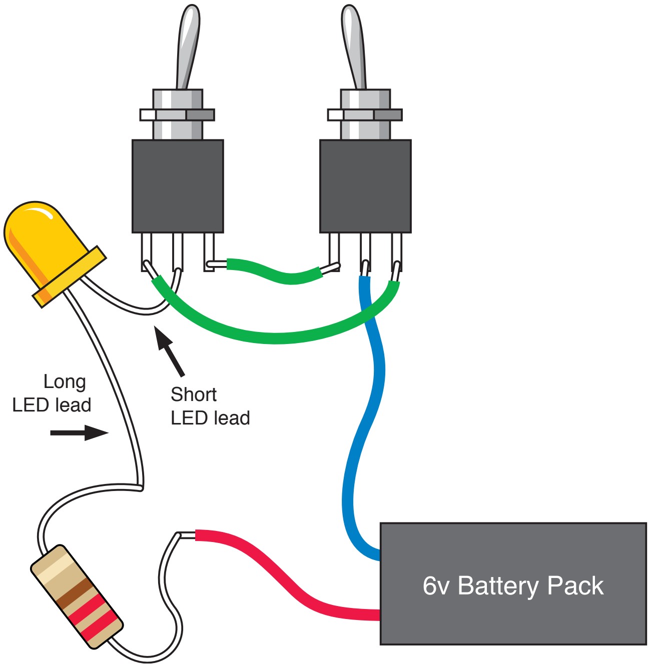

Figure 2-17. *If the LED is on, flipping either of the switches will turn it off. If the LED is off, either of the switches will turn it on. Use alligator clips to attach the wires to each other, and to the switches if your switches don't have screw terminals. Be careful that the clips don't touch each other.*

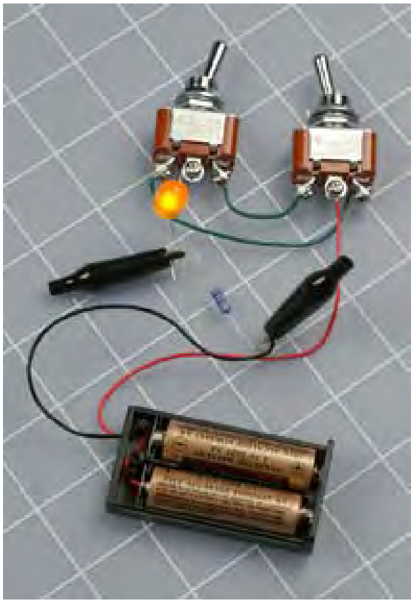

Figure 2-18. *Full-size toggle switches with screw terminals make it easy to hook up this simple circuit.*

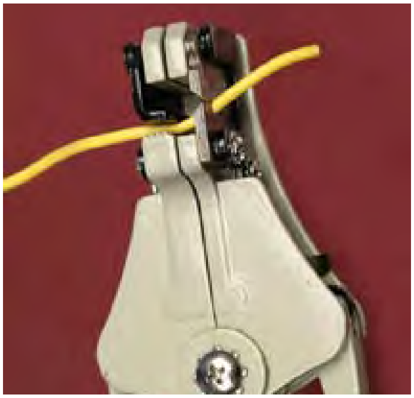

Figure 2-19. *Using automatic wire strippers, when you squeeze the handles the jaw on the left clamps the wire, the sharp grooves on the right bite into the insulation. Squeeze harder and the jaws pull away from each other, stripping the insulation from the wire.*

Tools

If automatic wire strippers (Figure 2-19) don't grip skinny 22-gauge wire very effectively, try the Ideal brand of wire strippers shown back in Figure 2-4, or use plain and simple wire cutters as shown in Figure 2-20. When using wire cutters, you hold the wire in one hand and apply the tool in your other hand, squeezing the handles with moderate pressure—just enough to bite into the insulation, but not so much that you chop the wire. Pull the wire down while you pull the cutters up, and with a little practice you can rip the insulation off to expose the end of the wire.

Macho hardware nerds may use their teeth to strip insulation from wires. When I was younger, I used to do this. I have two slightly chipped teeth to prove it. Really, it's better to use the right tool for the job.

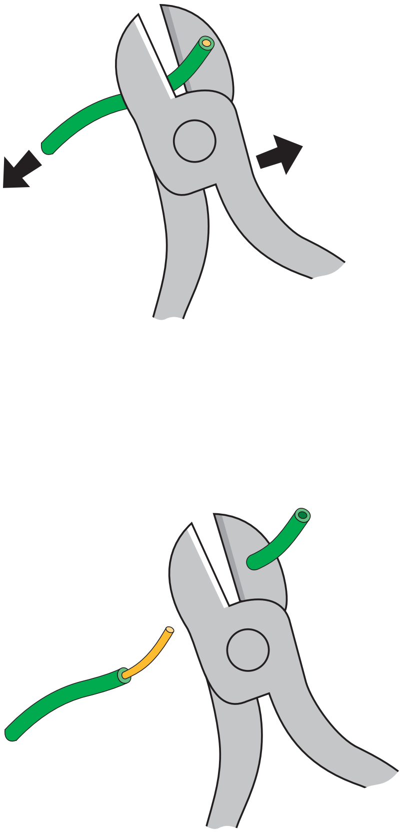

Figure 2-20. *To remove insulation from the end of a thin piece of wire, you can also use wire cutters. This takes a little practice.*

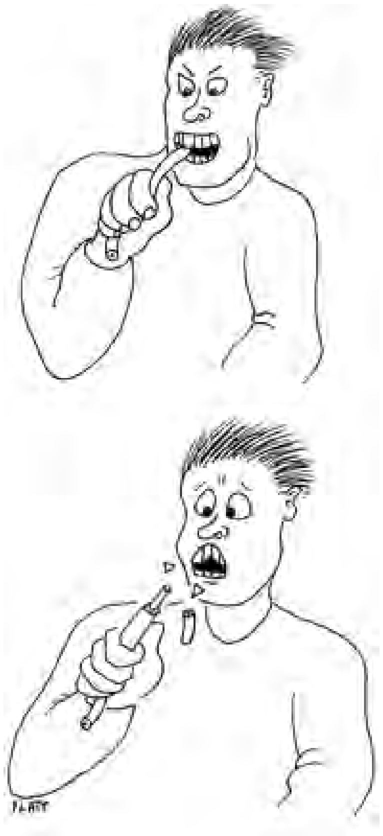

Figure 2-21. *Those who tend to misplace tools, and feel too impatient to search for them, may feel tempted to use their teeth to strip insulation from wire. This may not be such a good idea.*

Connection Problems

Depending on the size of toggle switches that you are using, you may have trouble fitting in all the alligator clips to hold the wires together. Miniature toggle switches, which are more common than the full-sized ones these days, can be especially troublesome (see Figure 2-22). Be patient: fairly soon we'll be using a breadboard, which will eliminate alligator clips almost completely.

Testing

Make sure that you connect the LED with its long wire toward the positive source of power (the resistor, in this case). Now flip either of the toggle switches. If the LED was on, it will go off, and if it was off, it will go on. Flip the other toggle switch, and it will have the same effect. If the LED does not go on at all, you've probably connected it the wrong way around. Another possibility is that two of your alligator clips may have shorted out the battery.

Assuming your two switches do work as I described them, what's going on here? It's time to nail down some basic facts.

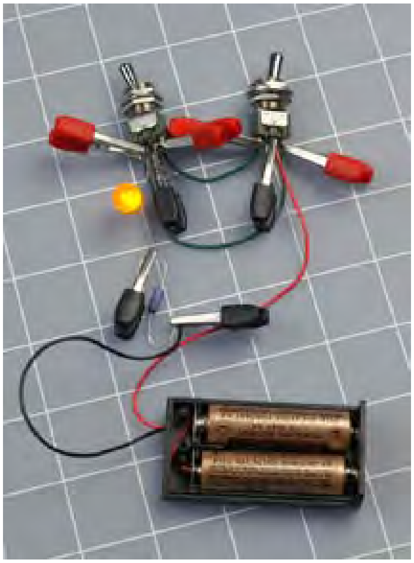

Figure 2-22. *Miniature toggle switches can be used—ideally, with miniature alligator clips—but watch out for short circuits.*

FUNDAMENTALS

All about switches

When you flip the type of toggle switch that you used in Experiment 6, it connects the center terminal with one of the outer terminals. Flip the switch back, and it connects the center terminal with the other outer terminal, as shown in Figure 2-23.

The center terminal is called the pole of the switch. Because you can flip, or throw, this switch to make two possible connections, it is called a *double-throw switch*. As mentioned earlier, a single-pole, double-throw switch is abbreviated *SPDT*.

Some switches are on/off, meaning that if you throw them in one direction they make a contact, but in the other direction, they make no contact at all. Most of the light switches in your house are like this. They are known as *single-throw switches*. A single-pole, single-throw switch is abbreviated *SPST*.

Some switches have two entirely separate poles, so you can make two separate connections simultaneously when you flip the switch. These are called *double-pole switches*. Check the photographs in Figures 2-24 through 2-26 of old-fashioned "knife" switches (which are still used to teach electronics to kids in school) and you'll see the simplest representation of single and double poles, and single and double throws. Various toggle switches that have contacts sealed inside them are shown in Figure 2-27.

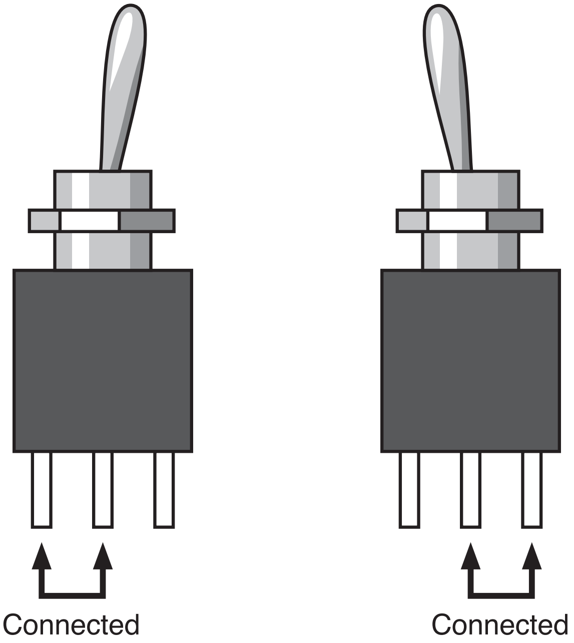

Figure 2-23. *The center terminal is the pole of the switch. When you flip the toggle, the pole changes its connection.*

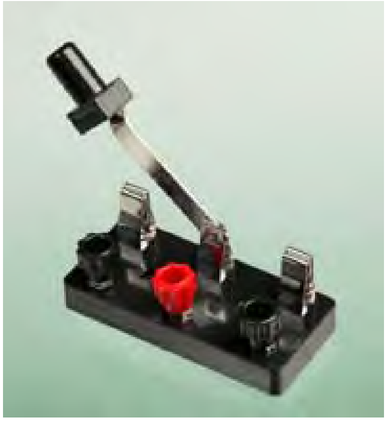

Figure 2-24. *This primitive-looking single-pole, double-throw switch does exactly the same thing as the toggle switches in Figures 2-23 and 2-27.*

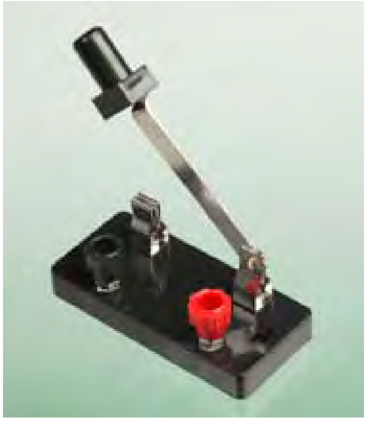

Figure 2-25. *A single-pole, single-throw switch makes only one connection with one pole. Its two states are simply open and closed, on and off.*

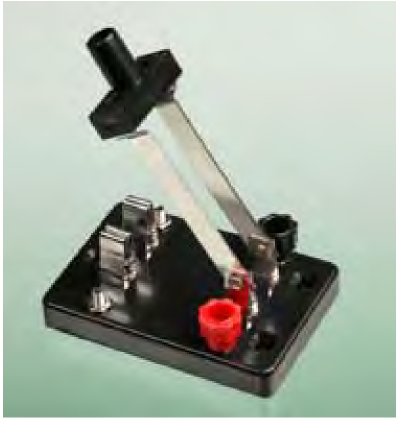

Figure 2-26. *A double-pole, single-throw switch makes two separate on/off connections.*

FUNDAMENTALS

All about switches (continued)

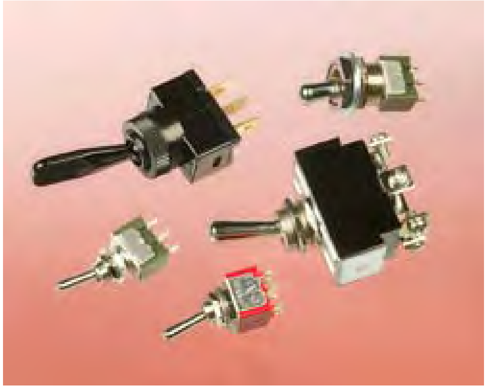

Figure 2-27. *These are all toggle switches. Generally, the larger the switch, the more current it can handle.*

To make things more interesting, you can also buy switches that have three or four poles. (Some rotary switches have even more, but we won't be using them.) Also, some double-throw switches have an additional "center off" position.

Putting all this together, I made a table of possible types of switches (Figure 2-28). When you're reading a parts catalog, you can check this table to remind yourself what the abbreviations mean.

	Single Pole	Double Pole	3-Pole	4-Pole
Single Throw	SPST ON-OFF	DPST ON-OFF	3PST ON-OFF	4PST ON-OFF
Double Throw	SPDT ON-ON	DPDT ON-ON	3PDT ON-ON	4PDT ON-ON
Double Throw with Center Off	SPDT ON-OFF-ON	DPDT ON-OFF-ON	3PDT ON-OFF-ON	4PDT ON-OFF-ON

Figure 2-28. *This table summarizes all the various options for toggle switches and pushbuttons.*

Now, what about pushbuttons? When you press a door bell, you're making an electrical contact, so this is a type of switch—and indeed the correct term for it is a momentary switch, because it makes only a momentary contact. Any spring-loaded switch or button that wants to jump back to its original position is known as a momentary switch. We indicate this by putting its momentary state in parentheses. Here are some examples:

- OFF-(ON): Because the ON state is in parentheses, it's the momentary state. Therefore, this is a single-pole switch that makes contact only when you push it, and flips back to make no contact when you let it go. It is also known as a "normally open" momentary switch, abbreviated "NO."
- ON-(OFF): The opposite kind of momentary single-pole switch. It's normally ON, but when you push it, you break the connection. So, the OFF state is momentary. It is known as a "normally closed" momentary switch, abbreviated "NC."
- (ON)-OFF-(ON): This switch has a center-off position. When you push it either way, it makes a momentary contact, and returns to the center when you let it go.

Other variations are possible, such as ON-OFF-(ON) or ON-(ON). As long as you remember that parentheses indicate the momentary state, you should be able to figure out what these switches are.

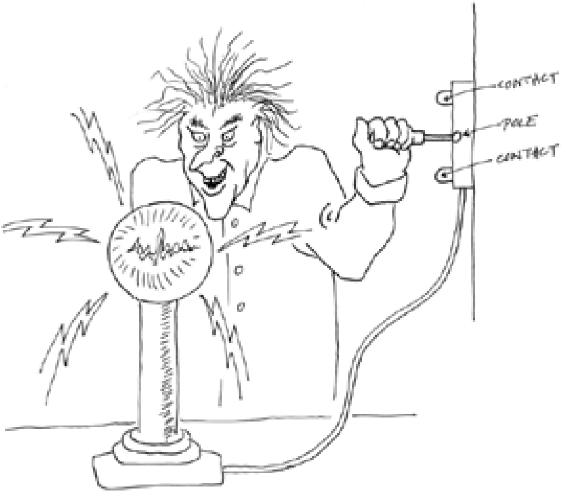

Figure 2-29. *This evil mad scientist is ready to apply power to his experiment. For this purpose, he is using a single-pole, double-throw knife switch, conveniently mounted on the wall of his basement laboratory.*

FUNDAMENTALS

All about switches (continued)

Sparking

When you make and break an electrical connection, it tends to create a spark. Sparking is bad for switch contacts. It eats them until the switch doesn't make a reliable connection anymore. For this reason, you must use a switch that is appropriate for the voltage and amperage that you are dealing with. Electronic circuits generally are low-current, and low-voltage, so you can use almost any switch, but if you are switching a motor, it will tend to suck an initial surge of current that is at least double the rating of the motor when it is running constantly. You should probably use a 4-amp switch to turn a 2-amp motor on and off.

Checking a switch

You can use your meter to check a switch. Doing this helps you find out which contacts are connected when you turn a switch one way or the other. It's also useful if you have a pushbutton and you can't remember whether it's the type that is normally open (you press it to make a connection) or normally closed (you press it to break the connection). Set your meter to measure ohms, and touch the probes to the switch terminals while you work the switch.

This is a hassle, though, because you have to wait while the meter makes an accurate measurement. When you just want to know whether there is a connection, your meter has a "continuity tester" setting. It beeps if it finds a connection, and stays silent if it doesn't. See Figures 2-30 through 2-32 for examples of meters set to test continuity. Figure 2-33 offers an example of a toggle switch being tested for continuity.

Use the continuity-testing feature on your meter only on circuits or components that have no power in them at the time.

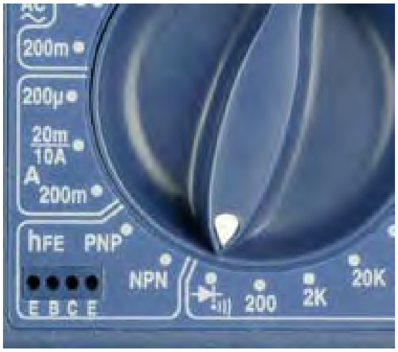

Figure 2-30

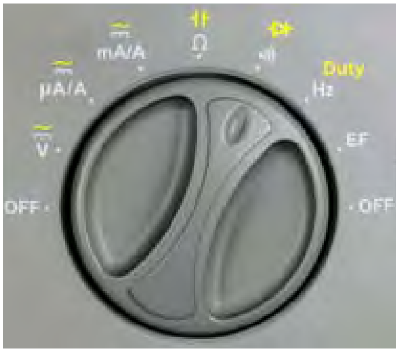

Figure 2-31

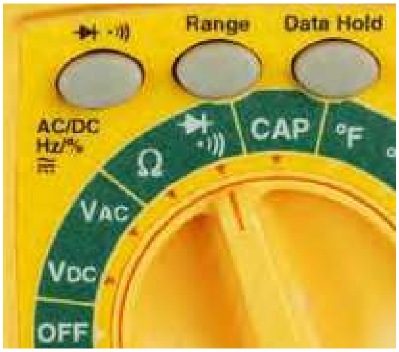

Figure 2-32. *To check a circuit for continuity, turn the dial of your meter to the symbol shown. Only use this feature when there is no power in the component or the circuit that you are testing.*

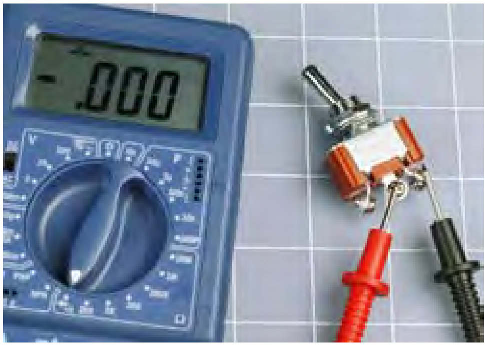

Figure 2-33. *When the switch connects two of its terminals, the meter shows zero resistance between them and will beep if you have set it to verify continuity.*

BACKGROUND

Early switching systems

Switches seem to be such a fundamental feature of our world, and their concept is so simple that it's easy to forget that they went through a gradual process of development and refinement. Primitive knife switches were quite adequate for pioneers of electricity who simply wanted to connect and disconnect electricity to some apparatus in a laboratory, but a more sophisticated approach was needed when telephone systems began to proliferate. Typically, an operator at a "switchboard" needed a way to connect any pair of 10,000 lines on the board. How could it be done?

In 1878, Charles E. Scribner (Figure 2-34) developed the "jack-knife switch," so called because the part of it that the operator held looked like the handle of a jackknife. Protruding from it was a plug, and when the plug was pushed into a socket, it made contact inside the socket. The socket, in fact, was the switch.

Figure 2-34. *Charles E. Scribner invented the "jack-knife switch" to satisfy the switching needs of telephone systems in the late 1800s. Today's audio jacks still work on the same basis.*[*]

Audio connectors on guitars and amplifiers still work on the same principle, and when we speak of them as being "jacks," the term dates back to Scribner's invention. Switch contacts still exist inside a jack socket.

Today, of course, telephone switchboards have become as rare as telephone operators. First they were replaced with relays—electrically operated switches, which I'll talk about later in this chapter. And then the relays were superceded by transistors, which made everything happen without any moving parts. Before the end of this chapter, you'll be switching current using transistors.

---

[*] The photo on which this drawing is based first appeared in *The History of the Telephone* by Herbert Newton Casson in 1910 (Chicago: A. C. McClurg & Co.).

Introducing Schematics

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

In Figure 2-35, I've redrawn the circuit from Experiment 6 in a simplified style known as a "schematic." From this point onward, I will be illustrating circuits with schematics, because they make circuits easier to understand. You just need to know a few symbols to interpret them.

Compare the schematic here with the drawing of the circuit in Figure 2-17. They both show exactly the same thing: Components, and connections between them. The gray rectangles are the switches, the zigzag thing is the resistor, and the symbol with two diagonal arrows is the LED.

The schematic LED symbol includes two arrows indicating that it emits light, because there are some kinds of diodes, which we'll get to later, that don't. The triangle inside the diode symbol always points from positive to negative.

Trace the path that electricity can take through the circuit and imagine the switches turning one way or the other. You should see clearly now why either switch will reverse the state of the LED from on to off or off to on.

This same circuit is used in houses where you have a switch at the bottom of a flight of stairs, and another one at the top, both controlling the same lightbulb. The wires in a house are much longer, and they snake around behind the walls, but because their connections are still the same, they could be represented with the same basic schematic. See Figure 2-36.

A schematic doesn't tell you exactly where to put the components. It just tells you how to join them together. One problem: Different people use slightly different schematic symbols to mean the same thing. Check the upcoming section, "Fundamentals: Basic schematic symbols," for the details.

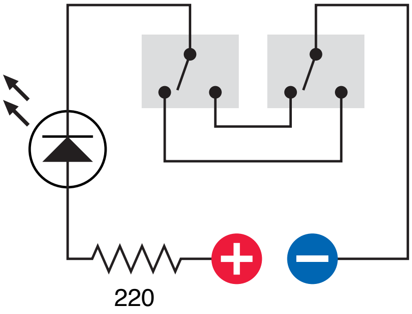

Figure 2-35. *This schematic shows the same circuit as in Figure 2-17 and makes it easier to see how the switches function.*

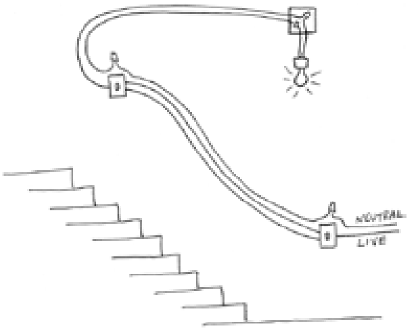

Figure 2-36. *The two-switch circuit shown in Figures 2-17 and 2-35 is often found in house wiring, especially where switches are located at the top and bottom of a flight of stairs. This sketch shows what you might find inside the walls. Wires are joined with "wire nuts" inside boxes that are hidden from everyday view.*

FUNDAMENTALS

Basic schematic symbols

Schematic symbols are like words in a language: they have mutated over the years into a confusing range of variations. A simple on/off (single-pole, single-throw, or SPST) switch, for instance, can be represented by any of the symbols shown in Figure 2-37. They all mean exactly the same thing.

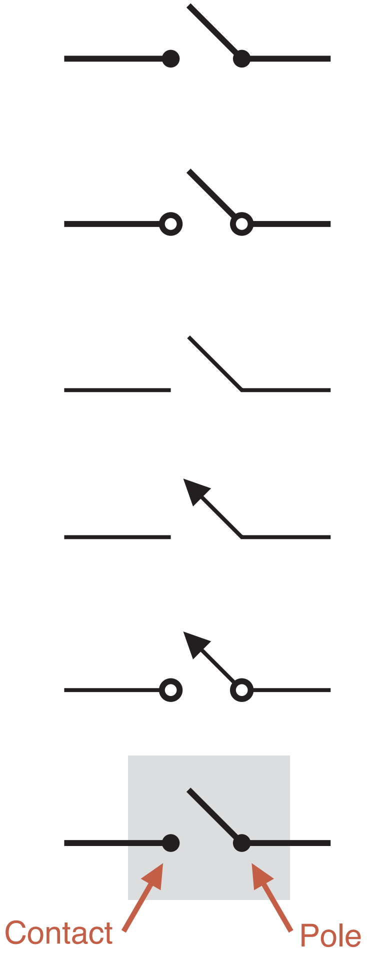

Figure 2-37. *Variations on a theme: Just some of the different styles used to depict a single-pole, single-throw switch in schematic diagrams. The bottom version is the style used in this book.*

Figure 2-38 shows double-pole, double-throw switches. A dotted line indicates a mechanical connection inside the switch, so that when you flip it, you affect both the poles simultaneously. Remember, the poles are electrically isolated from each other.

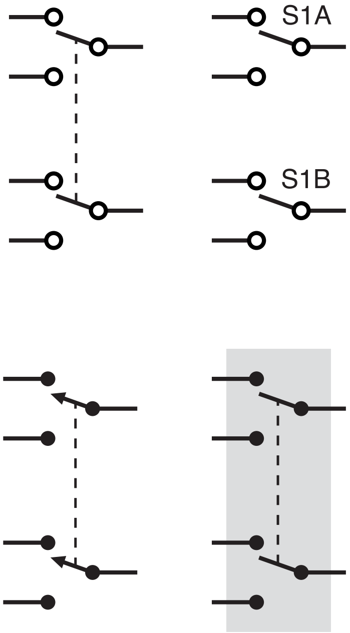

Figure 2-38. *More variations: some different styles for depicting a double-pole, double-throw switch. The style at bottom-right is used in this book.*

Once in a while, you may find a schematic in which switches seem to be scattered around, but the way they are identified (such as S1A, S1B, S1C, and so on) tells you that this is really all one switch with multiple poles.

In the schematics in this book, I'll place a gray rectangle behind each switch. This gray rectangle is not a standard symbol; you won't find it in other books. I'm just including it to remind you that the parts inside are all contained in one package.

A very important stylistic variation in schematics is the way they show whether wires make a connection with each other. Old schematics used to show a little semicircular bump in a wire if it crossed another wire without making a connection. Because modern circuit-drawing software doesn't create this style of schematic, it is no longer often used. The modern style, which you are likely to find if you browse through schematics online, can be summarized like this:

- A dot joining two wires indicates an electrical connection.
- No dot indicates no connection.

FUNDAMENTALS

Basic schematic symbols (continued)

The problem is that this is not very intuitive, especially when you're just beginning to use schematics. When you see two wires crossing, you can easily imagine that they are making a connection, even though there's no dot at the intersection. Therefore, in the interests of clarity, I've chosen to use the old "semicircular bump" style of schematic in this book (see Figure 2-39). It can be summarized like this:

- A dot joining two wires indicates an electrical connection.
- A bump in a wire that crosses another wire indicates no connection.

In this book, you won't find wires crossing each other without either a dot or a bump.

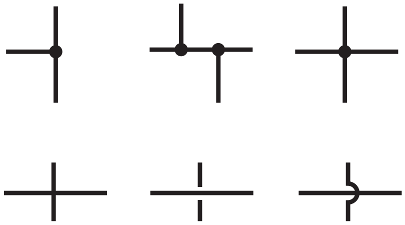

Figure 2-39. *In wiring schematics, a dot always indicates an electrical connection. However, the cross-shaped intersection of wires at top-right is considered bad style because if the dot is accidentally omitted or poorly printed, the intersection can be mistaken for the type shown at bottom left, in which the wires do not make a connection. All three of the configurations in the bottom row indicate no connection, the first example being the most common style, the center example being least common, and the third being the most old-fashioned—although for reasons of clarity, it is used in this book.*

In a battery-powered circuit, you may find a battery symbol, but more often you will find a little note indicating where positive voltage enters the system, while negative is indicated by a "ground" symbol. In fact there may be ground symbols all over the place. You have to remember that when you build a circuit, all the wires leading to grounds must actually be connected together, to the negative side of the voltage supply.

The idea of the ground symbol dates back to the time when electronic gadgets were mounted on a metal chassis, which was connected to the negative side of the power supply. The ground symbol really meant "connect to the chassis." Some variants in the ground symbol are shown in Figure 2-40.

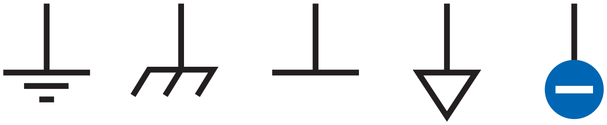

Figure 2-40. *All of these symbols are used to mean the same thing: connect the wire to "ground" or "chassis" or the negative side of the power source. The far-right symbol is used in this book.*

In this book, we have color throughout, so I'll show a red positive and blue negative to clarify where the power is connected, and I won't use ground symbols. Once again, my purpose is to minimize the risk of misunderstandings, because I know how frustrating it is to build a circuit that doesn't work.

A big inconsistency in schematics is the way in which they show resistors. The traditional zigzag symbol has been abandoned in Europe. Instead they use a rectangle with a number inside indicating the number of ohms. See Figure 2-41. The Europeans also changed the way in which decimal points are represented: they omit them as much as possible, because in badly printed schematics, the little dots tend to get lost (or can be confused with dust and dirt). So, a 4.7KΩ resistor will be listed as 4K7, and a 1.2MΩ resistor will be 1M2. I like this notation, so I'm going to be using it myself, but I'll be keeping the zigzag resistor symbol, which remains widely used in the United States.

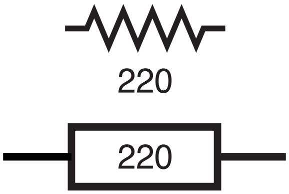

Figure 2-41. *Two styles for depicting a 220Ω resistor. The upper version is traditional, and still used in the United States. The lower version is European.*

FUNDAMENTALS

Basic schematic symbols (continued)

Potentiometers suffer from the same inconsistent style between the United States and Europe, but either way, you'll find an arrow showing where the wiper (usually, the center terminal) touches the resistance. See Figure 2-42. And sometimes LEDs are shown inside circles, and sometimes not. I prefer circles, myself. See Figure 2-46.

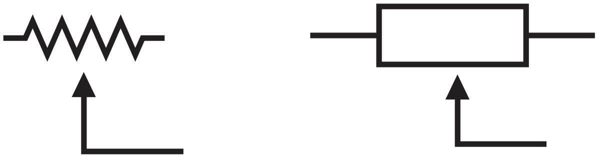

Figure 2-42. *Potentiometer symbols: the left is traditional and used in the United States, the right is European. In both cases the arrow indicates the wiper (usually the center terminal).*

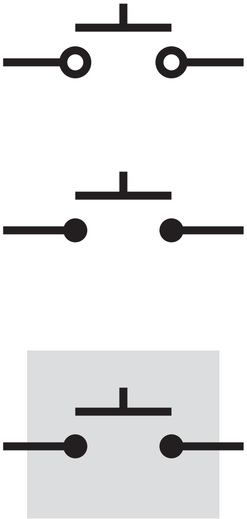

Figure 2-43. *Three ways of indicating a pushbutton switch.*

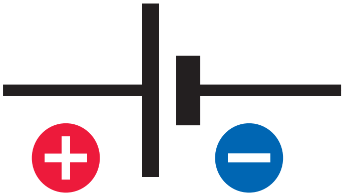

Figure 2-44. *The battery symbol is usually shown without + and – symbols. I've added them for clarity.*

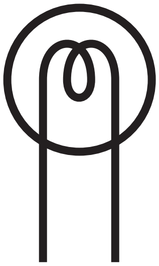

Figure 2-45. *Symbol for an incandescent lightbulb.*

I'll explore other symbol variants later in the book. Meanwhile, the most important things to remember are:

- The positions of components in a schematic are not important.
- The styles of symbols used in a schematic are not important.
- The connections between the components are extremely important.

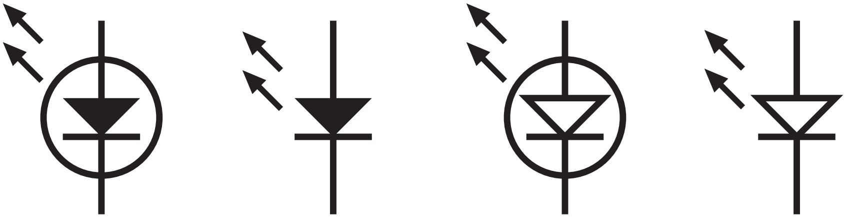

Figure 2-46. *Sometimes an LED is shown with a circle around it; sometimes not. In this book, I will include the circle. The arrows indicate emitted light.*

FUNDAMENTALS

Basic schematic symbols (continued)

For example, the three LED circuits that I have included in Figure 2-47 show components in different positions, using different symbols, but all three circuits function exactly the same way, because their connections are the same. In fact, they all depict the circuit that you built in Experiment 4, shown in Figure 1-50.

Often the symbols in a schematic are placed so that the circuit is most intuitively easy to understand, regardless of how you may build it with actual components. Compare the example in Figure 2-48, showing the two DPDT switches, with the version shown back in Figure 2-35. The previous one looked more like your bench-top version of it, but Figure 2-48 shows the flow of electricity more clearly.

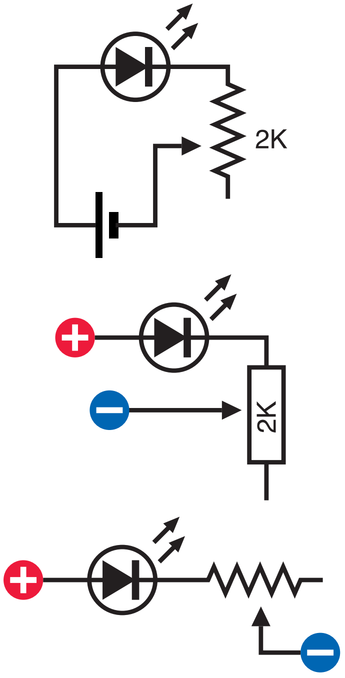

Figure 2-47. *These three schematics all depict the same basic circuit. It's the circuit that you built with the potentiometer in Experiment 4.*

In many schematics, the positive side of the power supply is shown at the top of the diagram, and negative or ground at the bottom. Many people also tend to draw a schematic with an input (such as an audio input, in an amplifier circuit) at the left side, and the output at the right. So, "positive voltage" flows from top to bottom while a signal tends to pass from left to right.

When I was planning this book, initially I drew the schematics to conform with this top-to-bottom, left-to-right convention, but as I started building and testing the circuits, I changed my mind. We use a device known as a "breadboard" to create circuits, and its internal connections require us to lay out components very differently from a typical schematic. When you're starting to learn electronics, it's very confusing to try to rearrange components from a schematic in the configuration that you need for a breadboard.

Therefore, throughout this book, you'll find that I have drawn the schematics to imitate the way you'll wire them on a breadboard. I believe the advantages of doing things this way outweigh the disadvantages of being a little different from the schematic styles that are used elsewhere.

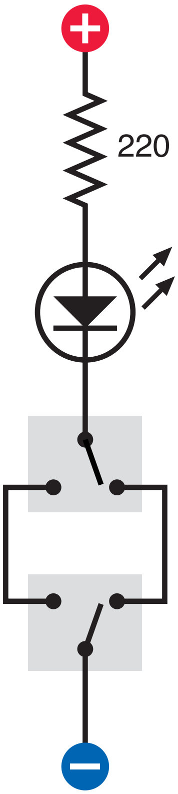

Figure 2-48. *This schematic is just another, clearer, simpler way of showing the circuit that appeared in Figure 2-35.*

Experiment 7: Relay-Driven LEDs

You will need:

- AC adapter, wire cutters and strippers.
- DPDT relay. Quantity: 2.
- LEDs. Quantity: 2.
- Resistor, 680Ω approx. Quantity: 1.
- Pushbutton, SPST. Quantity: 1.
- Hookup wire, 22 gauge, or patch cords.
- Alligator clips. Quantity: 8.
- Utility knife.

The next step in our exploration of switching is to use a remote-controlled switch. By "remote-controlled," I mean one to which you can send a signal to turn it on or off. This kind of switch is known as a *relay*, because it relays an instruction from one part of a circuit to another. Often a relay is controlled by a low voltage or small current, and switches a larger voltage or higher current.

This setup can be cost-effective. When you start your car, for instance, a relatively small, cheap switch sends a small signal down a relatively long, thin, inexpensive piece of wire, to a relay that is near the starter motor. The relay activates the motor through a shorter, thicker, more expensive piece of wire, capable of carrying as much as 100 amps.

Similarly, when you raise the lid on an a top-loading washing machine during its spin cycle, you close a lightweight switch that sends a small signal down a thin wire to a relay. The relay handles the bigger task of switching off the large motor spinning the drum full of wet clothes.

Before you begin this experiment, you need to upgrade your power supply. We're not going to use batteries anymore, because most relays require more than 6 volts, and in any case you should have a power supply that can give you a variety of voltages on demand. The simplest way to achieve this is by using an AC adapter.

First you'll set up the AC adapter. After you have it running, you'll use it to power the relay. Initially the relay will just switch between two LEDs, but then you'll modify the circuit to make the LEDs flash automatically. Finally you'll rebuild the circuit on a breadboard, and say goodbye to alligator clips, for most of the time at least.

Preparing Your AC Adapter

An AC adapter plugs into the wall and converts the high-voltage AC supply in your home into a safe, low DC voltage for electronic devices. Any charger that you use with your cell phone, or iPod, or laptop computer is a special-purpose AC adapter that delivers only one voltage via a specific type of plug. I've asked you to buy a general-purpose adapter that delivers many different voltages, and we're going to begin by getting rid of its plug.

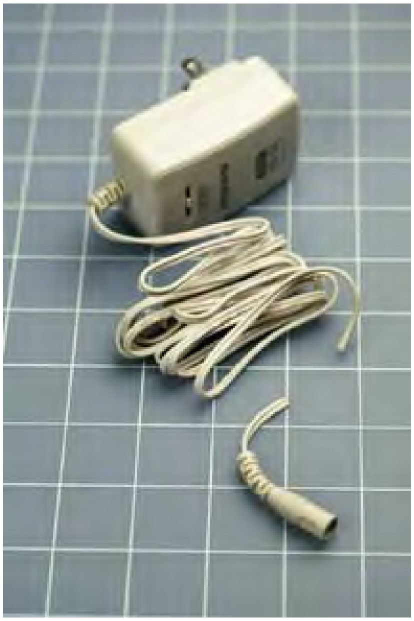

Figure 2-49. *Preparing an AC adapter. First, cut off the little low-voltage plug and throw it away.*

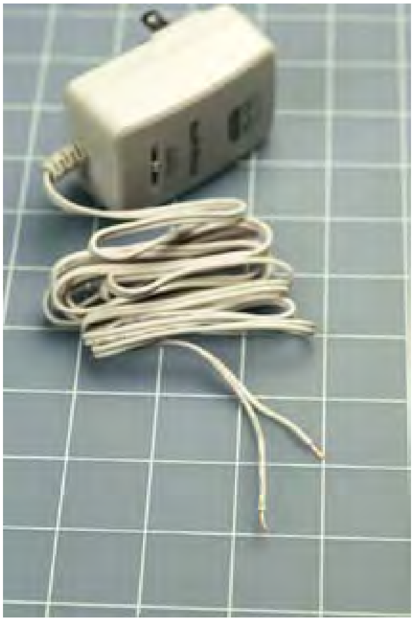

Figure 2-50. *Second, strip the wires, making one shorter than the other to reduce the risk of them touching. Color one of the adapter wires red with a marker, to identify it as the positive one.*

1. It's important to make sure that your AC adapter is not plugged into the wall!
2. Chop off the little plug at the end of its wire. See Figure 2-49.
3. Use a box cutter or utility knife or scissors to make a half-inch cut between the two conductors, and then pull the conductors apart a couple of inches.
4. Use wire cutters to trim one of the conductors shorter than the other, so that after you strip away a little of the insulation, the exposed copper wires cannot easily touch each other. This is a precaution against short-circuiting your AC adapter and burning it out.
5. Strip the two conductors using your wire strippers. Twist the copper strands between finger and thumb so that there are no loose strands sticking out. See Figure 2-50.
6. Make sure that the two wires are not touching each other, and plug your AC adapter into a wall outlet. Set your meter to DC volts and apply the meter probes to the wires from the adapter. If the voltage is preceded with a minus sign, you have the probes the wrong way around. Reverse them and the minus sign should go away. This tells you which wire is positive.
7. Mark the positive wire from the adapter. If the wire has white insulation, you can mark it with a red marker. If it has black insulation, you can tag it with a label. The positive wire will remain positive regardless of which way up you plug the AC adapter into a wall outlet.

The Relay

The type of relay that I want you to use has little spiky legs on the bottom, in a standardized layout. If you buy some other kind of relay, you will have to figure out for yourself which pins are connected to the coil inside, which pins go to the poles of the switch inside it, and which go to the normally closed and normally open contacts. You can check the manufacturer's data sheet for this purpose, but I strongly suggest you use one of the relays mentioned in the shopping list, so that you can follow the instructions here more easily.

I asked you to buy two relays so that you can use one for investigational purposes—meaning that you can break it open and take a look inside. If you do this very, very carefully, the relay should still be usable afterward. If not, well, you still have a spare.

The easiest way to open the relay is with a box cutter or utility knife. Figures 2-52, 2-53, and 2-54 show the technique. Shave the edges of the plastic shell containing the relay, beveling them until you see just a hair-thin opening. Don't go any farther; the parts inside are very, very close to its housing. Now pop the top off. You can use needle-nosed pliers to nibble the rest of the shell away. Read the following section, "Fundamentals: Inside a relay," and then apply power to the relay to see how it works.

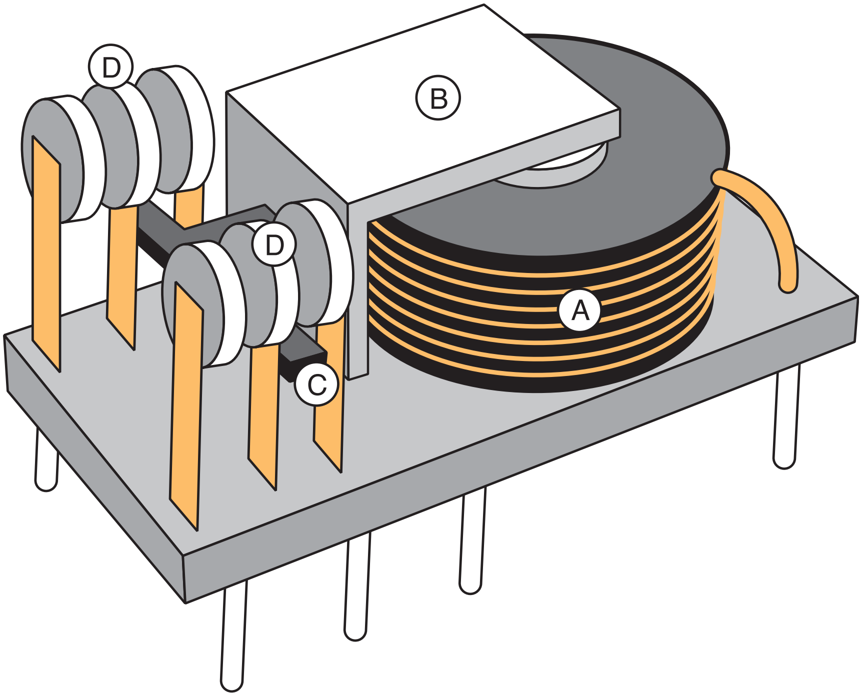

Figure 2-51. *This is one way that the parts inside a relay can be arranged. The coil, A, generates a magnetic attraction pulling lever B downward. A plastic extension, C, pushes outward against flexible metal strips and moves the poles of the relay, D, between the contacts.*

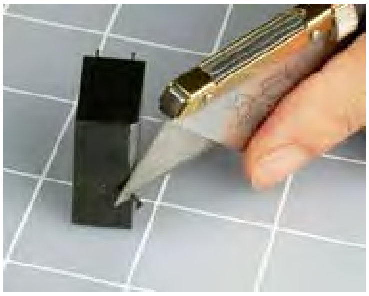

Figure 2-52. *To look inside a sealed relay, shave the top edges of the plastic package with a utility knife til you open a thin crack.*

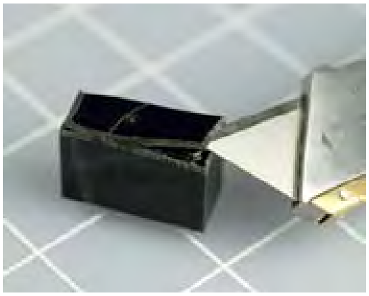

Figure 2-53. *Insert the blade of your knife to pry open the top, then repeat the procedure for the sides.*

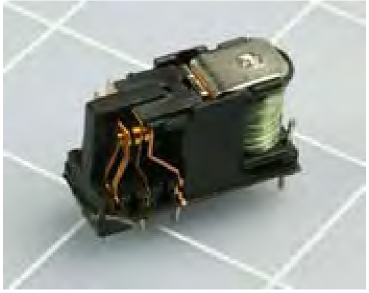

Figure 2-54. *If you are really, really careful, the relay should still work after you open it.*

Figure 2-55

Figure 2-56. *Patience is essential when carving the edges of a relay package in order to open it. Faster methods such as a tomahawk or a flamethrower will satisfy the emotional needs of those with a short attention span, but results may be unpredictable.*

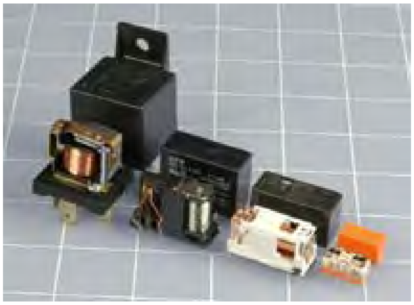

Figure 2-57. *Four assorted 12-volt relays, shown with and without their packages. The automotive relay (far left) is the simplest and easiest to understand, because it is designed without much concern for the size of the package. Smaller relays are more ingeniously designed, more complex, and more difficult to figure out. Usually, but not always, a smaller relay is designed to switch less current than a larger one.*

FUNDAMENTALS

Inside a relay

A relay contains a coil of wire wrapped around an iron core. When electricity runs through the coil, the iron core exerts a magnetic force, which pulls a lever, which pushes or pulls a springy strip of metal, closing two contacts. So as long as electricity runs through the coil, the relay is "energized" and its contacts remain closed.

When the power stops passing through the coil, the relay lets go and the springy strip of metal snaps back into its original position, opening the contacts. (The exception to this rule is a latching relay, which requires a second pulse through a separate coil to flip it back to its original position; but we won't be using latching relays until later in the book.)

Relays are categorized like switches. Thus, you have SPST relays, DPST, SPDT, and so on.

Compare the schematics in Figure 2-58 with the schematics of switches in Figure 2-38. The main difference is that the relay has a coil that activates the switch. The switch is shown in its "relaxed" mode, when no power flows through the coil.

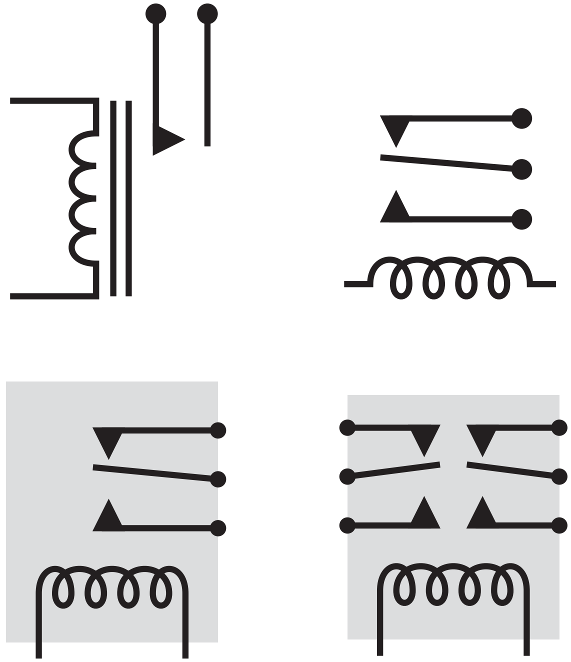

Figure 2-58. *Various ways to show a relay in a schematic. Top left: SPST. Top right and bottom left: SPDT. Bottom right: DPDT. The styles at bottom-left and bottom-right will be used in this book.*

The contacts are shown as little triangles. When there are two poles instead of one, the coil activates both switches simultaneously.

Most relays are nonpolarized, meaning that you can run electricity through the coil in either direction, and the relay doesn't care. You should check the data sheet to make sure, though. Some relay coils work on AC voltage, but almost all low-voltage relays use direct current—a steady flow of electricity, such as you would get from a battery. We'll be using DC relays in this book.

Relays suffer from the same limitations as switches: their contacts will be eroded by sparking if you try to switch too much voltage. It's not worth saving a few dollars by using a relay that is rated for less current or voltage than your application requires. The relay will fail you when you need it most, and may be inconvenient to replace.

Because there are so many different types of relays, read the specifications carefully before you buy one. Look for these basics:

Coil voltage

The voltage that the relay is supposed to receive when you energize it.

Set voltage

The minimum voltage that the relay needs to close its switch. This will be a bit less than the ideal coil voltage.

Operating current

The power consumption of the coil, usually in milliamps, when the relay is energized. Sometimes the power is expressed in milliwatts.

Switching capacity

The maximum amount of current that you can switch with contacts inside the relay. Usually this is for a "resistive load," meaning a passive device such as light bulb. When you use a relay to switch on a motor, the motor takes a big initial surge of current before it gets up to speed. In this case, you should choose a relay rated for double the current that the motor draws when it is running.

Procedure

Turn the relay with its legs in the air and attach wires and LEDs as shown in Figure 2-59, with a 680Ω resistor (a 1K resistor will be OK if you don't have the correct value). Also attach a pushbutton switch. (Your pushbutton switch may look different from the one shown, but as long as it is a SPST pushbutton with two contacts at the bottom, it will work the same way.) When you press the pushbutton, the relay will make the first LED go out and the second LED light up. When you release the pushbutton, the first LED lights up and the second one goes out.

How It Works

Check the schematic in Figure 2-60 and compare it with Figure 2-59. Also see Figure 2-62, which shows how the pins outside the relay make connections inside the relay when its coil is energized, and when it is not energized.

This is a DPDT relay, but we are only using one pole and ignoring the other. Why not buy a SPDT relay? Because I want the pins to be spaced the way they are when you will upgrade this circuit by transferring it onto a breadboard, which will happen very shortly.

On the schematic, I have shown the switch inside the relay in its relaxed state. When the coil is energized, the switch flips upward, which seems counterintuitive, but just happens to be the way that this particular relay is made.

When you're sure you understand how the circuit works, it's time to move on to the next step: making a small modification to get the relay to switch itself on and off, as we'll do in Experiment 8.

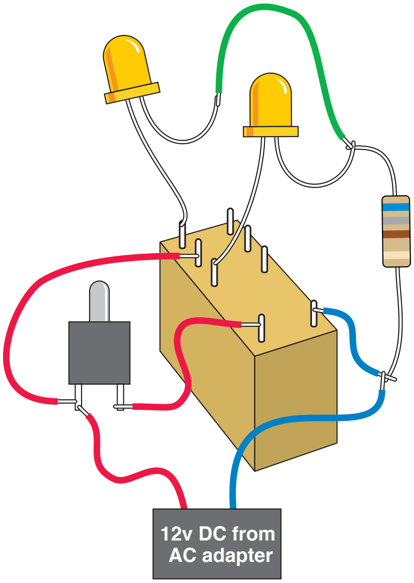

Figure 2-59. *As before, you can use patch cords, if you have them, instead of some of the wired connections shown here.*

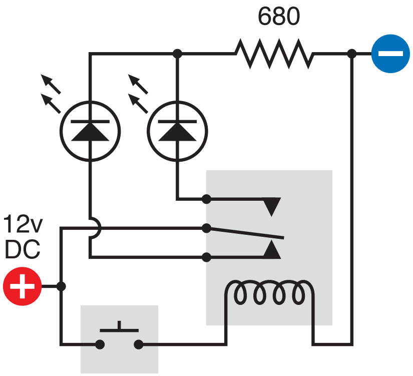

Figure 2-60. *Same circuit, shown in schematic form.*

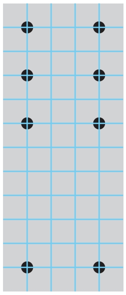

Figure 2-61. *The layout of the pins of the relay, superimposed on a grid of 1/10-inch squares. This is the type of relay that you will need in Experiment 8.*

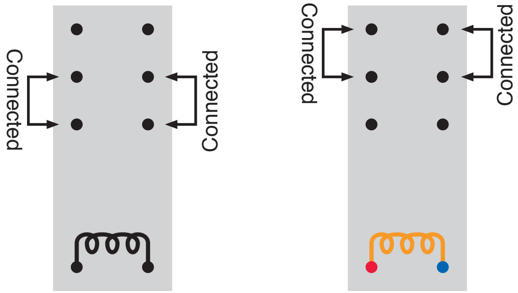

Figure 2-62. *How the relay connects the pins, when it is not energized (left) and when it is energized (right).*

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

Experiment 8: A Relay Oscillator

You will need:

- AC adapter, breadboard, wire, wire cutters and strippers.
- DPDT relay. Quantity: 1.
- LEDs. Quantity: 2.
- Pushbutton, SPST. Quantity: 1.
- Alligator clips. Quantity: 8.
- Resistor, approximately 680Ω. Quantity: 1.
- Capacitor, electrolytic, 1,000 µF. Quantity: 1.

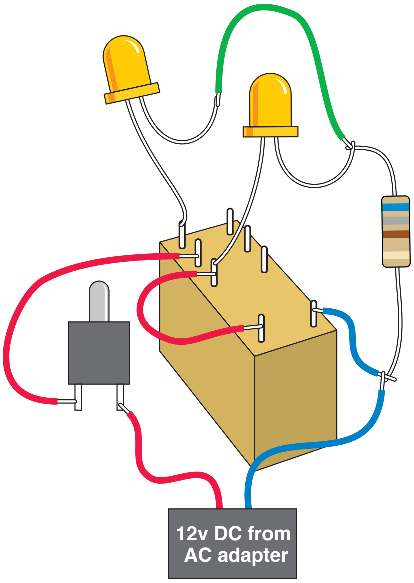

Figure 2-63. *A small revision to the previous circuit causes the relay to start oscillating when power is applied.*

Look at the revised drawing in Figure 2-63 and the revised schematic in Figure 2-64 and compare them with the previous ones. Originally, there was a direct connection from the pushbutton to the coil. In the new version, the power gets to the coil by going, first, through the contacts of the relay.

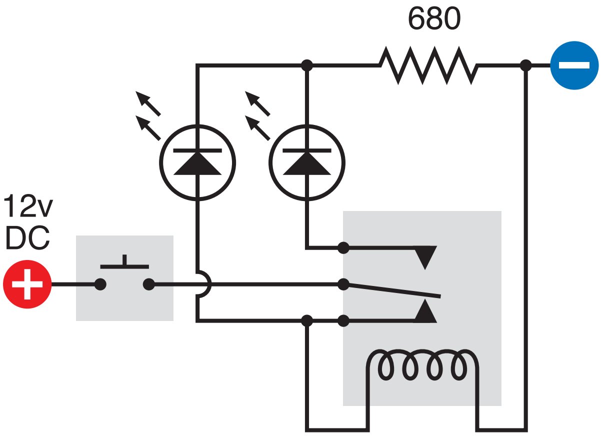

Figure 2-64. *The oscillator circuit shown in schematic form.*

Now, when you press the button, the contacts in their relaxed state feed power to the coil as well as to the lefthand LED. But as soon as the coil is energized, it opens the contacts. This interrupts the power to the coil—so the relay relaxes, and the contacts close again. They feed another pulse of power to the coil, which opens the contacts again, and the cycle repeats endlessly.

Because we're using a very small relay, it switches on and off extremely fast. In fact, it oscillates perhaps 50 times per second (too fast for the LEDs to show what's really happening). Make sure your circuit looks like the one in the diagram, and then press the pushbutton very briefly. You should hear the relay make a buzzing sound. If you have impaired hearing, touch the relay lightly with your finger, and you should feel the relay vibrating.

When you force a relay to oscillate like this, it's liable to burn itself out or destroy its contacts. That's why I asked you to press the pushbutton briefly. To make the circuit more practical, we need something to slow the relay down and prevent it from self-destructing. That necessary item is a capacitor.

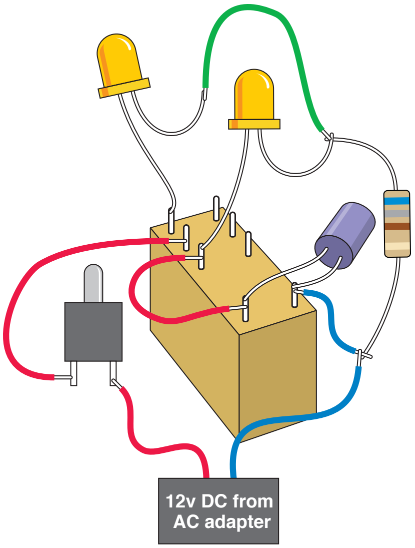
Adding Capacitance

Add a 1,000 µF electrolytic capacitor in parallel with the coil of the relay as shown in the diagram in Figure 2-65 and the schematic in Figure 2-66. Check Figure 2-14 if you're not sure what a capacitor looks like. The 1,000 µF value will be printed on the side of it, and I'll explain what this means a little later.

Make sure the capacitor's *short* wire is connected to the *negative* side of the circuit; otherwise, it won't work. In addition to the short wire, you should find a minus sign on the body of the capacitor, which is there to remind you which side is negative. Electrolytic capacitors are fussy about this.

When you press the button now, the relay should click slowly instead of buzzing. What's happening here?

A capacitor is like a tiny rechargeable battery. It's so small that it charges in a fraction of a second, before the relay has time to open its lower pair of contacts. Then, when the contacts are open, the capacitor acts like a battery, providing power to the relay. It keeps the coil of the relay energized for about one second. After the capacitor exhausts its power reserve, the relay relaxes and the process repeats.



12v DC from AC adapter

Figure 2-65. *Adding a capacitor makes the relay oscillate more slowly.*

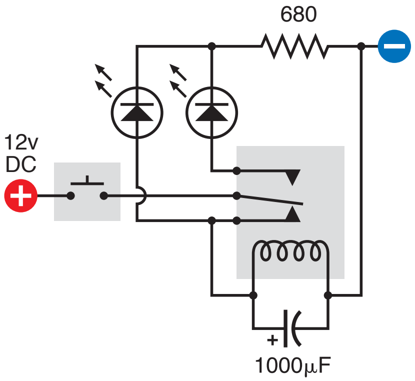


Figure 2-66. *The capacitor appears at the bottom of this schematic diagram.*

FUNDAMENTALS

Farad basics

The Farad is an international unit to measure capacitance. Modern circuits usually require small capacitors. Consequently it is common to find capacitors measured in microfarads (one-millionth of a farad) and even picofarads (one-trillionth of a farad). Nanofarads are also used, more often in Europe than in the United States. See the following conversion table.

0.001 nanofarad	1 picofarad	1 pF
0.01 nanofarad	10 picofarads	10 pF
0.1 nanofarad	100 picofarads	100 pF
1 nanofarad	1,000 picofarads	1,000 pF
0.001 microfarad	1 nanofarad	1 nF
0.01 microfarad	10 nanofarads	10 nF
0.1 microfarad	100 nanofarads	100 nF
1 microfarad	1,000 nanofarads	1,000 nF
0.000001 Farad	1 microfarad	1 µF
0.00001 Farad	10 microfarads	10 µF
0.0001 Farad	100 microfarads	100 µF
0.001 Farad	1,000 microfarads	1,000 µF

(You may encounter capacitances greater than 1,000 microfarads, but they are uncommon.)

FUNDAMENTALS

Capacitor basics

DC current does not flow through a capacitor, but voltage can accumulate very quickly inside it, and remains after the power supply is disconnected. Figures 2-67 and 2-68 may help to give you an idea of what happens inside a capacitor when it is fully charged.

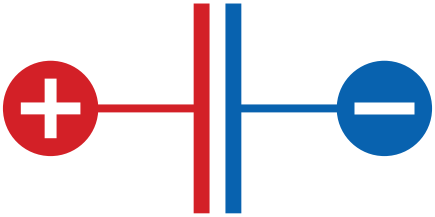

Figure 2-67. *When DC voltage reaches a capacitor, no current flows, but the capacitor charges itself like a little battery. The positive and negative charges are equal and opposite.*

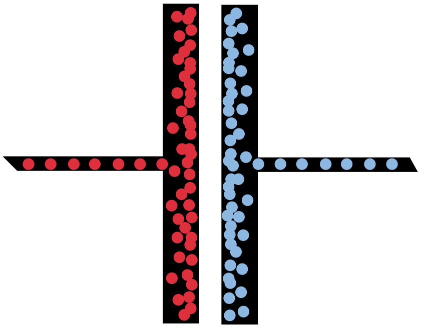

Figure 2-68. *You can imagine positive "charge particles" accumulating on one side of the capacitor and attracting negative "charge particles" to the opposite side.*

In most modern electrolytic capacitors, the plates have been reduced to two strips of very thin, flexible, metallic film, often wrapped around each other, separated by an equally thin insulator. Disc ceramic capacitors typically consist of just a single disc of nonconductive material with metal painted on both sides and leads soldered on.

The two most common varieties of capacitors are ceramic (capable of storing a relatively small charge) and electrolytic (which can be much larger). Ceramics are often disc-shaped and yellow in color; electrolytics are often shaped like miniature tin cans and may be just about any color. Refer back to Figures 2-13 and 2-14 for some examples.

Getting Zapped by Capacitors

If a large capacitor is charged with a high voltage, it can retain that voltage for a long time. Because the circuits in this book use low voltages, you don't have to be concerned about that danger here, but if you are reckless enough to open an old TV set and start digging around inside (which I do not recommend), you may have a nasty surprise. An undischarged capacitor can kill you as easily as if you stick your finger into an electrical outlet. Never touch a large capacitor unless you really know what you're doing.

FUNDAMENTALS

Capacitor basics (continued)

Ceramic capacitors have no polarity, meaning that you can apply negative voltage to either side of them. Electrolytics do have polarity, and won't work unless you connect them the right way around.

The schematic symbol for a capacitor has two significant variants: with two straight lines (symbolizing the plates inside a capacitor), or with one straight line and one curved line, as shown in Figure 2-69. When you see a curved line, that side of the capacitor should be more negative than the other. The schematic symbol may also include a + sign. Unfortunately, some people don't bother to draw a curved plate on a polarized capacitor, yet others draw a curved plate even on a nonpolarized capacitor.

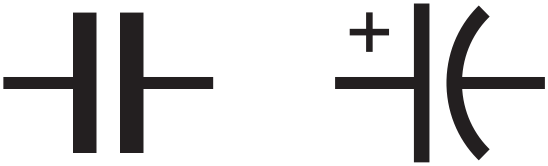

Figure 2-69. *The generic schematic for a capacitor is on the left. The version on the right indicates a polarized capacitor which requires its left plate to be "more positive" than its right plate. The plus sign is often omitted.*

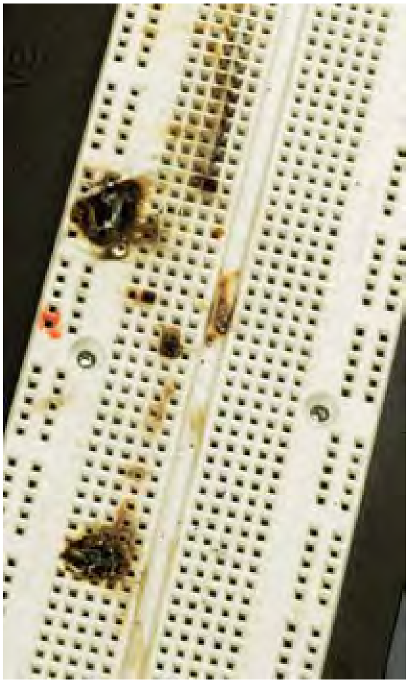

Figure 2-70. *A tantalum capacitor was plugged into this breadboard, accidentally connected the wrong way around to a power source capable of delivering a lot of current. After a minute or so of this abuse, the capacitor rebelled by popping open and scattering small flaming pieces, which burned their way into the plastic of the breadboard. Lesson learned: observe polarity!*

Capacitor Polarity

You must connect an electrolytic capacitor so that its longer wire is more positive than its shorter wire. The shell of the capacitor is usually marked with a negative sign near the shorter wire.

Some capacitors may behave badly if you don't observe their polarity. One time I connected a tantalum capacitor to a circuit, using a power supply able to deliver a lot of current, and was staring at the circuit and wondering why it wasn't working when the capacitor burst open and scattered little flaming fragments of itself in a 3-inch radius. I had forgotten that tantalum capacitors can be fussy about positive and negative connections. Figure 2-70 shows the aftermath.

BACKGROUND

Michael Faraday and capacitors

The earliest capacitors consisted of two metal plates with a very small gap between them. The principle of the thing was simple:

- If one plate was connected to a positive source, the positive charges attracted negative charges onto the other plate.
- If one plate was connected to a negative source, the negative charges attracted positive charges onto the other plate.

Figures 2-67 and 2-68, shown previously, convey the basic idea.

The electrical storage capacity of a capacitor is known as its *capacitance*, and is measured in farads, named after Michael Faraday (Figure 2-71), another of the pantheon of electrical pioneers. He was an English chemist and physicist who lived from 1791 to 1867.

Although Faraday was relatively uneducated and had little knowledge of mathematics, he had an opportunity to read a wide variety of books while working for seven years as a bookbinder's apprentice, and thus was able to educate himself. Also, he lived at a time when relatively simple experiments could reveal fundamental properties of electricity. Thus he made major discoveries including electromagnetic induction, which led to the development of electric motors. He also discovered that magnetism could affect rays of light.

His work earned him numerous honors, and his picture was printed on English 20-pound bank notes from 1991 through 2001.

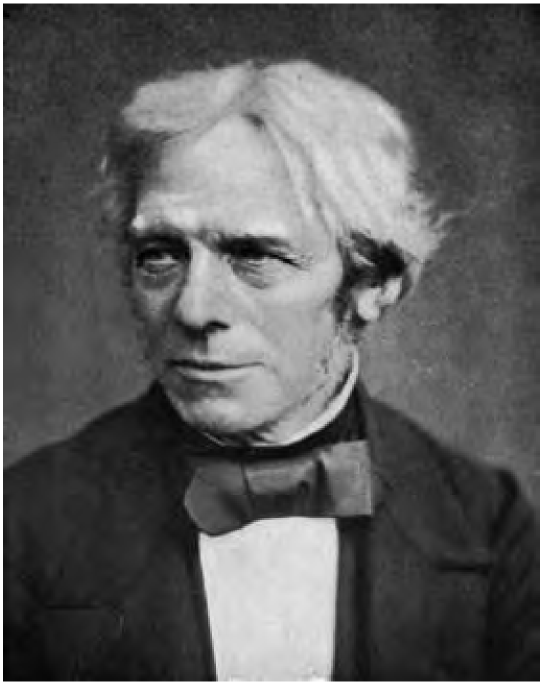

Figure 2-71. *Michael Faraday*

Breadboarding the Circuit

I promised to free you in time from the frustrations of alligator clips, and that time has come. Please turn your attention to the block of plastic with lots of little holes in it that I asked you to buy. For reasons that I do not know, this is called a *breadboard*. When you plug components into the holes, hidden metal strips inside the breadboard connect the components for you, allowing you to set up a circuit, test it, and modify it very easily. Afterward you can pull the components off the breadboard and put them away for future experiments.

Without a doubt, breadboarding is the most convenient way to test something before you decide whether you want to keep it.

Almost all breadboards are designed to be compatible with integrated circuit chips (which we will be using in Chapter 4 of this book). The chip straddles an empty channel in the center of the breadboard with rows of little holes either side—usually five holes per row. You insert other components into these holes.

In addition, the breadboard should have columns of holes running down each side. These are used to distribute positive and negative power.

Take a look at Figures 2-72 and 2-73, which show the upper part of a typical breadboard seen from above, and the same breadboard seen as if with X-ray vision, showing the metal strips that are embedded behind the holes.

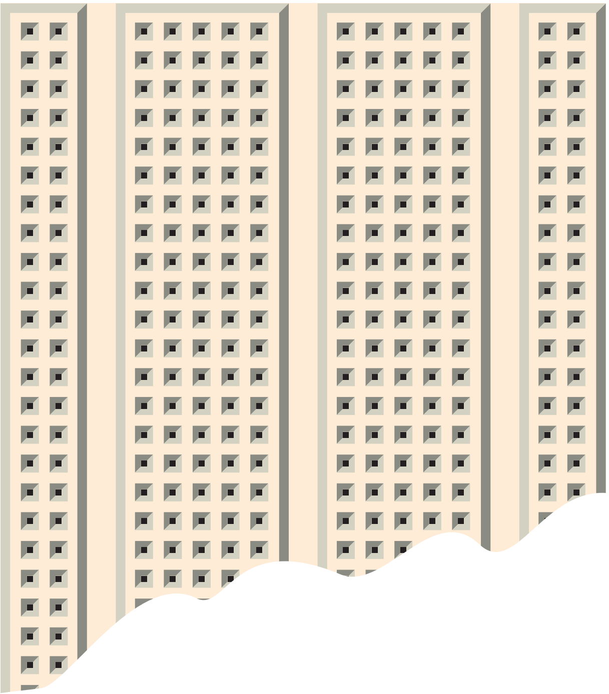

Figure 2-72. *A typical breadboard. You can plug components into the holes to test a circuit very quickly.*

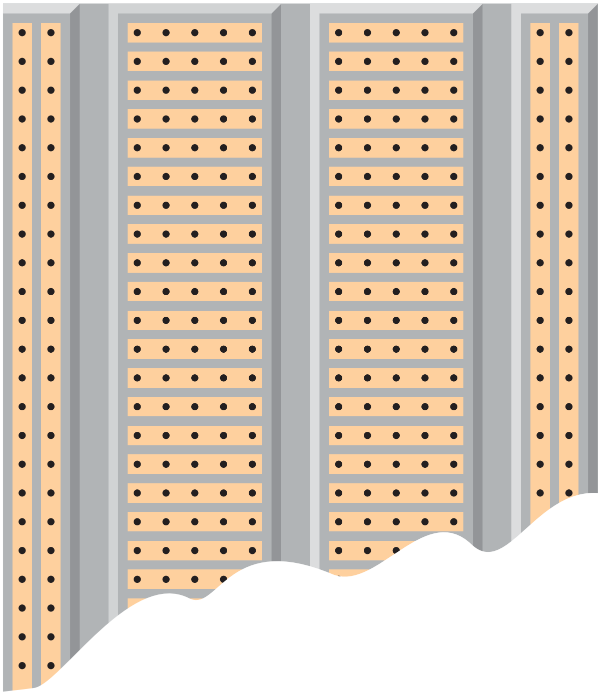

Figure 2-73. *This X-ray-vision view of the breadboard reveals the copper strips that are embedded in it. The strips conduct electricity from one component to another.*

Important note: some breadboards divide each vertical column of holes, on the left and the right, into two separate upper and lower sections. Use your meter's continuity testing feature to find out if your breadboard conducts power along its full length, and add jumper wires to link the upper and lower half of the breadboard if necessary.

Figure 2-74 shows how you can use the breadboard to replicate your oscillating relay circuit. To make this work, you need to apply the positive and negative power from your AC adapter. Because the wire from your AC adapter is almost certainly stranded, you'll have difficulty pushing it into the little holes. A way around this is to set up a couple of pieces of bare 22-gauge wire, and use them as terminals to which you clip the wire from the adapter, as in Figure 2-75. (Yes, you still need just a couple of alligator clips for this purpose.) Alternatively, you can use a breadboard with power terminals built into it, which is more convenient.

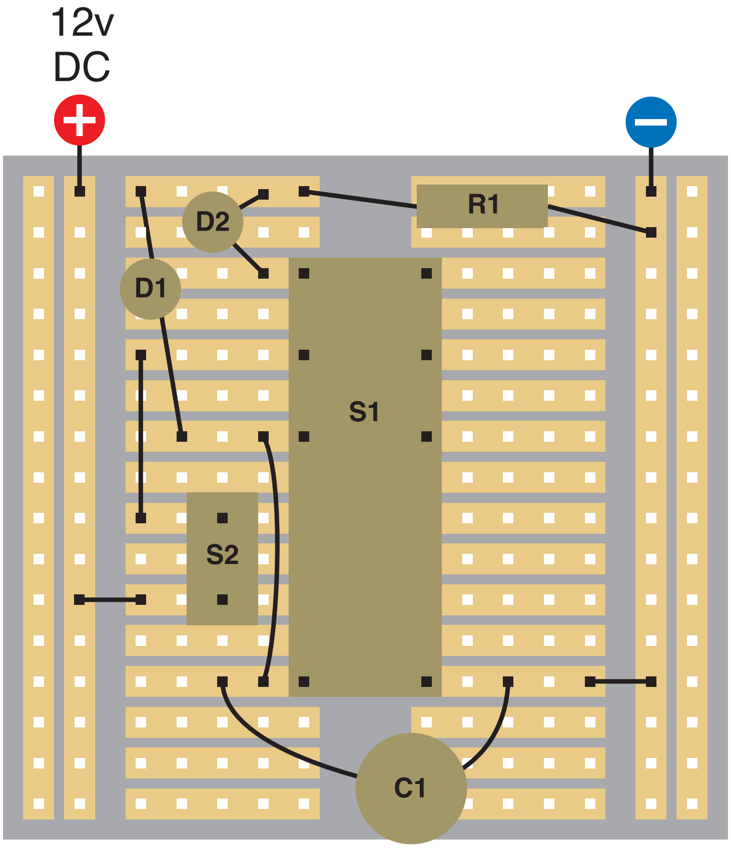

Figure 2-74. *If you place the components on your breadboard in the positions shown, they will create the same circuit that you built from wire and alligator clips in Experiment 8. Component values:*

D1, D2: Light-emitting diodes
S1: DPDT relay
S2: SPST momentary switch
C1: Electrolytic capacitor, 1,000 µF
R1: Resistor, 680Ω minimum

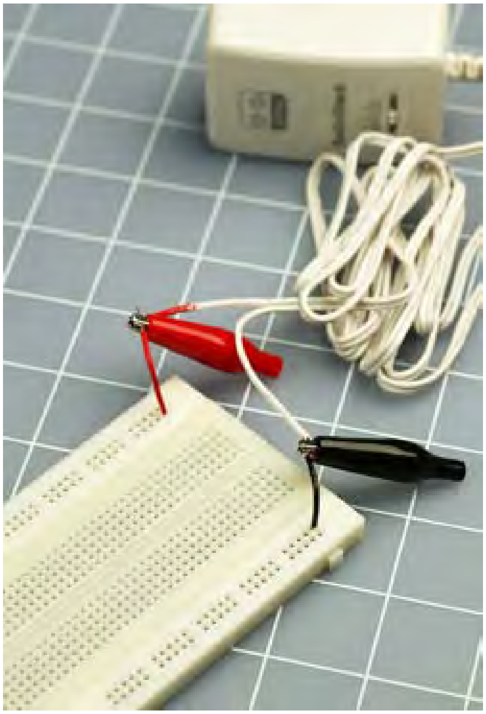

Figure 2-75. *If your breadboard doesn't have screw terminals, insert two short pieces of solid-core wire with stripped ends and then attach the stranded wires from the adapter using alligator clips.*

You'll need some more 22-gauge wire, or some precut hookup wire, to supply the power to your components, which are plugged into the breadboard as shown in Figures 2-76 and 2-77. If you get all the connections right, the circuit should function the same way as before.

The geometry of the metal connecting strips in the breadboard often forces you to connect components in a roundabout way. The pushbutton, for instance, supplies power to the pole of the relay but cannot be connected directly opposite, because there isn't room for it.

Remember that the strips inside the breadboard that don't have any wires or components plugged into them are irrelevant; they don't do anything.

I'll include some suggested breadboard layouts for circuits as you continue through this book, but eventually you'll have to start figuring out breadboard layouts for yourself, as this is an essential part of hobby electronics.

Larger versions of all schematics and breadboard photos are available online at this book's website: http://oreilly.com/catalog/9780596153748.

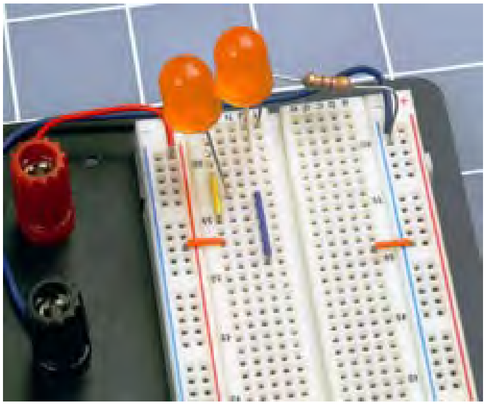

Figure 2-76. *Two oversized LEDs, one resistor, and the necessary jumper wires have been added to the breadboard.*

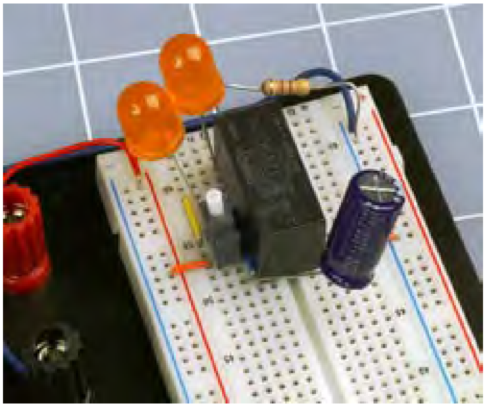

Figure 2-77. *Now the pushbutton, relay, and capacitor have been added to complete the circuit shown in the diagram and the schematic. When the pushbutton is pressed, the relay oscillates and the LEDs flash.*

Experiment 9: Time and Capacitors

You will need:

- AC adapter, breadboard, wire, wire cutters, and strippers.
- Multimeter.
- Pushbutton, SPST. Quantity: 1.
- Resistors and electrolytic capacitors, assorted.

In Experiment 8, when you put a capacitor in parallel with the coil of the relay, the capacitor charged almost instantly before discharging itself through the relay coil. If you add a resistor in series with a capacitor, the capacitor will take longer to charge. By making a capacitor take longer to charge, you can measure time, which is a very important concept.

Clean the components off your breadboard and use it to set up the very simple circuit shown in Figure 2-78, where C1 is a 1,000 μF capacitor, R1 is a 100K resistor, R2 is a 100Ω resistor, and S1 is the pushbutton that you used previously. Set your meter to measure volts DC, place the probes around the capacitor, and hold down the pushbutton. You should see the meter counting upward as the voltage accumulates on the capacitor. (This is easier with a meter that doesn't have autoranging, because you won't have to wait while the meter figures out which range to apply.) Resistor R1 slows the charging time for the capacitor.

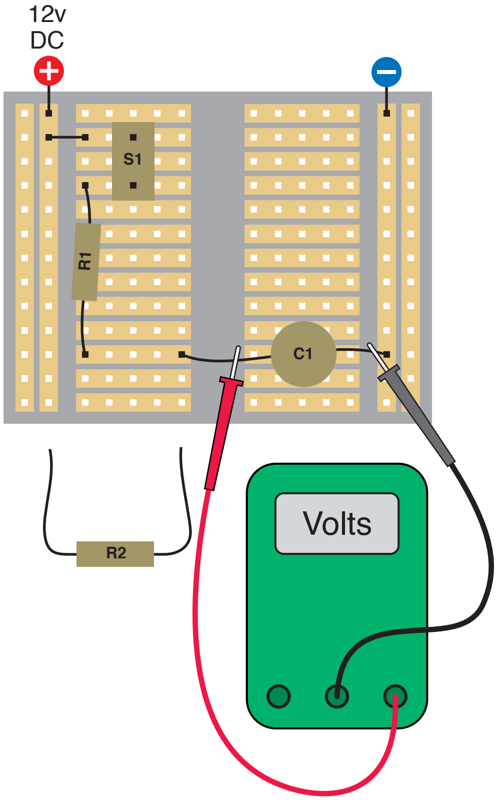

Figure 2-78. *Watch the voltage building up on the capacitor while you hold down the pushbutton. Substitute other values for R1, discharge the capacitor by touching R2 across it, and then repeat your measurement process.*

S1: Momentary pushbutton, OFF (ON)
R1: 100K initially
R2: 100Ω
C1: 1,000 μF

Release the pushbutton, set aside your meter, and discharge the capacitor by touching R2 across it for a second or two. Now substitute a 50K resistor for R1, and repeat the measurement. The meter should count upward almost twice as fast as before.

Voltage, Resistance, and Capacitance

Think of the resistor as a faucet, and the capacitor as a balloon that you are trying to fill with water. When you screw down the faucet until only a trickle comes through, the balloon will take longer to fill. But a slow flow of water will still fill the balloon completely if you wait long enough, and (assuming the balloon doesn't burst) the process ends when the pressure inside the balloon is equal to the water pressure in the pipe supplying the faucet. See Figure 2-79.

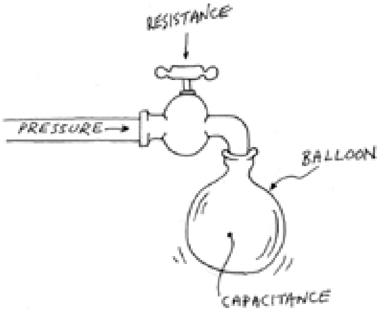

Figure 2-79. *When the faucet is closed half-way, the balloon will take longer to fill, but will still contain as much water and as much pressure in the end.*

Similarly, in your circuit, if you wait long enough, eventually the voltage across the capacitor should reach the same value as the voltage of the power supply. In a 12-volt circuit, the capacitor should eventually acquire 12 volts (although "eventually" may take longer than you think).

This may seem confusing, because earlier you learned that when you apply voltage at one end of a resistor, you get less voltage coming out than you have going in. Why should a resistor deliver the full voltage when it is paired with a capacitor?

Forget the capacitor for a moment, and remember how you tested just two 1K resistors. In that situation, each resistor contained half the total resistance of the circuit, so each resistor dropped half the voltage. If you held the negative probe of your meter against the negative side of your power supply and touched the positive probe to the center point between the two resistors, you would measure 6 volts. Figure 2-80 illustrates this.

Now, suppose you remove one of the 1K resistors and substitute a 9K resistor. The total resistance in the circuit is now 10K, and therefore the 9K resistor drops 90% of the 12 volts. That's 10.8 volts. You should try this and check it with your meter. (You are unlikely to find a 9K resistor, because this is not a standard value. Substitute the nearest value you can find.)

Now suppose you remove the 9K resistor and substitute a 99K resistor. Its voltage drop will be 99% of the available voltage, or 11.88 volts. You can see where this is heading: the larger the resistor, the larger its contribution to voltage drop.

However, I noted previously that a capacitor blocks DC voltage completely. It can accumulate an electrical charge, but no current passes through it. Therefore, a capacitor behaves like a resistor that has infinite resistance to DC current.

(Actually the insulation inside the capacitor allows a little bit of "leakage," but a perfect capacitor would have infinite resistance.)

The value of any resistor that you put in series with the capacitor is trivial by comparison. No matter how high the value of the resistor is, the capacitor still provides much more resistance in the circuit. This means that the capacitor steals almost the complete voltage drop in the circuit, and the voltage difference between one end of the resistor and the other will be zero (assuming that we ignore little imperfections in the components). Figure 2-80 may help to clarify this concept.

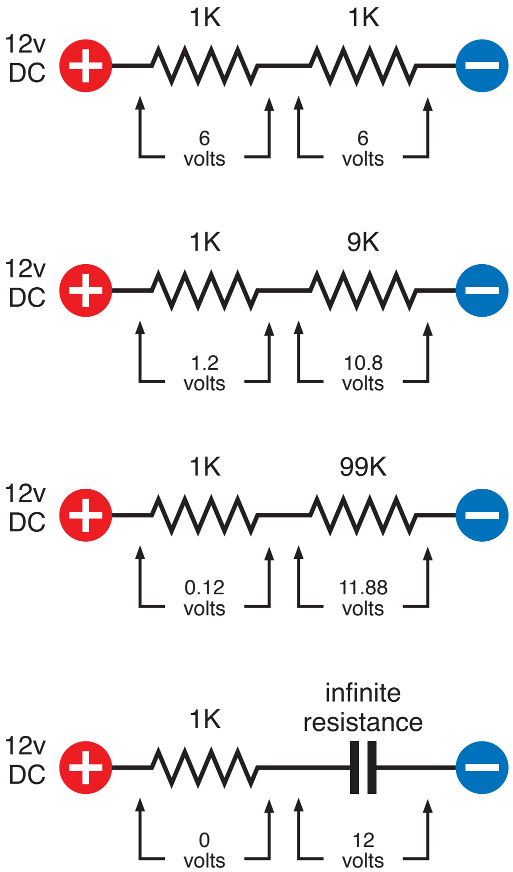

Figure 2-80. *When two resistances are in series, the larger one drops the voltage more than the smaller one. If the larger resistance becomes infinite (as in the case of a capacitor), the smaller one no longer has any measurable contribution to the voltage drop, and the voltage is almost exactly the same at both ends.*

You should try this using real resistors and capacitors—although if you do, you will run into a little problem. When you use your meter in its "DC volts" mode, it diverts a little of the current in the circuit—just a tiny taste—in the process of measuring it. The meter steals such a small amount, it doesn't affect the reading significantly when you are checking voltage across a resistor. The internal resistance of the meter is higher than the values of most resistors. However, remember that the internal resistance of a capacitor is almost infinite. Now the internal resistance of the meter becomes significant. Because you can never have an ideal meter, any more than you can have an ideal capacitor or resistor, your meter will always interfere with the circuit slightly, and you will get only an approximate indication.

If you try to measure the voltage on a capacitor that has been charged but is now not connected to anything else, you'll see the number slowly falling, as the capacitor discharges itself through the meter.

THEORY

The time constant

You may be wondering if there's a way to predict exactly how much time it takes for various capacitors to charge, when they are paired with various resistors. Is there a formula to calculate this?

Of course, the answer is yes, but the way we measure it is a bit tricky, because a capacitor doesn't charge at a constant rate. It accumulates the first volt very quickly, the second volt not quite as quickly, the third volt even less quickly—and so on. You can imagine the electrons accumulating on the plate of a capacitor like people walking into an auditorium and looking for a place to sit. The fewer seats that are left, the longer people take to find them.

The way we describe this is with something called a "time constant." The definition is very simple:

TC = R × C

where TC is the time constant, and a capacitor of C farads is being charged through a resistor of R ohms.

Going back to the circuit you just tested, try using it again, this time with a 1K resistor and the 1,000 µF capacitor. We have to change those numbers to farads and ohms before we can put them in the formula. Well, 1,000 µF is 0.001 farads, and 1K is 1,000 ohms, so the formula looks like this:

TC = 1,000 × 0.001

In other words, TC = 1—a lesson that could not be much easier to remember:

> ***A 1K resistor in series with a 1,000 µF capacitor has a time constant of 1.***

Does this mean that the capacitor will be fully charged in 1 second? No, it's not that simple. TC, the time constant, is the time it takes for a capacitor to acquire *63%* of the voltage being supplied to it, if it starts with zero volts.

(Why 63%? The answer to that question is too complicated for this book, and you'll have to read about time constants elsewhere if you want to know more. Be prepared for differential equations.) Here's a formal definition for future reference:

> TC, the time constant, is the time it takes for a capacitor to acquire 63% of the difference between its current charge and the voltage being applied to it. When TC=1, the capacitor acquires 63% of its full charge in 1 second. When TC=2, the capacitor acquires 63% of its full charge in 2 seconds. And so on.

What happens if you continue to apply the voltage? History repeats itself. The capacitor accumulates *another* 63% of the *remaining* difference between its current charge, and the voltage being applied to it.

Imagine someone eating a cake. In his first bite he's ravenously hungry, and eats 63% of the cake in one second. In his second bite, not wanting to seem too greedy, he takes just another 63% of the cake that is left—and because he's not feeling so hungry anymore, he requires the same time to eat it as he took to eat the first bite. In his third bite, he takes 63% of what still remains, and still takes the same amount of time. And so on. He is behaving like a capacitor eating electricity (Figure 2-81).

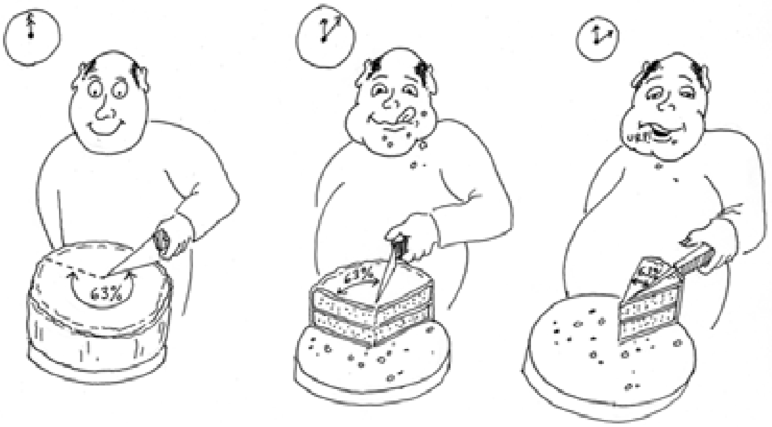

Figure 2-81. *If our gourmet always eats just 63% of the cake still on the plate, he "charges up" his stomach in the same way that a capacitor charges itself. No matter how long he keeps at it, his stomach is never completely filled.*

THEORY

The time constant (continued)

The cake eater will always have a few crumbs to eat, because he never takes 100% of the remainder. Likewise, the capacitor will never acquire a full charge. In a perfect world of perfect components, this process would continue for an infinite time.

In the real world, we say rather arbitrarily:

> After 5 × TC the capacitor will be so nearly fully charged, we won't care about the difference.

In the table is a calculation (rounded to two decimal places) showing the charge accumulating on a capacitor in a 12-volt circuit where the time constant is 1 second.

Here's how to understand the table. V1 is the current charge on the capacitor. Subtract this from the supply voltage (12 volts) to find the difference. Call the result V2. Now take 63% of V2, and add this to the current charge (V1) and call the result V4. This is the new charge that the capacitor will have after 1 second, so we copy it down to the next line in the table, and it becomes the new value for V1.

Now we repeat the same process all over again. Figure 2-82 shows this in graphical form. Note that after 5 seconds, the capacitor has acquired 11.92 volts, which is 99% of the power supply voltage. This should be close enough to satisfy anyone's real-world requirements.

If you try to verify these numbers by measuring the voltage across the capacitor as it charges, remember that because your meter steals a little current, there will be a small discrepancy that will increase as time passes. For practical purposes, the system works well enough.

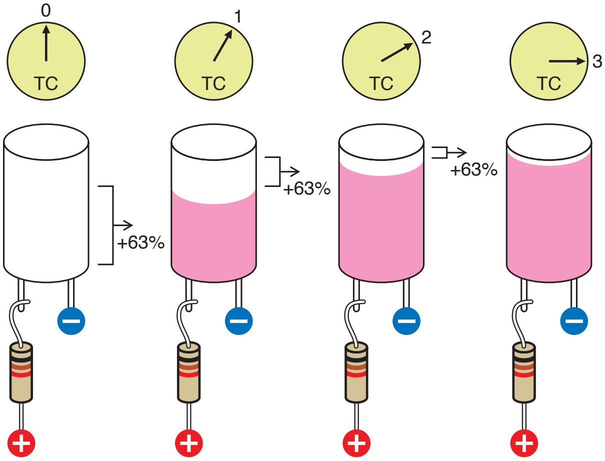

Figure 2-82. *A capacitor starts with 0 volts. After 1 time constant it adds 63% of the available voltage. After another time constant, it adds another 63% of the remaining voltage difference, and so on.*

Time in secs	V1: Charge on capacitor	V2: 12 – V1	V3: 63% of V2	V4: V1 + V3
0	0.00	12.00	7.56	7.56
1	7.56	4.44	2.80	10.36
2	10.36	1.64	1.03	11.39
3	11.39	0.61	0.38	11.77
4	11.77	0.23	0.15	11.92
5	11.92			

Experiment 10: Transistor Switching

You will need:

- AC adapter, breadboard, wire, and meter.
- LED. Quantity: 1.
- Resistors, various.
- Pushbutton, SPST. Quantity: 1.
- Transistor, 2N2222 or similar. Quantity: 1.

A transistor can switch a flow of electricity, just like a relay. But it's much more sensitive and versatile, as this first ultra-simple experiment will show.

We'll start with the 2N2222 transistor, which is the most widely used semiconductor of all time (it was introduced by Motorola in 1962 and has been in production ever since).

First, you should get acquainted with the transistor. Because Motorola's patents on the 2N2222 ran out long ago, any company can manufacture their own version of it. Some versions are packaged in a little piece of black plastic; others are enclosed in a little metal "can." (See Figure 2-83.) Either way, it contains a piece of silicon divided into three sections known as the collector, the base, and the emitter. I'll describe their function in more detail in a moment, but initially you just need to know that in this type of transistor, the collector receives current, the base controls it, and the emitter sends it out.

Use your breadboard to set up the circuit shown in Figure 2-85. Be careful to get the transistor the right way around! (See Figure 2-84.) For the three brands I have mentioned in the shopping list, the flat side should face right, if the transistor is packaged in black plastic, or the little tab should face toward the lower left, if the transistor is packaged in metal.

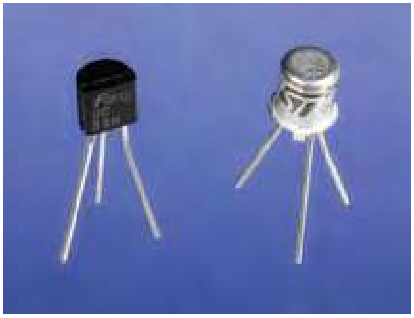

Figure 2-83. *A typical transistor is packaged either in a little metal can or a molded piece of black plastic. The manufacturer's data sheet tells you the identities of the three wire leads, relative to the flat side of a black plastic transistor or the tab that sticks out of a metal-can transistor.*

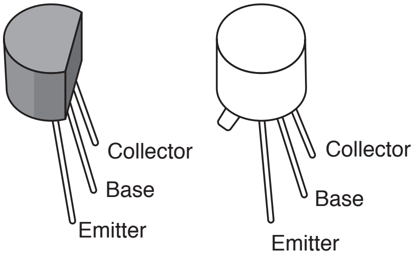

Figure 2-84. *The 2N2222 transistor may be packaged in either of these formats. Left: RadioShack or Fairchild. Right: STMicroelectronics (note the little tab sticking out at the lower-left side). If you use a different brand, you'll have to check the manufacturer's data sheet. Insert the transistor in your breadboard with the flat side facing right, as seen from above, or the tab pointing down and to the left, seen from above.*

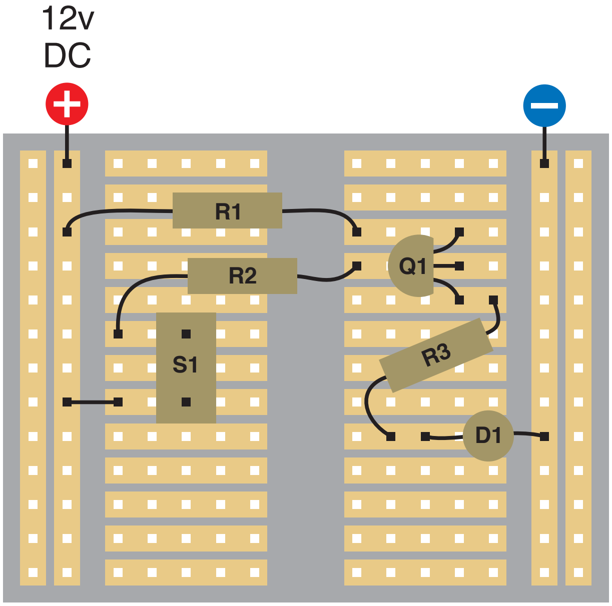

Figure 2-85. *The transistor blocks voltage that reaches it through R1. But when pushbutton S1 is pressed, this tells the transistor to allow current to pass through it. Note that transistors are always identified with letter Q in wiring diagrams and schematics.*

S1: Pushbutton, momentary, OFF (ON)
R1: 180Ω
R2: 10K
R3: 680Ω
Q1: 2N2222 or similar
D1: LED

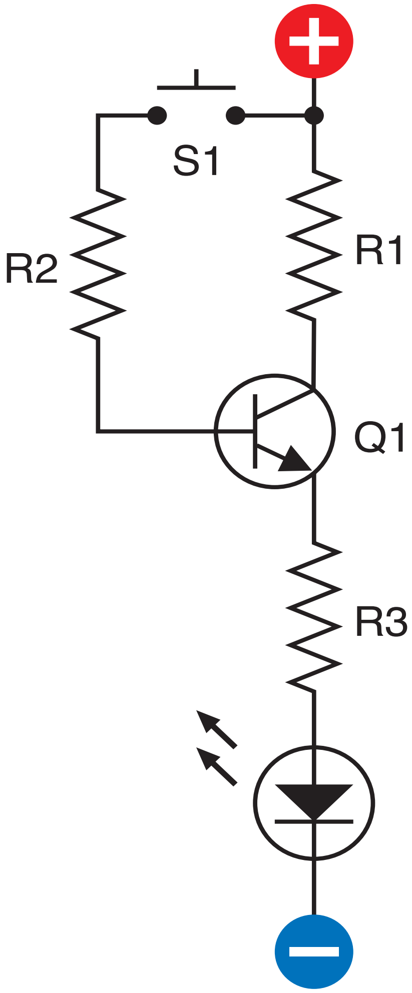

Figure 2-86. *This shows the same circuit as the breadboard diagram in Figure 2-85.*

Initially, the LED should be dark. Now press the pushbutton and the LED should glow brightly. Electricity is following two paths here. Look at the schematic in Figure 2-86, which shows the same circuit more clearly. I've shown positive at the top and negative at the bottom (the way most schematics do it) because it helps to clarify the function of this particular circuit. If you view the schematic from the side, the similarity with the breadboard layout is easier to see.

Through R1, voltage reaches the top pin (the collector) of the transistor. The transistor only lets a tiny trickle of it pass through, so the LED stays dark. When you press the button, voltage is also applied along a separate path, through R2 to the middle pin (the base) of the transistor. This tells the transistor to open its solid-state switch and allow current to flow out through its third pin (the emitter), and through R3, to the LED.

You can use your meter in volts DC mode to check the voltage at points in the circuit. Keep the negative probe from the meter touching the negative voltage source while you touch the positive probe to the top pin of the transistor, the middle pin, and the bottom pin. When you press the button, you should see the voltage change.

Fingertip Switching

Now here's something more remarkable. Remove R2 and the pushbutton, and insert two short pieces of of wire as shown in Figure 2-87. The upper piece of wire connects with the positive voltage supply; the lower piece connects with the middle pin of the transistor (its base). Now touch the tip of your finger to the two wires. Once again, the LED should glow, although not as brightly as before. Lick the tip of your finger, try again, and the LED should glow more brightly.

Never Use Two Hands

The fingertip switching demo is safe if the electricity passes just through your finger. You won't even feel it, because it's 12 volts DC from a power supply of 1 amp or less. But it's not a good idea to put the finger of one hand on one wire, and the finger of your other hand on the other wire. This would allow the electricity to pass through your body. Although the chance of hurting yourself this way is extremely small, you should never allow electricity to run through you from one hand to the other. Also, when touching the wires, don't allow them to penetrate your skin.

Your finger is conducting positive voltage to the base of the transistor. Even though your skin has a high resistance, the transistor still responds. It isn't just switching the LED on and off; it is *amplifying the current* applied to its base. This is an essential concept: *a transistor amplifies any changes in current that you apply to its base*.

Check Figure 2-88 to see more clearly what's happening.

If you studied the section "Background: Positive and negative" in Chapter 1, you learned that there is really no such thing as positive voltage. All we really have is negative voltage (created by the pressure of free electrons) and an absence of negative voltage (where there are fewer free electrons). But because the idea of a flow of electricity from positive to negative was so widely believed before the electron was discovered, and because the inner workings of a transistor involve "holes" which are an absence of electrons and can be thought of as positive, we can still pretend that electricity flows from positive to negative. See the following section, "Essentials: All about NPN and PNP transistors," for more details.

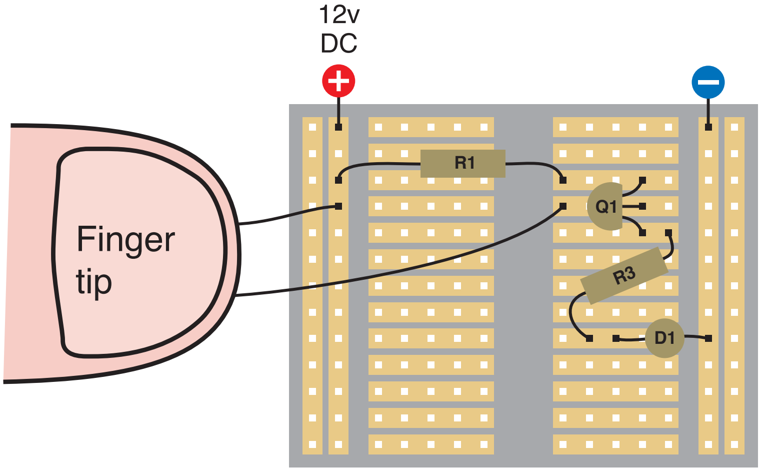

Figure 2-87

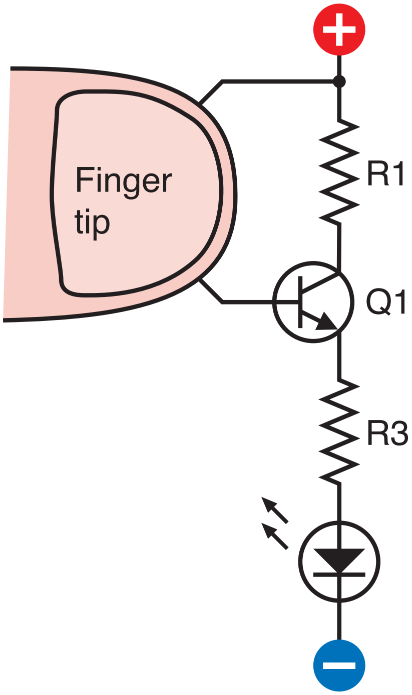

Figure 2-88. *These two diagrams show the same components as before, with a fingertip substituted for R2. Although only a trickle of voltage now reaches the base of the transistor, it's enough to make the transistor respond.*

ESSENTIALS

All about NPN and PNP transistors

A transistor is a semiconductor, meaning that sometimes it conducts electricity, and sometimes it doesn't. Its internal resistance varies, depending on the power that you apply to its base.

NPN and PNP transistors are bipolar semiconductors. They contain two slightly different variants of silicon, and conduct using both polarities of carriers—holes and electrons.

The NPN type is a sandwich with P-type silicon in the middle, and the PNP type is a sandwich with N-type silicon in the middle. If you want to know more about this terminology, and the behavior of electrons when they try to cross an NP junction or a PN junction, you'll have to read a separate source on this subject. It's too technical for this book. All you need to remember is:

- All bipolar transistors have three connections: Collector, Base, and Emitter, abbreviated as C, B, and E on the manufacturer's data sheet, which will identify the pins for you.
- NPN transistors are activated by *positive* voltage on the base relative to the emitter.
- PNP transistors are activated by *negative* voltage on the base relative to the emitter.

In their passive state, both types block the flow of electricity between the collector and emitter, just like an SPST relay in which the contacts are normally open. (Actually a transistor allows a tiny bit of current known as "leakage.")

You can think of a bipolar transistor as if it contains a little button inside, as shown in Figures 2-89 and 2-90. When the button is pressed, it allows a large current to flow. To press the button, you inject a much smaller current into the base by applying a small voltage to the base. In an NPN transistor, the control voltage is positive. In a PNP transistor, the control voltage is negative.

NPN transistor basics

- To start the flow of current from collector to emitter, apply a relatively positive voltage to the base.
- In the schematic symbol, the arrow points from base to emitter and shows the direction of positive current.
- The base must be at least 0.6 volts "more positive" than the emitter, to start the flow.
- The collector must be "more positive" than the emitter.

PNP transistor basics

- To start the flow of current from emitter to collector, apply a relatively negative voltage to the base.
- In the schematic symbol, the arrow points from emitter to base and shows the direction of positive current.
- The base must be at least 0.6 volts "more negative" than the emitter, to start the flow.
- The emitter must be "more positive" than the collector.

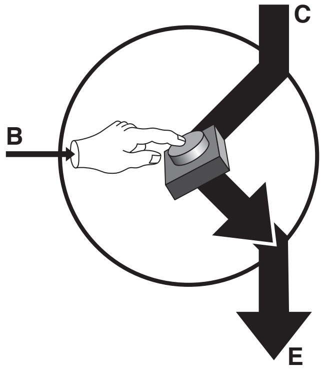

Figure 2-89. *You can think of a bipolar transistor as if it contains a button that can connect the collector and the emitter. In an NPN transistor, a small positive potential presses the button.*

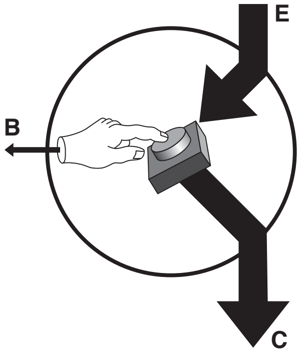

Figure 2-90. *In a PNP transistor, a small negative potential has the same effect. The arrows point in the direction of "positive current flow."*

ESSENTIALS

All about NPN and PNP transistors (continued)

All-transistor basics

- Never apply a power supply directly across a transistor. You can burn it out with too much current.
- Protect a transistor with a resistor, in the same way you would protect an LED.
- Avoid reversing the connection of a transistor between positive and negative voltages.
- Sometimes an NPN transistor is more convenient in a circuit; sometimes a PNP happens to fit more easily. They both function as switches and amplifiers, the only difference being that you apply a relatively positive voltage to the base of an NPN transistor, and a relatively negative voltage to the base of a PNP transistor.
- PNP transistors are used relatively seldom, mainly because they were more difficult to manufacture in the early days of semiconductors. People got into the habit of designing circuits around NPN transistors.
- Remember that bipolar transistors amplify current, not voltage. A small fluctuation of current through the base enables a large change in current between emitter and collector.
- Schematics sometimes show transistors with circles around them, and sometimes don't. In this book, I'll use circles to draw attention to them. See Figures 2-91 and 2-92.
- Schematics may show the emitter at the top and the collector at the bottom, or vice versa. The base may be on the left, or on the right, depending on what was most convenient for the person drawing the schematic. Be careful to look carefully at the arrow in the transistor to see which way up it is, and whether it is NPN or PNP. You can damage a transistor by connecting it incorrectly.
- Transistors come in various different sizes and configurations. In many of them, there is no way to tell which wires connect to the emitter, the collector, or the base, and some transistors have no part numbers on them. Before you throw away the packaging that came with a transistor, check to see whether it identifies the terminals.
- If you forget which wire is which, some multimeters have a function that will identify emitter, collector, and base for you. Check your multimeter instruction booklet for more details.

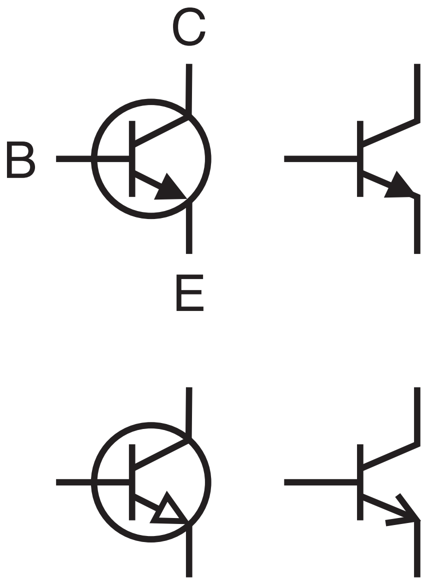

Figure 2-91. *The symbol for an NPN transistor always has an arrow pointing from its base to its emitter. Some people include a circle around the transistor; others don't bother. The style of the arrow may vary. But the meaning is always the same. The top-left version is the one I use in this book.*

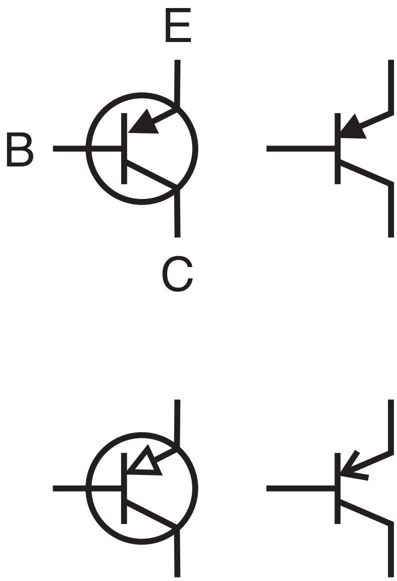

Figure 2-92. *The symbol for a PNP transistor always has an arrow pointing from its emitter to its base. Some people include a circle around the transistor; others don't bother. The style of the arrow may vary. But the meaning is always the same. The top-left version is the one I use in this book.*

BACKGROUND

Transistor origins

Though some historians trace the origins of the transistor back to the invention of diodes (which allow electricity to flow in one direction while preventing reversal of the flow), there's no dispute that the first working transistor was developed at Bell Laboratories in 1948 by John Bardeen, William Shockley, and Walter Brattain (Figure 2-93).

Shockley was the leader of the team, who had the foresight to see how potentially important a solid-state switch could be. Bardeen was the theorist, and Brattain actually made it work. This was a hugely productive collaboration—until it succeeded. At that point, Shockley started maneuvering to have the transistor patented exclusively under his own name. When he notified his collaborators, they were—naturally—unhappy about this idea.

A widely circulated publicity photograph didn't help, in that it showed Shockley sitting at the center in front of a microscope, as if he had done the hands-on work, while the other two stood behind him, implying that they had played a lesser role. In fact Shockley, as the supervisor, was seldom present in the laboratory where the real work was done.

The productive collaboration quickly disintegrated. Brattain asked to be transferred to a different lab at AT&T. Bardeen moved to the University of Illinois to pursue theoretical physics. Shockley eventually left Bell Labs and founded Shockley Semiconductor in what was later to become Silicon Valley, but his ambitions outstripped the capabilities of the technology of his time. His company never manufactured a profitable product.

Eight of Shockley's coworkers in his company eventually betrayed him by quitting and establishing their own business, Fairchild Semiconductor, which became hugely successful as a manufacturer of transistors and, later, integrated circuit chips.

Figure 2-93. *Photographs provided by the Nobel Foundation show, left to right, John Bardeen, William Shockley, and Walter Brattain. For their collaboration in development of the world's first working transistor in 1948, they shared a Nobel prize in 1956.*

ESSENTIALS

Transistors and relays

One limitation of NPN and PNP transistors is that they are naturally "off" until you turn them "on." They behave like a normally open pushbutton, which conducts electricity only for as long as you hold it down. They don't normally behave like a normal on switch, which stays on until you apply a signal to turn it off.

A relay offers more switching options. It can be normally open, normally closed, or it can contain a double-throw switch, which gives you a choice of two "on" positions. It can also contain a double-pole switch, which makes (or breaks) two entirely separate connections when you energize it. Single-transistor devices cannot provide the double-throw or double-pole features, although you can design more complex circuits that emulate this behavior.

Here's a list of transistor and relay characteristics.

	Transistor	Relay
Long-term reliability	Excellent	Limited
Configurable for DP and DT switching	No	Yes
Ability to switch large currents	Limited	Good
Able to switch alternating current (AC)	Usually not	Yes
Can be triggered by alternating current (AC)	Usually not	Optional
Suitability for miniaturization	Excellent	Very limited
Sensitive to heat	High	Moderate
Ability to switch at high speed	Excellent	Limited
Price advantage for low-voltage low-current	Yes	No
Price advantage for high-voltage high-current	No	Yes
Current leakage when "off"	Yes	No

The choice between relays or transistors will depend on each particular application.

THEORY

See the current

If you want to get a more precise understanding of how a transistor works, you should try this little test. It shows the precise behavior and limits of the 2N2222 transistor that you used in the previous experiment.

I've said that in an NPN transistor, the collector should always be more positive than the emitter and that the base should have a potential somewhere between those two voltages. Figure 2-94 shows this rather vague relationship. Now I want to substitute some numbers for these general statements.

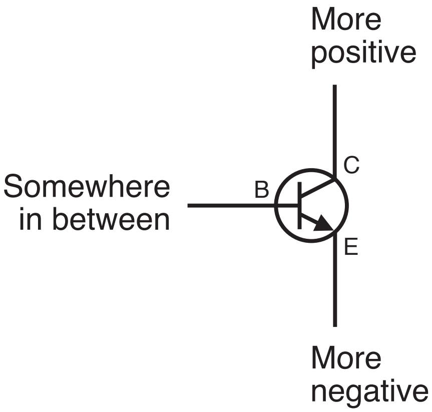

Figure 2-94. *The proper functioning of an NPN transistor requires you to maintain these voltage relationships.*

Take a look at the schematic in Figure 2-95, and check the component values. Notice that the total resistance above the transistor, from R1 + R2, is the same as the total resistance below it, from R3 + R4. Therefore the potential on the base of the transistor should be halfway between the two extremes—until you use potentiometer P1 to adjust the voltage of the base of the transistor up and down.

The two 180Ω resistors, R1 and R3, protect the transistor from passing excessive current. The two 10K resistors, R2 and R4, protect the base when the potentiometer is turned all the way up or all the way down.

I would like you to see what the transistor is doing by measuring the amperage flowing into the base at the position marked A1, and the total amperage flowing out through the emitter at the position marked A2. To do this, it would be really helpful if you had two meters. As that may be impractical, the breadboard diagrams in Figures 2-96 and 2-97 show how you can swap one meter between the two locations.

Remember that to measure milliamps, you have to pass electricity through the meter. This means that the meter must be inserted into the circuit, and whenever you remove the meter, you have to remake the connection where the meter was. The breadboard diagram shows how you can do this. Fortunately, it's very easy to remove and replace wires in a breadboard. Where wires are connected to the potentiometer, you may need to revert to using alligator clips.

Begin with the potentiometer turned about halfway through its range. Measure at A1 and A2. Turn the potentiometer up a bit, and measure current at the two locations again. Following is a table showing some actual readings I obtained at those two locations, using two digital meters simultaneously.

Milliamps passing through location A1	Milliamps passing through location A2
0.01	1.9
0.02	4.9
0.03	7.1
0.04	9.9
0.05	12.9
0.06	15.5
0.07	17.9
0.08	19.8
0.09	22.1
0.10	24.9
0.11	26.0
0.12	28.3

There's a very obvious relationship. The current emerging from the emitter of the transistor, through location A2, is about 24 times the current passing through location A1, into the base. The ratio of current coming out from the emitter of an NPN transistor to current going into the base is known as the *beta value* for a transistor. The beta value expresses the transistor's amplifying power.

It's a very constant ratio, until you push it a little too far. Above 0.12 mA, this particular transistor becomes "saturated," meaning that its internal resistance cannot go any lower.

THEORY

See the current (continued)

In my little experiment, I found that the maximum current at A2 was 33mA. A simple calculation using Ohm's Law showed me that this meant the transistor's internal resistance was near zero. This is why you should protect a transistor with some additional resistance in the circuit. If you don't, its low internal resistance would allow a huge current flow that would immediately burn it out.

What about the other end of its range? When it passes only 1.9 mA, the transistor has an internal resistance of around 6,000Ω. The conclusion is that depending how much current you apply to this transistor, its internal resistance varies between zero and 6,000Ω, approximately.

So much for the theory. Now what can we do with a transistor that's fun, or useful, or both? We can do Experiment 11!

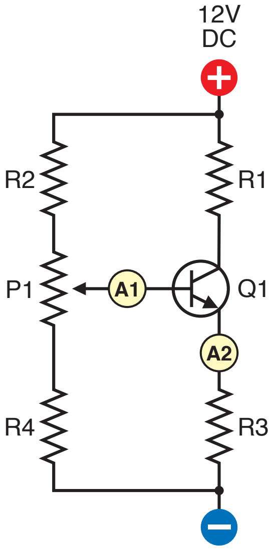

Figure 2-95. *This is basically the same as the previous circuit, with a potentiometer added and the LED removed. Component values:*

R1: 180Ω
R2: 10K
R3: 180Ω
R4: 10K
P1: 1M linear potentiometer
Q1: 2N2222 transistor

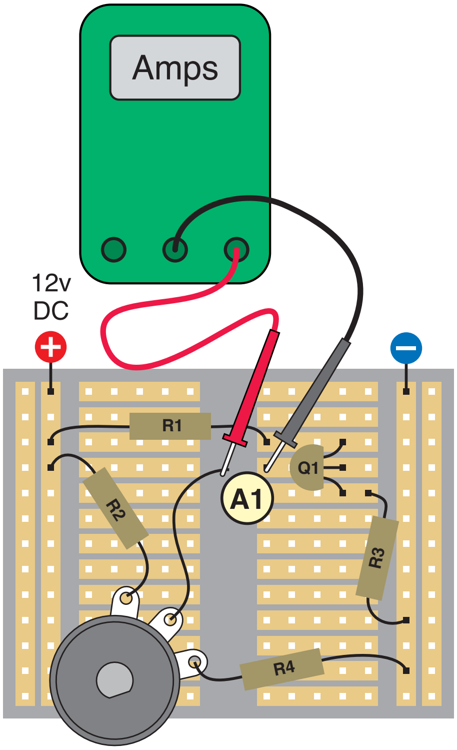

Figure 2-96. *The meter is measuring current flowing from the potentiometer into the base of the transistor at position A1 (see Figure 2-95).*

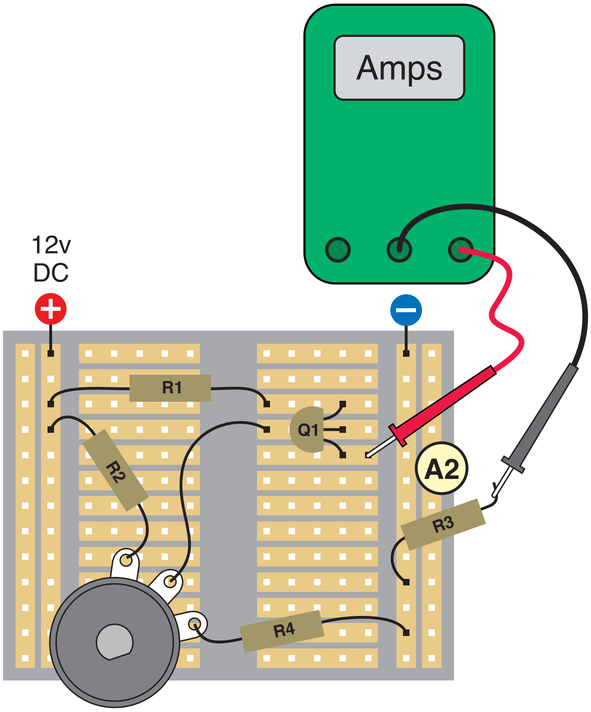

Figure 2-97. *One end of resistor R3 has been unplugged from the breadboard so that the meter now measures current flowing out through the emitter of the transistor, into R3, at position A2.*

Experiment 11: A Modular Project

You will need:

- AC adapter, breadboard, wire, and meter.
- LED. Quantity: 1.
- Resistors, various.
- Capacitors, various.
- Transistor, 2N2222 or similar. Quantity: 2.
- 2N6027 programmable unijunction transistor (PUT). Quantity: 2.
- Miniature 8Ω loudspeaker. Quantity: 1.

So far, I've described small circuits that perform very simple functions. Now it's time to show how modules can be combined to create a device that does a bit more.

The end product of this experiment will be a circuit that makes a noise like a small siren, which could be used in an intrusion alarm. You may or may not be interested in owning an alarm, but the four-step process of developing it is important, because it shows how individual clusters of components can be persuaded to communicate with each other.

I'll begin by showing how to use a transistor to make a solid-state version of the oscillating circuit that you built with a relay in Experiment 8. The relay, you may remember, was wired in such a way that the coil received power through the contacts of the relay. As soon as the coil was energized, it opened the contacts, thus cutting off its own power. As soon as the contacts relaxed they restored the power, and the process repeated itself.

There's no way to do this with a single bipolar transistor. You actually need two of them, switching each other on and off, and the way that this works is quite hard to understand. An easier option is to use a different thing known as a programmable unijunction transistor, or PUT.

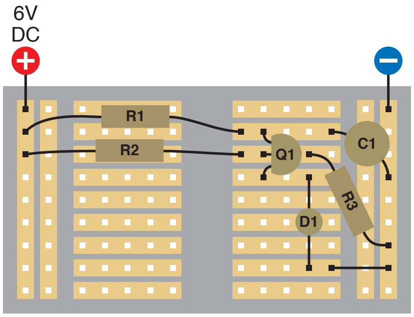

Figure 2-98. *Assemble these components, apply power, and the LED should start flashing.*

R1: 470K
R2: 15K
R3: 27K
C1: 2.2 μF electrolytic capacitor
D1: LED
Q1: 2N6027 programmable unijunction transistor

Unijunction transistors were developed during the 1950s, but fell into disuse when simple silicon chips acquired the ability to perform the same kinds of functions, more accurately and more cheaply. However, the so-called programmable unijunction transistor is still widely available, often used in applications such as lamp dimmers and motor controllers. Because its primary use is in generating a stream of pulses, it's ideal for our purposes.

If you put together the components shown in Figure 2-98, the LED should start flashing as soon as you apply power.

Note that this circuit will work on 6 volts. You won't damage anything if you run it with 12 volts, but as we continue adding pieces to it, you'll find that it actually performs better at 6 volts than at 12. If you read the next section, "Essentials: All about programmable unijunction transistors," you'll find out how the circuit works.

ESSENTIALS

All about programmable unijunction transistors

The schematic symbol for a programmable unijunction transistor, or PUT, looks very different from the symbol for a bipolar transistor, and its parts are named differently, too. Nevertheless, it does have a similar function as a solid-state switch. The symbol and the names of the three connections are shown in Figure 2-99.

Note that this is a rare case (maybe the only one in the whole of electronics!) in which you won't run into confusing variations of the basic schematic symbol. A PUT always seems to look the way I've drawn it here. Personally I think it would be clearer if we added a circle around it, but no one seems to do that, so I won't, either.

The 2N6027 is probably the most common PUT, and seems to be standardized in its packaging and pin-outs. I've only seen it in a plastic module rather than a little tin can. Figure 2-100 shows the functions of the leads if your 2N6027 is manufactured by Motorola or On Semiconductor. If you have one from another source, you should check the data sheet.

Note that the flat side of the plastic module faces the opposite way around compared with the 2N2222 bipolar transistor, when the two devices are functioning similarly.

The PUT blocks current until its internal resistance drops to allow flow from the "anode" to the "cathode." In this way, it seems very similar to an NPN transistor, but there's a big difference in the circumstances that cause the PUT to lower its resistance. The voltage at the anode determines when the PUT allows current to flow.

Suppose you start with, say, 1 volt at the anode. Slowly, you increase this voltage. The transistor blocks it until the anode gets close to 6 volts. Suddenly this pressure breaks down the resistance and current surges from the anode to the cathode. If the voltage goes back down again, the transistor reverts to its original state and blocks the flow.

I've included another version of the "finger on the button" drawing to convey this concept. The voltage on the anode is itself responsible for pushing the button that opens the pathway to the cathode. See Figure 2-101.

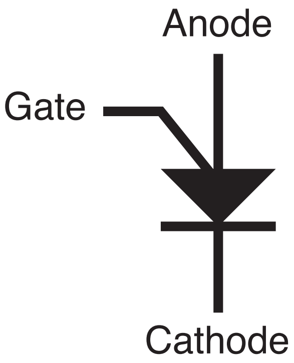

Figure 2-99. *The schematic symbol for a PUT.*

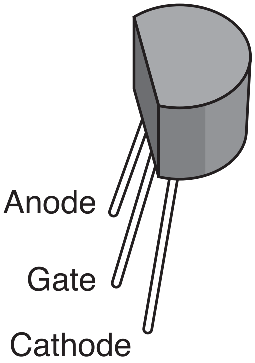

Figure 2-100. *In PUTs manufactured by On Semiconductor and Motorola, the leads have these functions.*

ESSENTIALS

All about programmable unijunction transistors (continued)

This may cause you to wonder what the function of the gate is. You can think of it as "assisting" the finger on the button. In fact, the gate is the "programmable" part of a PUT. By choosing a voltage for the gate, you establish the threshold point when current starts to flow.

Here's a simple take-home summary:

- The anode has to be more positive than the cathode, and the gate should be between those two extremes.
- If anode voltage increases above a threshold point, current bursts through and flows from the anode to the cathode.
- If anode voltage drops back down below the threshold, the transistor stops the flow.
- The voltage you apply to the gate determines how high the threshold is.
- The gate voltage is adjusted with two resistors, shown as R1 and R2 in the simple schematic in Figure 2-102. Typically, each resistor is around 20K. The PUT is protected from full positive voltage by R3, which can have a high value, 100K or greater, because very little current is needed to bias the transistor.
- You add your input signal in the form of positive voltage at the anode. When it exceeds the threshold, it flows out of the cathode and can work some kind of output device.

The only remaining question is how we make a PUT oscillate, to create a stream of on/off pulses. The answer is the capacitor that you included in the circuit that you breadboarded at the beginning of Experiment 11.

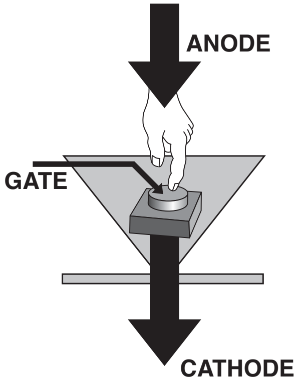

Figure 2-101. *When voltage at the anode of a PUT crosses a threshold (determined by a preset voltage at the gate), current breaks through and surges from the anode to the cathode. In this sense, the anode voltage acts as if it presses a button itself to open a connection inside the PUT, with some assistance from control voltage at the gate.*

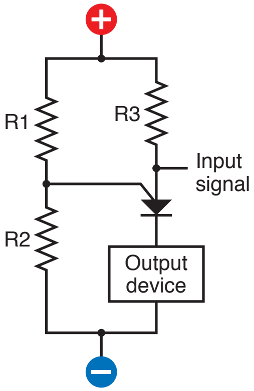

Figure 2-102. *This simple schematic shows how a PUT is used. R1 and R2 determine the voltage at the gate, which sets the threshold point for the input at the anode. Above the threshold, current flows from anode to cathode.*

Step 1: Slow-Speed Oscillation

Figure 2-103 is a schematic version of the previous PUT breadboard circuit shown in Figure 2-98, drawn so that the layout looks as much like the breadboard as possible.

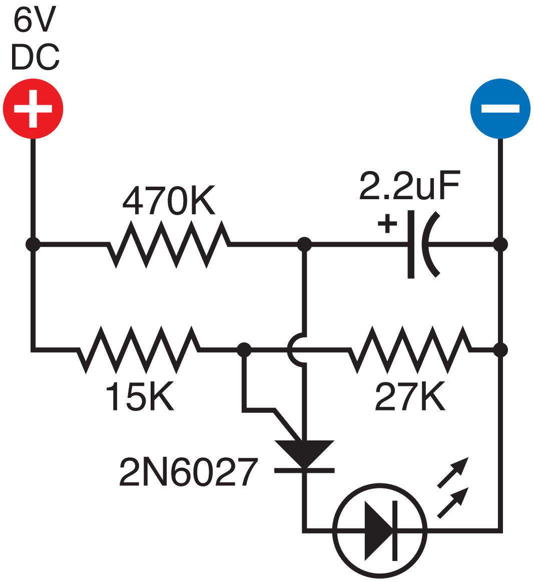

Figure 2-103. *This makes it easier to see what's happening in the breadboard version.*

The 15K resistor and 27K resistor establish the voltage at the gate. The 470K resistor supplies the anode of the PUT, but the PUT begins in its "off" condition, blocking the voltage. So the voltage starts to charge the 2.2 μF capacitor.

You may remember that a resistor slows the rate at which a capacitor accumulates voltage. The bigger the resistor and/or the larger the capacitor, the longer the capacitor takes to reach a full charge. In this circuit, the capacitor takes about half a second to get close to 6 volts.

But notice that the PUT is connected directly with the capacitor. Therefore, whatever voltage accumulates on the capacitor is also experienced by the PUT. As the voltage gradually increases, finally it reaches the threshold, which flips the PUT into its "on" state. The capacitor immediately discharges itself through the PUT, through the LED (which flashes), and from there to the negative side of the power supply.

The surge depletes the capacitor. The voltage drops back down, and the PUT returns to its original state. Now the capacitor has to recharge itself all over again, until the whole process repeats itself.

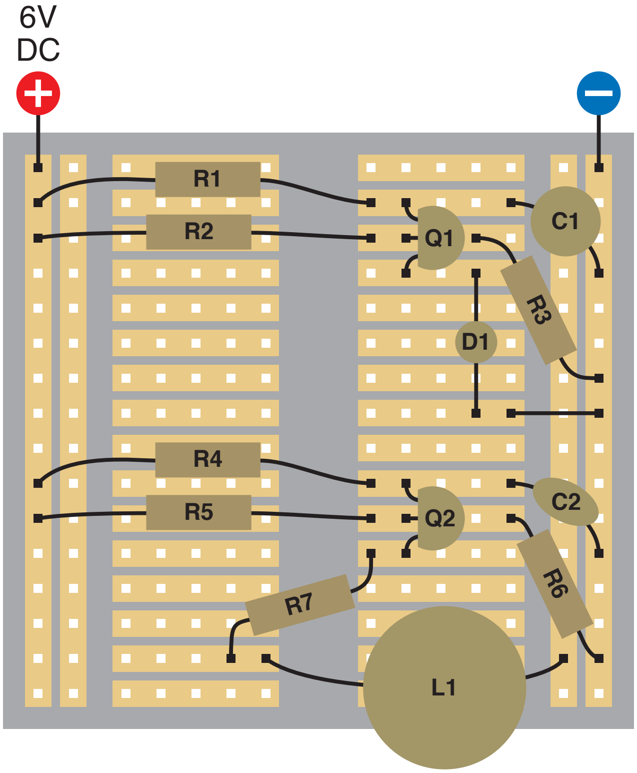
If you substitute a 22 μF capacitor, the charge/discharge cycle should take about 10 times as long, which will give you time to measure it. Set your meter to measure volts DC and place its probes on either side of the capacitor. You can actually watch the charge increasing until it reaches the threshold, at which point the capacitor discharges and the voltage drops back down again.

So now we have an oscillator. What's next?

Step 2: Beyond the Persistence of Vision

If you substitute a much smaller capacitor, it will charge much more quickly, and the LED will flash faster. Suppose you use a capacitor of 0.0047 µF (which can also be expressed as 47 nanofarads, or 47 nF). This seems like an odd number, but it's a standard value for a capacitor. This will reduce the capacitance by a factor of more than 500, and therefore the LED should flash about 500 times as fast, which should be about 1,000 times per second. The human eye cannot detect such rapid pulses. The human ear, however, can hear frequencies up to 10,000 per second and beyond. If we substitute a miniature loudspeaker for the LED, we should be able to hear the oscillations.

Figure 2-104 shows how I'd like you to make this happen. Please leave your original, slow-flashing circuit untouched, and make a duplicate of it farther down the breadboard, changing a couple of component values as indicated. In the schematic in Figure 2-105, the new part of the circuit is in solid black, while the previous section is in gray.



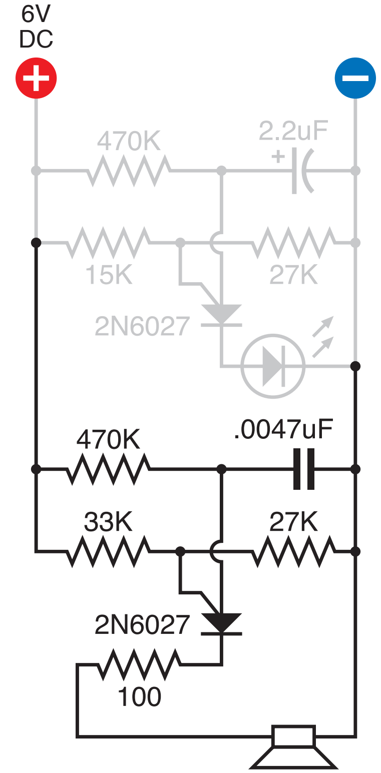


Figure 2-104. *The extra components which have been added at the lower half of the breadboard have the same functions as the components at the top, but some values are slightly different:*

R4: 470K
R5: 33K
R6: 27K
R7: 100Ω
C2: 0.0047 µF
Q2: 2N6027
L1: 8Ω 1-inch loudspeaker

Figure 2-105. *The previous section that you built is shown in gray. Just add the new section in black.*

I want you to keep the slow-flashing circuit separately, untouched, because I have an idea to make use of it a little later. You can leave the LED blinking.

The loudspeaker should be wired in series with a 100Ω resistor to limit the current that flows out of the PUT. The loudspeaker doesn't have any polarity, even though it is fitted with a red wire and a black wire. You can connect it either way around.

Initially, you may be disappointed, because the circuit will not seem to be doing anything. However, if you place your ear very, very close to the loudspeaker, and if you wired the circuit correctly, you should hear a faint buzz, like a mosquito. Obviously, this isn't loud enough to serve any practical purpose. We need to make it louder. In other words, we need to amplify it.

Maybe you remember that the 2N2222, which you played with previously, can function as an amplifier. So let's try using that.

Step 3: Amplification

Disconnect the loudspeaker and its 100Ω series resistor. Then add the 2N2222, which is linked with the output from the PUT via a 1K resistor to protect it from excessive current. See Figure 2-107.

The emitter of the 2N2222 is connected to ground, and the collector is supplied through the loudspeaker and its 100Ω series resistor. This way, small fluctuations in the output from the PUT are sensed by the base of the 2N2222 which converts them into bigger fluctuations between the collector and the emitter, which draw current through the loudspeaker. Check the schematic in Figure 2-108.

Now the sound should be louder than an insect buzz, but still not really loud enough to be useful. What to do?

Well—how about if we add another 2N2222? Bipolar transistors can be placed in series, so that the output from the first one goes to the base of the second one. The 24:1 amplification of the first one is multiplied by another 24:1, giving a total amplification of more than 500:1.

There are limits to this technique. The 2N2222 can only conduct so much current before getting overloaded, and excess amplification can cause distortion. But when I built this circuit, I used a meter to verify that we're still within the design limits of a 2N2222, and for this project, I don't care whether the sound is slightly distorted.

BACKGROUND

Mounting a loudspeaker

The diaphragm or cone of a loudspeaker is designed to radiate sound, but as it oscillates to and fro, it emits sound from its back side as well as its front side. Because the sounds are opposite in phase, they tend to cancel each other out.

The perceived output from a loudspeaker can increase dramatically if you add a horn around it in the form of a tube to separate the output from the front and back of the speaker. For a miniature 1-inch loudspeaker, you can bend and tape a file card around it. See Figure 2-106.

Better still, mount it in a box so that the box absorbs the sound from the rear of the loudspeaker. For purposes of these simple experiments, I won't bother to go into the details of vented enclosures and bass-reflex designs.

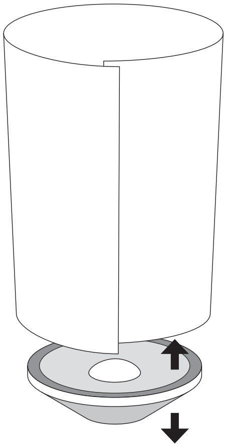

Figure 2-106. *A loudspeaker emits sound from its bottom surface as well as its top surface. To increase the perceived audio volume, use a cardboard tube to separate the two sound sources, or mount the speaker in a small box.*

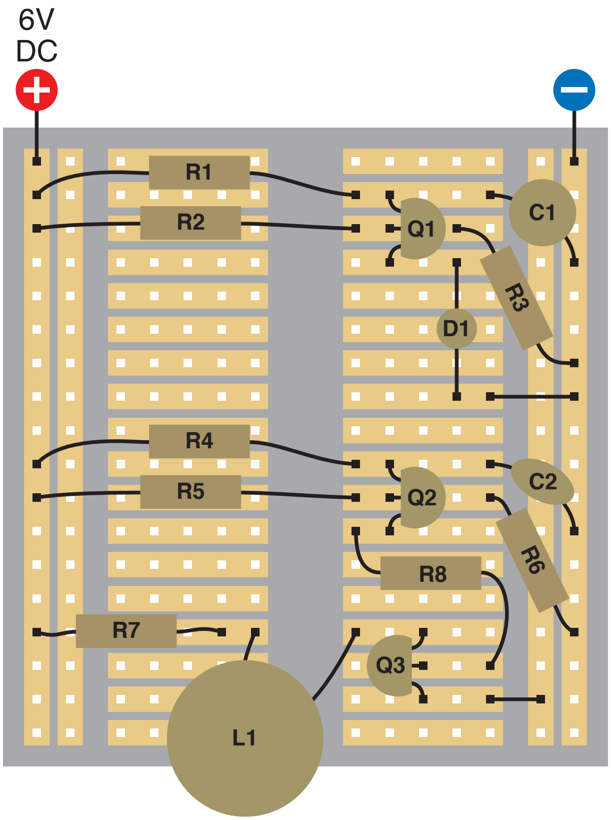

Figure 2-107. *By adding a 2N2222 general-purpose transistor, we amplify the signal from Q2:*

R8: 1K
Q3: 2N2222

Other components are the same as in the previous step in constructing this circuit.

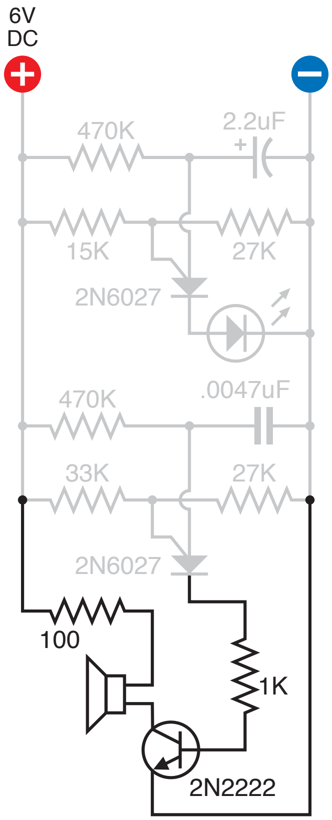

Figure 2-108

Add the second 2N2222 as shown in Figure 2-109. In Figure 2-110, once again the previously wired section is in gray.

If the accumulation of electrical components is beginning to seem confusing, remember that each cluster of parts has a separate defined function. We can draw a block diagram to illustrate this, as in Figure 2-112.

Using the second 2N2222, you should find that the output is more clearly audible, at least within the limits of your tiny 1-inch loudspeaker. Cup your hands around it to direct the sound, and you'll find that the volume seems to increase. You can also try using a 3-inch loudspeaker, which will create a generally better audio output while still remaining within the limits of the little 2N2222 transistor. See Figure 2-106, shown previously, and Figure 2-111.

Figure 2-111. *The 2N2222 transistor is quite capable of driving a 3-inch loudspeaker, which will create much better sound than a 1-inch speaker.*

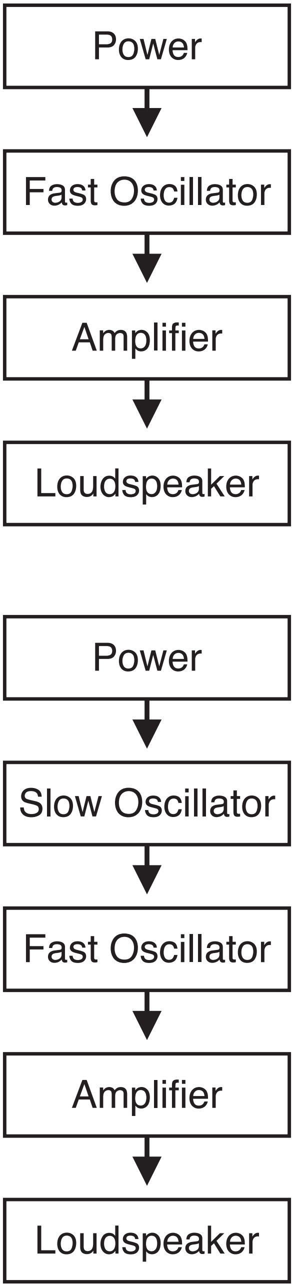

Figure 2-112. *Top: The basic functions of the noisemaking oscillator circuit shown as a block diagram. Bottom: The same functions with a slow oscillator added to control the fast oscillator.*

Step 4: Pulsed Output

If you wanted to use this audio signal as some kind of an alarm, a steady droning noise is not very satisfactory. A pulsing output would be a much better attention-getter.

Well, the first section of the circuit that you assembled created a pulsing signal about twice per second. You used it to flash an LED. Maybe we can get rid of the LED and feed the output from the first section to the second section. The lower block diagram in Figure 2-112 explains this concept.

Can it really be that simple? Well, yes and no. The trick is to make the output from the first section compatible with the input to the second section. If you simply connect a wire from the cathode of the first PUT to the anode of the second PUT, that's not going to work, because the second PUT is already oscillating nicely between low and high voltage, about 1,000 times each second. Add more voltage, and you will disrupt the balance that enables oscillation.

However, remember that the voltage on the gate of a PUT affects its threshold for conducting electricity. Maybe if we connect the output from Q1 to the gate of Q2, we'll be able to adjust that threshold automatically. The voltage still has to be in a range that the PUT finds acceptable, though. We can try various resistors to see which one works well.

This sounds like trial and error—and that's exactly what it is. Doing the math to predict the behavior of a circuit like this is far too complicated—for me, anyway. I just looked at the manufacturer's data sheet, saw the range of resistor values that the PUT would tolerate, and chose one that seemed as if it should work.

If you remove the LED and substitute R10 as shown in the breadboard diagram in Figure 2-113, you'll find that the fluctuating output from Q1 makes Q2 emit a two-tone signal. This is more interesting, but still not what I want. I'm thinking that if I make the pulses out of Q1 less abrupt, the result could be better, and the way to smooth a pulsing output is to hook up another capacitor that will charge at the beginning of each pulse and then release its charge at the end of each pulse. This is the function of C3 in Figure 2-114, and it completes the circuit so that it makes a whooping sound almost like a "real" alarm.

If you don't get any audio output, check your wiring very carefully. It's easy to make a wrong connection on the breadboard, especially between the three legs of each transistor. Use your meter, set to DC volts, to check that each section of the circuit has a positive voltage relative to the negative side of the power supply.

Figure 2-115 shows how your circuit should actually look on the breadboard.

Tweaking it

There's still a lot of room for creativity here:

- Adjust the frequency of the sound: Use a smaller or larger capacitor instead of C2 (half or twice the current value). Use a smaller or larger value for R5.
- Adjust the pulsing feature: Use a smaller or larger capacitor instead of C1 (half or twice the current value). Use a smaller or larger value for R2.
- General performance adjustments: try a larger value for R1. Try smaller or larger values for C3.
- Try running the circuit at 7.5 volts, 10 volts, and 12 volts.

The circuits in this book are suggested as only a starting point. You should always try to tweak them to make them your own. As long as you follow the general rule of protecting transistors and LEDs with resistors, and respecting their requirements for positive and negative voltage, you're unlikely to burn them out. Of course, accidents will happen—I myself tend to be careless, and fried a couple of LEDs while working on this circuit, just because I connected them the wrong way around.

Step 5: Enhancements

A noisemaking circuit is just the output of an alarm. You would need several enhancements to make it useful:

1. Some kind of an intrusion sensor. Maybe magnetic switches for windows and doors?
2. A way to start the sound if any one of the sensors is triggered. The way this is usually done is to run a very small but constant current through all of the switches in series. If any one switch opens, or if the wire itself is broken, this interrupts the current, which starts the alarm. You could make this happen with a double-throw relay, keeping the relay energized all the time until the circuit is broken, at which point, the relay relaxes, opening one pair of contacts and closing the other pair, which can send power to the noisemaker.

   The trouble is that a relay draws significant power while it's energized, and it also tends to get hot. I want my alarm system to draw very little current while it's in "ready" mode, so that it can be powered by a battery. Alarm systems should never depend entirely on AC house current.

   If we don't use a relay, can we use a transistor to switch on the rest of the circuit when the power is interrupted? Absolutely; in fact, one transistor will do it.
3. But how do we arm the alarm in the first place? Really, we need a three-step procedure. First, check a little light that comes on when all the doors and windows are closed. Second, press a button that starts a 30-second countdown, giving you time to leave, if that's what you want to do. And third, after 30 seconds, the alarm arms itself.

4. If the alarm is triggered, what then? If someone forces open a window, should the alarm stop sounding as soon as the window is closed again? No, the alarm should lock itself on, until you turn it off.
5. How do you turn it off? Some kind of secret-code keypad would be good.
6. But to avoid driving everyone crazy if the alarm is triggered when you're not there, it should eventually stop itself, perhaps after about 10 minutes. At that point it should remain quiet but should light an LED to tell you what happened. You can then press a reset button to switch off the LED.

Implementing the Wish List

I've compiled a wish list that seems likely to make the project at least five times as complicated as it is already. Well, that's what tends to happen when you go beyond little demo circuits and try to design something that will be useful in everyday life. Suddenly you find yourself having to accommodate all kinds of circumstances and situations.

Actually, I can and will show you how to take care of all the enhancements on the wish list, but I'm thinking that they will require us to get a little more serious about electronics projects in general first. If you're going to build something ambitious, you'll want to make it more permanent, and probably more compact, than a breadboard with components pushed into it.

You will need to know how to connect everything permanently with solder, on a piece of perforated board that you can install in a neat little project box with switches and lights on the outside.

I'm going to deal with soldering and packaging in the next chapter. After that, we'll get back to the alarm project.

3

Getting Somewhat More Serious

IN THIS CHAPTER

Shopping List: Experiments 12 Through 15
Experiment 12: Joining Two Wires Together
Experiment 13: Broil an LED
Experiment 14: A Pulsing Glow
Experiment 15: Intrusion Alarm Revisited

I don't know how far you'll want to delve into electronics, but I do know that I've shown you about as much as I can with just a handful of components, some wires, a breadboard, and a few tools. To continue, you'll need:

- Some more tools and supplies
- Basic soldering skills
- Additional knowledge about:
    - Integrated circuits
    - Digital electronics
    - Microcontrollers
    - Motors

The tools are not particularly exotic or expensive, and the soldering skills are easily acquired. Learning to join wires with solder is far easier than mastering high-level crafts such as jewelry making or welding.

As for additional areas of knowledge about electronics, they are no more challenging than those that I have covered already.

By the end of this section, you should be able to transplant components from a breadboard onto perforated board, where you will solder everything together, and then mount the board in a little box with switches and warning lights on the front, for everyday use.

Shopping List: Experiments 12 Through 15

Tools

Each of the following tools is rated Essential, Recommended, or Optional. The Essential tools will take you through this chapter of the book. If you supplement them with the Recommended tools, they should be sufficient to get you to the end of the book. The Optional tools will make your work easier, but whether they're worth the money is for you to decide. Remember that URLs for manufacturers and sources of supply are all listed in the appendix.

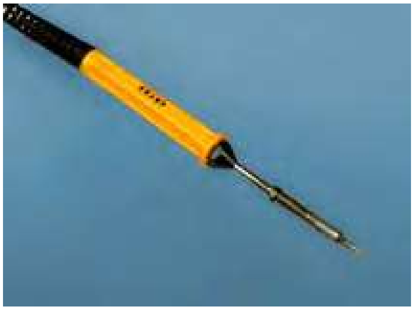

Figure 3-1. *The low wattage of this pencil-style soldering iron enables you to use it safely on sensitive components, and the sharp tip helps to apply heat selectively.*

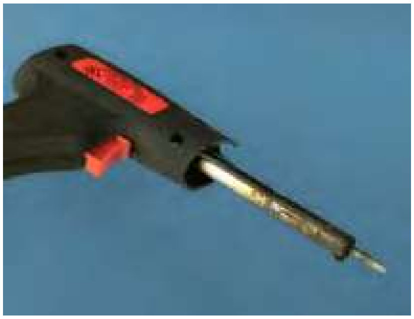

Figure 3-2. *This higher-wattage soldering iron delivers the additional heat necessary for thicker wire or larger components. The discoloration quickly occurs as a result of everyday use and has no effect on the capability of the iron, as long as the tip of it is clean.*

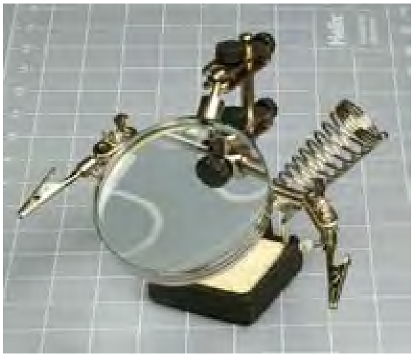

Figure 3-3. *The helping hand is fitted with two alligator clips to hold your work. The metal spiral is a safe place to holster a hot soldering iron, and you use the sponge to wipe its tip.*

I am assuming that you already have some commonly used workshop basics, such as an electric drill.

Essential: Pencil-type 15-watt soldering iron

Examples are RadioShack part 64-2051, McMaster-Carr catalog item 7016A34, or Xytronic model 252. See Figure 3-1. Soldering irons rated at 15 watts are less common than those that deliver 25 watts or more. Still, the 15-watt size is desirable for the small-scale work you'll be doing, and greatly reduces the risk of damaging components by inflicting excess heat.

When comparing prices, remember that a plated tip, which costs a little more, will last longer, will be easier to keep clean, and will conduct heat more reliably than a plain copper tip. If the manufacturer's specification doesn't mention a plated tip, the soldering iron probably doesn't have one.

Essential: General-duty soldering iron, 30 to 40 watts

Although most of the projects in this book entail small, heat-sensitive components and thin wire, at some point you're likely to want to make a solder joint with larger components and/or thicker wire. A 15-watt soldering iron will be unable to deliver enough heat. You should consider having a larger soldering iron in reserve, especially because they are relatively inexpensive.

Personally, I like the Weller Therma-Boost, shown in Figure 3-2, because it has an extra button that delivers more heat on demand. This is useful when you want the iron to get hot quickly, or if you are trying to solder very thick wire, which absorbs a lot of heat.

If you can't find or don't like the Weller, almost any 30-watt or 40-watt soldering iron will do. Check eBay or your local hardware store.

Essential: Helping hand

The so-called "helping hand" (or "third hand") has two alligator clips that hold components or pieces of wire precisely in position while you join them with solder. Some versions of the "helping hand" also feature a magnifying lens, a wire spiral in which you can rest your soldering iron, and a little sponge that you use to clean the tip of your iron when it becomes dirty. These additional features are desirable. Helping hands are available from all electronics hobby sources. Examples are the catalog item HH55 from Elenco or model 64-2991 from RadioShack. See Figure 3-3.

Essential: Magnifying lens

No matter how good your eyes are, a small, handheld, powerful magnifying lens is essential when you are checking solder joints on perforated board. The three-lens set in Figure 3-4 is designed to be held close to your eye, and is more powerful than the large lens on a "helping hand." The folding lens in Figure 3-5 stands on your workbench for hands-free operation. Both are available from RadioShack and similar items are stocked by art supply stores and hobby shops. Plastic lenses are quite acceptable if you treat them carefully.

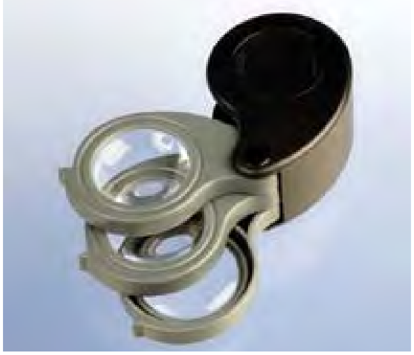

Figure 3-4. *As long as you treat it carefully, a cheap set of plastic magnifying lenses is perfectly acceptable. Handheld magnification is essential for inspecting the solder joints that you make on perforated board.*

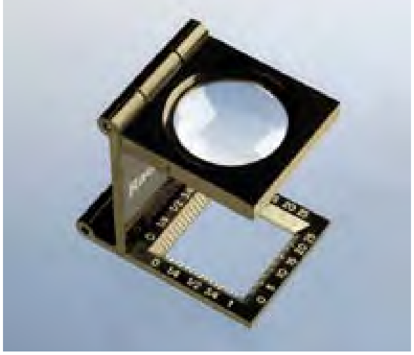

Figure 3-5. *This kind of folding magnifier can stand on your desktop and is useful for checking part numbers on tiny components.*

Essential: Clip-on meter test leads

The probes that came with your multimeter require you to hold them in contact while you make a reading. This requires both hands, preventing you from doing anything else at the same time.

When you use a pair of "minigrabber" probes with little spring-loaded clips at the end, you can attach the Common (negative) lead from your meter to the negative side of your circuit and leave it there, while you touch or attach the positive probe elsewhere.

The Pomona model 6244-48-0 (shown in Figure 3-6) from Meter Superstore and some other suppliers is what you need. If you have trouble finding it or you object to the cost, you may consider making your own by buying a couple of "banana plugs" (such as RadioShack part 274-721) that will fit the sockets on your meter, and then use 16-gauge or thicker stranded wire to connect the plugs with IC test clips, such as Kobiconn 13IC331 or RadioShack "mini hook clips," part number 270-372C. See Figures 3-7 and 3-8.

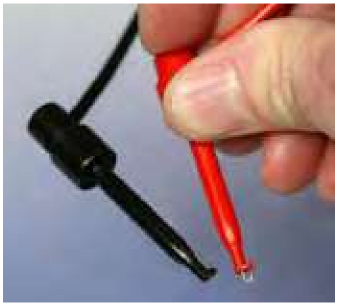

Figure 3-6. *These "minigrabber" add-ons for meter leads make it much easier to measure voltage or current. Push the spring-loaded button, and a little copper hook slides out. Attach it to a wire, release the button, and you have your hands free for other tasks. It's a mystery that meters are not supplied with these grabbers as standard equipment.*

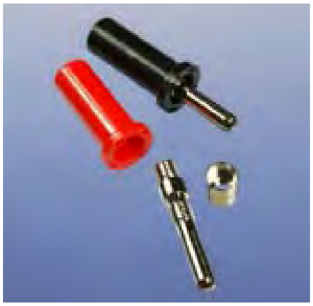

Figure 3-7. *To make your own minigrabber meter leads, first attach a banana plug to a wire by sliding the wire through the cap, into the plug, and out through a hole in the side.*

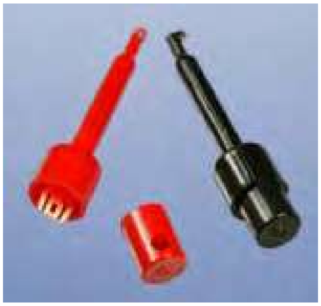

Figure 3-8. *Then screw a collar over the protruding piece of wire, and screw on the cap. The other end of the wire is soldered to a probe.*

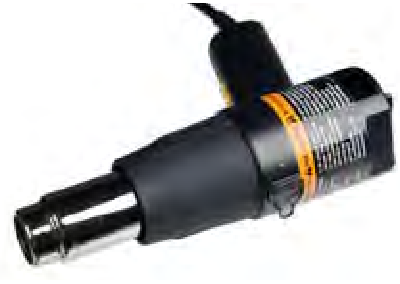

Figure 3-9. *Like an overpowered hair dryer, the heat gun is used with heat-shrink tubing to create a snug, insulated sheath around bare wire.*

Essential: Heat gun

After you join two wires with solder, you often need to insulate them. Electrical tape, sometimes called insulating tape, is messy and tends to come unstuck. You'll be using heat-shrink tube, which forms a safe, permanent sheath around a bare-metal joint. To make the tube shrink, use a heat gun, which is like a very powerful hair dryer. They're available from any hardware supply source, and I suggest you buy the cheapest one you can find. See Figure 3-9.

Essential: Solder pump

This little gadget sucks up hot, melted solder when you are trying to remove a solder joint that you made in the wrong place. Available from All Electronics (catalog item SSR-1) or RadioShack 64-2086. See Figure 3-10.

Essential: Desoldering wick

Also known as desoldering braid. See Figure 3-11. You use this to soak up solder, in conjunction with the Solder Pump. Available from All Electronics (catalog item SWK) or RadioShack (part 64-2090).

Essential: Miniature screwdriver set

Dinky little electronic parts often have dinky little screws in them, and if you try to use the wrong size of screwdriver, you'll tend to mash the heads of the screws. I like the Stanley precision set, part number 66-052, shown in Figure 3-12. But any set will do as long as it has both small Phillips and straight-blade screwdrivers.

Recommended: Soldering stand

Like a holster for a gun, you rest your soldering iron in this stand when the iron is hot but not on use. Examples are catalog item 50B-205 from All Electronics, RadioShack model 64-2078, or check eBay. See Figure 3-13. This item may be built into the helping hand, but you need an extra one for your second soldering iron.

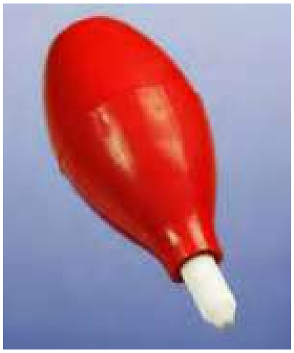

Figure 3-10. *To remove a solder joint, you can heat the solder until it's liquid, then suck it up into this squeezable rubber bulb.*

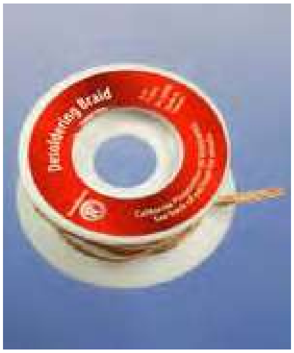

Figure 3-11. *An additional option for removing liquid solder is to soak it up in this copper braid.*

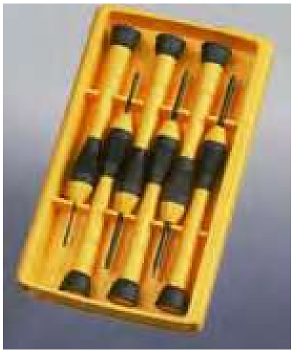

Figure 3-12. *A set of small screwdrivers is essential.*

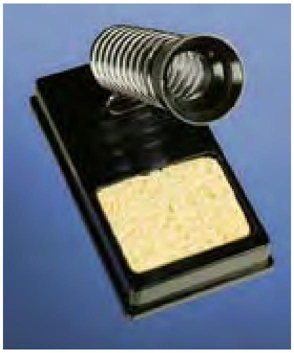

Figure 3-13. *A safe and simple additional stand for a hot soldering iron.*

Recommended: Miniature hand saw

I assume that you will want to mount a finished electronics project in a decent-looking enclosure. Consequently, you are likely to need tools to cut, shape, and trim thin plastic. For example, you may want to cut a square hole so that you can mount a square power switch in it.

Power tools are not suitable for this kind of delicate work. A miniature handsaw (a.k.a. a "hobby saw") is ideal for trimming things to fit. X-Acto makes a range of tiny saw blades. I suggest the #15 blade, plus the handle that it fits in, shown in Figure 3-14. Available online from Tower Hobbies, Hobbylinc, ArtCity, and many other arts/crafts sources. Also look for the larger X-Acto saw blade, #234 or #239, which you can use for cutting perforated board.

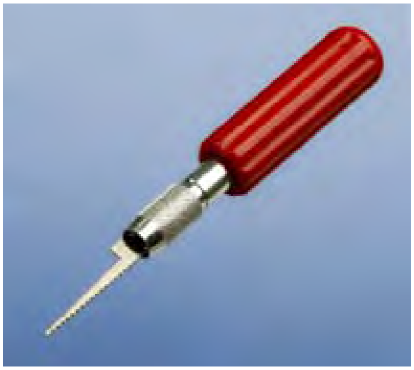

Figure 3-14. *X-Acto makes a range of small saw blades that are ideal for cutting square holes to mount components in plastic panels.*

Recommended: Miniature vise

A miniature vise can do things that the helping hand cannot. I use mine when I'm sawing small pieces of plastic and as a dead weight to anchor a piece of perforated board while I'm working on it. See Figure 3-15.

Look for a cast-iron vise that is listed as being 1 inch or slightly larger, available from Megahobby, eBay, and other arts/crafts sources. Also consider the PanaVise, which has a tilting head to allow you to turn your work to any angle.

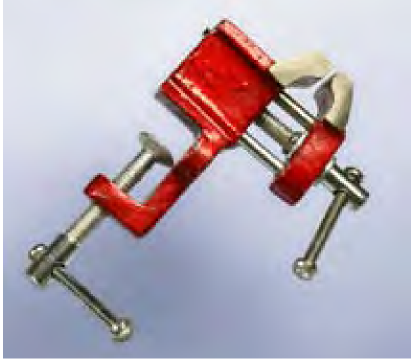

Figure 3-15. *This one-inch vise is available from the McMaster-Carr catalog.*

Recommended: Deburring tool

A deburring tool instantly smoothes and bevels any rough edge (when you have sawn or drilled a piece of plastic, for instance) and also can enlarge holes slightly. This may be necessary because some components are manufactured to metric sizes, which don't fit in the holes that you drill with American bits. Your small local hardware store may not stock deburring tools, but they are very inexpensively available from Sears, McMaster-Carr, KVM Tools, or Amazon. See Figure 3-16.

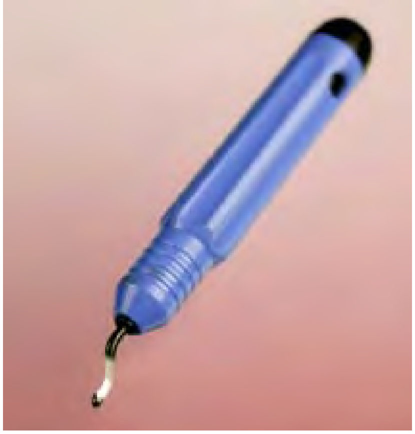

Figure 3-16. *This cunning little blade, safety-tipped with a round bump on the end, removes rough edges from saw cuts with a single stroke, and can enlarge holes that are almost big enough—but not quite.*

Optional: Hand-cranked countersink

You need a countersink to bevel the edges of screw holes to accept flat-headed screws. If you use a countersink bit in an electric drill, it won't give you precise control when you're working with thin, soft plastic.

Handheld countersinks that you grasp and turn like a screwdriver are easy to find, but McMaster-Carr (catalog item 28775A61) is the only source I've found for a hand-cranked tool that is much quicker to use. It comes with a set of bits, as shown in Figure 3-17.

Optional: Pick and hook set

Made by Stanley, part number 82-115, available from Amazon and hardware stores. You can find imported imitations for a few dollars less. See Figure 3-18.

Optional: Calipers

These may seem like a luxury, but are useful for measuring the external diameter of a round object (such as the screw thread on a switch or a potentiometer) or the internal diameter of a hole (into which you may want a switch or potentiometer to fit).

I like Mitutoyo calipers, and the low-end model 505-611 (shown in Figure 3-19) does everything I need. You can find cheaper brands, but economizing on precision measuring tools may not be a wise policy in the long term. The manufacturer's site will show you all their available models, after which you can Google "Mitutoyo" to find retail sources.

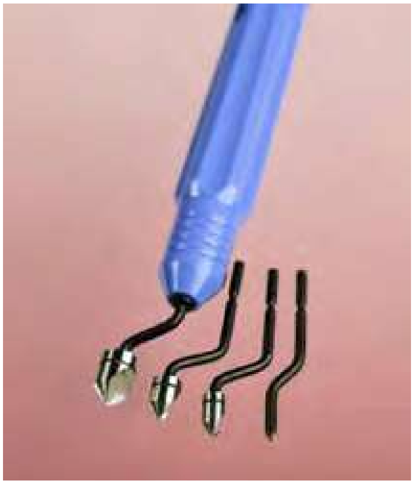

Figure 3-17. *You spin this countersink tool like a hand crank to add just the right amount of bevel to a hole, so that it will accommodate a flat-head screw.*

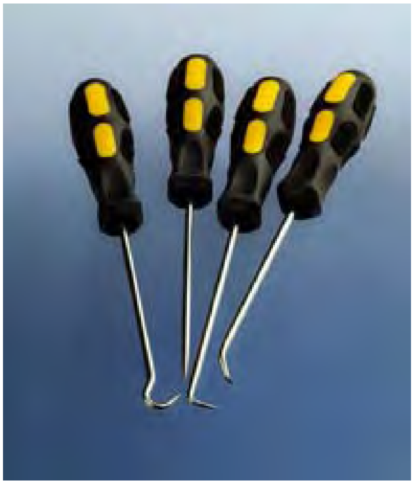

Figure 3-18. *This pick-and-hook set is useful in many unexpected ways.*

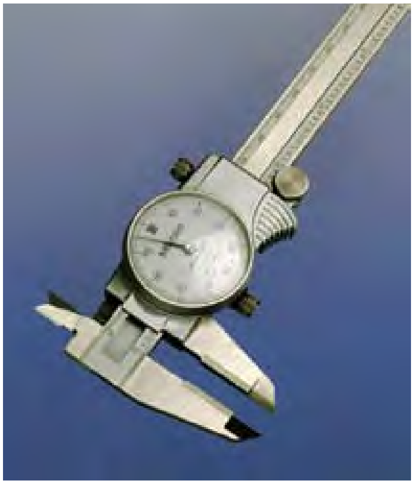

Figure 3-19. *Calipers can be digital (which automatically convert from millimeters to 1/64 inch to 1/1,000 inch), or analog like these (so you never need to worry about a dead battery).*

Supplies

Solder

This is the stuff that you will melt to join components together on a permanent (we hope) basis. You need some very thin solder, size 0.022 inches, for very small components, and thicker solder, 0.05 inches, for heavier items. Avoid buying solder that is intended for plumbers, or for craft purposes such as creating jewelry. A range of solder thicknesses is shown in Figure 3-20. You want to make sure to get lead-free solder.

Electronics solder has a nonacidic rosin core that is appropriate for electronic components. Rolls of solder are available from all hobby-electronics sources including All Electronics, RadioShack, and Jameco, or search for "electronic solder" on Amazon.

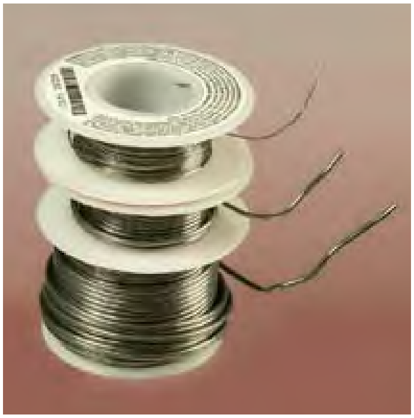

Figure 3-20. *Spools of solder in various thicknesses.*

Wire

You'll need some stranded wire to make flexible external connections with the circuit that you'll be building. Look for 22-gauge stranded hookup wire, in red, black, and green, 10 feet (minimum) of each.

If you want to install the intrusion alarm after completing that project in Experiment 15, you'll need white-insulated two-conductor wire of the type sold for doorbells or furnace controls. This is available by the foot from Lowe's, Home Depot, Ace Hardware, and similar stores. You'll decide how much to buy after you measure the distances between the magnetic sensor switches that you decide to install.

Heat-shrink tube

For use in conjunction with your heat gun, described previously. You'll need a range of sizes in any colors of your choice. See Figure 3-21. Check RadioShack part 278-1627, other electronics suppliers, or your local hardware store. Prices will vary widely. You can buy the cheapest.

Copper alligator clips

These absorb heat when you are soldering delicate components. The Mueller BU-30C is a full-size solid copper alligator clip for maximum heat absorption. RadioShack sells smaller clips (part number 270-373, shown in Figure 3-22) that are suitable for tiny components.

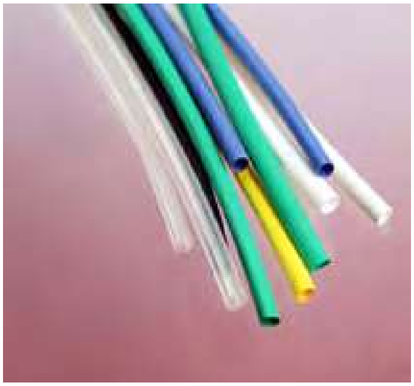

Figure 3-21. *Slide heat-shrink tubing over a bare joint and apply heat from a heat gun to make a tight insulating seal around the joint.*

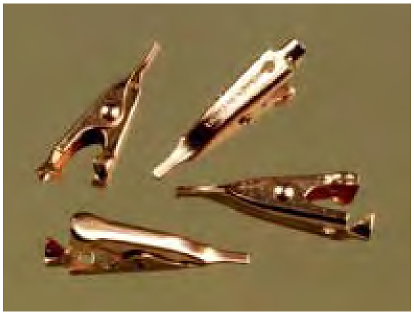

Figure 3-22. *These small clips absorb heat to protect components when you're soldering them.*

Perforated board

When you're ready to move your circuit from a breadboard to a more permanent location, you'll want to solder it to a piece of perforated board, often known as "prototyping board" but also called "perfboard."

You need the type that has copper strips etched onto the back, in exactly the same "breadboard layout" as the conductors hidden inside a breadboard, so that you can retain the same layout of your components when you solder them into place. Examples are RadioShack part 276-150 (shown in Figure 3-23) for small projects and part 276-170 (in Figure 3-24) for larger projects, such as Experiment 15.

For very small projects in which you will connect components using their wires alone, you need perfboard that isn't etched with copper strips connecting the holes. I like the Twin Industries 7100 range (available from Mouser.com) or Vectorboard from Newark Electronics, shown in Figure 3-25. You use a saw to cut out as small a piece as you need. Cheaper options are RadioShack part 276-147 (shown in Figure 3-26), or PC-1 from All Electronics. These have little copper circles around each hole that are not necessary for our purposes, but not a problem, either.

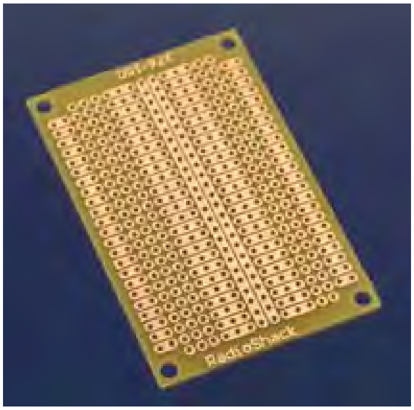

Figure 3-23. *This perforated board has a pattern of copper traces similar to the pattern inside a breadboard, so that you can lay out the components with minimal risk of wiring errors, when you're ready to create a permanently soldered version of your project.*

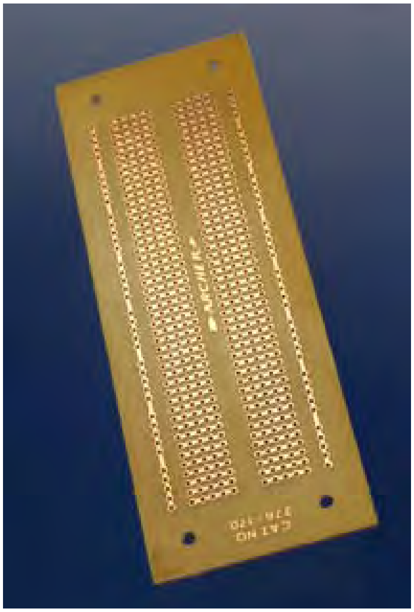

Figure 3-24. *A larger example of perforated board with breadboard geometry.*

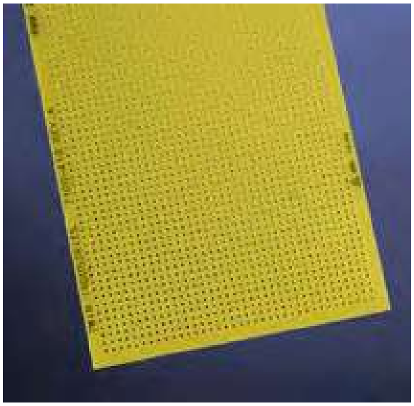

Figure 3-25. *Plain perforated board (with no copper traces) can be used for mounting components when you want to do point-to-point wiring.*

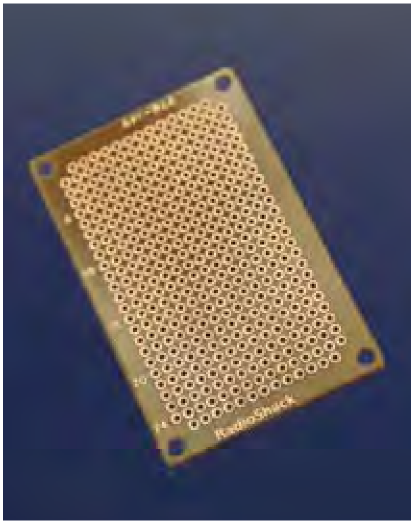

Figure 3-26. *A small piece of perforated board with individual copper solder pads to assist you in mounting components.*

Plywood

When you use a soldering iron, hot drops of solder tend to fall onto your table or workbench. The solder solidifies almost instantly, can be difficult to remove, and will leave a scar. Consider using a 2-foot square of half-inch plywood to provide disposable protection. You can buy it precut at Home Depot or Lowe's.

Machine screws

To mount components behind a panel, you need small machine screws (or "bolts"). They look nice if they have flat heads that fit flush against the panel. I suggest stainless-steel machine screws, #4 size, in 1/2-, 5/8-, 3/4-, and 1-inch lengths, 100 of each, plus 400 washers and 400 #4 locknuts of the type that have nylon inserts, so that they won't work loose. Check McMaster-Carr for a large and reasonably priced selection.

Project boxes

A project box is just a small box (usually plastic) with a removable lid. You mount your switches, potentiometers, and LEDs in holes that you drill through the box, and you attach your circuit on a perforated board that goes inside the box. Search All Electronics for "project box" or RadioShack for "project enclosure."

You need a box measuring approximately 6 inches long, 3 inches wide, and 2 inches high, such as RadioShack part 270-1805. Anything similar will do. I suggest you buy a couple other sizes as well, as they will be useful in the future.

Components

Power plugs, sockets, and binding posts

After you finish a project and put it in a box, you'll need a convenient way to supply it with power. Buy yourself a pair of insulated binding posts, such as RadioShack part 274-661, shown in Figure 3-27. Also obtain a panel-mounted power jack, size N, such as RadioShack part 274-1583, and DC power plug, size N, such as RadioShack 274-1573. The plug-and-socket pair is pictured in Figure 3-28.

Finally, you will need interconnects that are sized to fit a perforated board that is drilled at intervals of 1/10 inch. Sometimes known as "single inline sockets and headers," but also known as "boardmount sockets and pin-strip headers," they come in strips of 36 or more, and you can snip off as many as you need. Examples are Mill-Max part numbers 800-10-064-10-001000 and 801-93-050-10-001000, or 3M part numbers 929974-01-36-RK and 929834-01-36-RK. You can buy them from the usual electronics suppliers. Figure 3-29 shows headers before and after being snapped into small sections. Make sure that the interconnects have a terminal spacing of 0.1 inch.

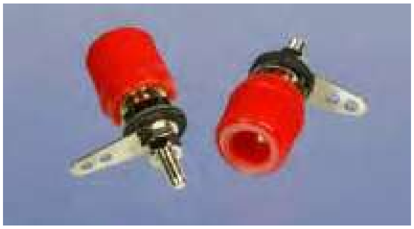

Figure 3-27. *These terminals, also known as binding posts, enable a solderless connection with wires that have stripped ends. Also available in black.*

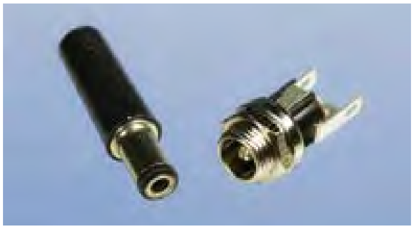

Figure 3-28. *The socket on the right can be mounted in a project box to receive power from the plug on the left.*

Battery

After you complete Experiment 15 at the end of this section of the book, if you want to use the project on a practical basis, you'll need a 12-volt battery. Search online for "12v battery" and you'll find many sealed, rechargeable lead-acid batteries that are designed for alarm systems, some measuring as small as 1×2×3-inch and costing under $10. You need a charger with it, which will probably cost you about $10.

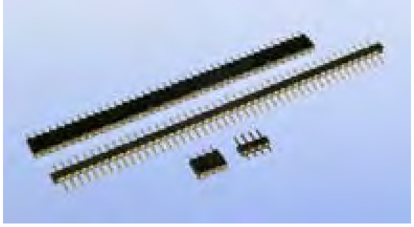

Figure 3-29. *Single inline sockets (top) and headers (middle) allow you to make very compact plug-and-socket connections to a PC board. They can be sawn, cut, or snapped into smaller sections (bottom). The terminals are 0.1 inch apart.*

Switches and relays

You will need the same DPDT relay and the same SPDT toggle switch that were mentioned in Chapter 2 shopping list.

For Experiment 15, you'll need magnetic switches that you can apply to doors or windows, such as the Directed model 8601, available from dozens of sources online.

Also you will need a DPDT pushbutton switch, ON-(ON) type, with solder terminals. Examples are model MPG206R04 by Tyco or model MB2061SS1W01-RO by NKK (with optional cap). Or search eBay for "DPDT pushbutton."

Diodes

Buy at least half-a-dozen red 5 mm LEDs rated for approximately 2 volts, such as the Optek part number OVLFR3C7, Lumex part number SSL-LX-5093IT, or Avago part HLMP-D155. Buy half-a-dozen similar green LEDs at the same time.

In addition, you'll need a signal diode, type 1N4001 (any brand will do). Figure 3-30 shows an example, highly magnified. They're cheap, and likely to be useful in the future, so buy 10 of them.

Figure 3-30. *This 1N4001 diode is about 1/4 inch long and can handle up to 50 volts.*

Loudspeaker

To complete the project in Experiment 15, you'll need a loudspeaker small enough to fit inside your project box but louder than the 1-inch speaker that you used previously. It should be 2 inches or 2.5 inches (50 to 60 mm) in diameter. If you can find a 100Ω speaker, it will give you more output, but an 8Ω speaker will be acceptable.

Experiment 12: Joining Two Wires Together

Your adventure into soldering begins with the prosaic task of joining one wire to another, but will lead quickly to creating a full electronic circuit on perforated board. So let's get started!

You will need:

- 30-watt or 40-watt soldering iron
- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Medium solder (0.05 inches or similar)
- Wire strippers and cutters
- "Helping hand" gadget to hold your work
- Shrink-wrap tubing, assorted
- Heat gun
- Something to protect your work area from drops of solder

Your First Solder Joint

We'll start with your general-duty soldering iron—the one rated for 30 or 40 watts. Plug it in, leave it safely in its holder, and find something else to do for five minutes. If you try to use a soldering iron without giving it time to get fully hot, you will *not* make good joints.

Strip the insulation from the ends of two pieces of 22-gauge solid wire and clamp them in your helping hand so that they cross each other and touch each other, as shown in Figure 3-31.

To make sure that the iron is ready, try to melt the end of a thin piece of solder on the tip of the iron. The solder should melt instantly. If it melts slowly, the iron isn't hot enough yet.

Soldering Irons Get Hot!

Please take these basic precautions:

Use a proper stand (such as the one incorporated in your helping hands) to hold your soldering iron. Don't leave it lying on a workbench.

If you have infants or pets, remember that they may play with, grab, or snag the wire to your soldering iron. They could injure themselves (or you).

Be careful never to rest the hot tip of the iron on the power cord that supplies electricity to the iron. It can melt the plastic in seconds and cause a dramatic short circuit.

If you drop a soldering iron, don't be a hero and try to catch it. Most likely you will grab the hot part, which hurts. (I speak from experience.) When you burn your hand, you will instinctively let go of the iron, so you may as well let it drop freely without the intermediate step of burning yourself while it's on its way to the floor. Naturally, you should pick it up quickly after it does hit the floor, but by then you will have gained the necessary time in which to make a sensible decision to grab it by the cool end.

Always bear in mind that others in your home are more at risk of hurting themselves on a soldering iron than you are, because they won't know that it's hot. Most soldering irons have no warning lights to tell you that they're plugged in. As a general rule, always assume that a soldering iron is hot, even if it's unplugged. It may retain sufficient heat to burn you for longer than you expect.

Now follow these steps (shown in Figures 3-32 through 3-36):

1. Make sure the tip of the soldering iron is clean (wipe it on the moistened sponge in the base of your helping hand if necessary), then touch it against the intersection of the wires steadily for three seconds to heat them. If you have hard tap water, use distilled water to wet the sponge to avoid a buildup of mineral deposits on the tip of your soldering iron.
2. While maintaining the iron in this position, feed a little solder onto the intersection of the wires, also touching the tip of the soldering iron. Thus, the two wires, the solder, and the tip of the iron should all come together at one point. The solder should spread over the wires within another two seconds.
3. Remove the iron and the solder. Blow on the joint to cool it. Within 10 seconds, it should be cool enough to touch.
4. Unclamp the wires and try to tug them apart. Tug hard! If they defeat your best attempts to separate them, the wires are electrically joined and should stay joined. If you didn't make a good joint, you will be able to separate the wires relatively easily, probably because you didn't apply enough heat or enough solder to connect them.

The reason I asked you to begin by using the higher-powered soldering iron is that it delivers more heat, which makes it easier to use.

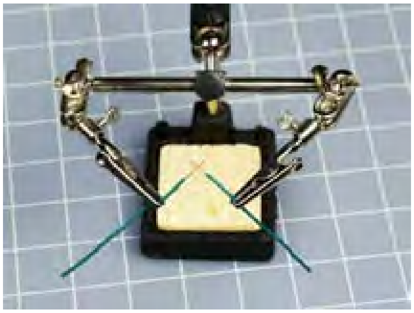

Figure 3-31. *A helping hand work aid is shown here holding two wires with their stripped ends touching. The magnifying glass has been hinged out of the way.*

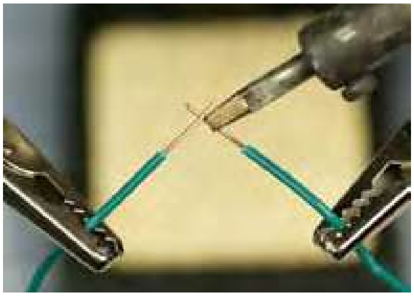

Figure 3-32

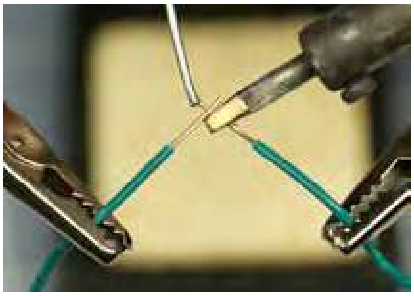

Figure 3-33

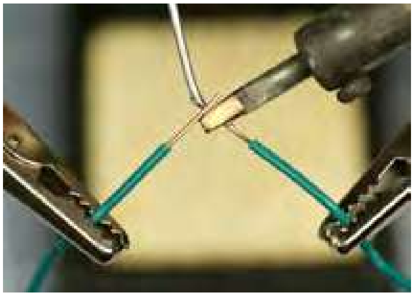

Figure 3-34

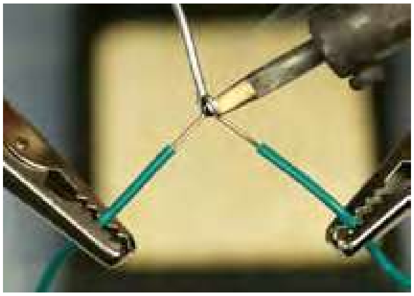

Figure 3-35. *This and the preceding three figures illustrate four steps to making a solder joint: apply heat to the wires, bring in the solder while maintaining the heat, wait for the solder to start to melt, and wait a moment longer for it to form a completely molten bead. The whole process should take between 4 and 6 seconds.*

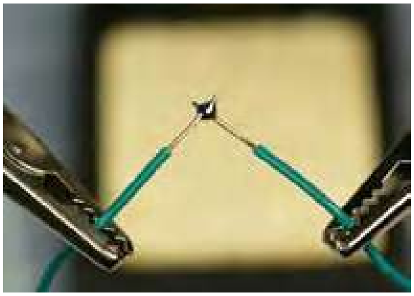

Figure 3-36. *The completed joint should be shiny, uniform, and rounded in shape.*

BACKGROUND

Soldering myths

Myth #1: Soldering is very difficult.

Millions of people have learned how to do it, and statistically, you are unlikely to be less coordinated than all of them. I have a lifelong problem with a tremor in my hands that makes it difficult for me to hold small things steadily. I also get impatient with repetitive detail work. If I can solder components, almost anyone should be able to.

Myth #2: Soldering involves poisonous chemicals.

Modern solder contains no lead. You should avoid inhaling the fumes for prolonged periods, but that also applies to everyday products such as bleach and paint. If soldering was a significant health hazard, we should have seen a high death rate among electronics hobbyists decades ago.

Myth #3: Soldering is hazardous.

A soldering iron is less hazardous than the kind of iron that you might use to iron a shirt, because it delivers less heat. In fact, in my experience, soldering is safer than most activities in a typical home or basement workshop. That doesn't mean you can be careless!

Soldering alternatives

As recently as the 1950s, connections inside electronic appliances such as radio sets were still being hand-soldered by workers on production lines. But the growth of telephone exchanges created a need for a faster way to make large numbers of rapid, reliable point-to-point wiring connections, and "wire wrap" became a viable alternative.

In a wire-wrapped electronics project, components are mounted on a circuit board that has long, gold-plated, sharp-cornered square pins sticking out of the rear. Special silver-plated wire is used, with an inch of insulation stripped from its ends. A manual or power-driven wire-wrap tool twirls the end of a wire around one of the pins, applying sufficient tension to "cold-weld" the soft silver plating of the wire to the pin. The wrapping process exerts sufficient pressure to make a very reliable joint, especially as 7 to 9 turns of wire are applied, each turn touching all four corners of the pin.

During the 1970s and 1980s, this system was adopted by hobbyists who built their own home computers. A wire-wrapped circuit board from a hand-built computer is shown in Figure 3-37. The technique was used by NASA to wire the computer in the Apollo spacecraft that went to the moon, but today, wire-wrapping has few commercial applications.

The widespread industrial use of "through-hole" components, such as the chips on early desktop computers, encouraged development of wave soldering, in which a wave or waterfall of molten solder is applied to the underside of a preheated circuit board where chips have been inserted. A masking technique prevents the solder from sticking where it isn't wanted.

Today, surface-mount components (which are significantly smaller than their through-hole counterparts) are glued to a circuit board with a solder paste, and the entire assembly is then heated, melting the paste to create a permanent connection.

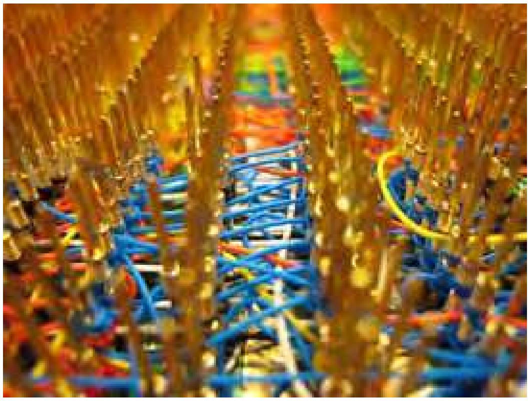

Figure 3-37. *This picture shows some of the wire-wrapping in Steve Chamberlin's custom-built, retro 8-bit CPU and computer. "Back in the day," connecting such a network of wires with solder joints would have been unduly time-consuming and prone to faults. Photo credit: Steve Chamberlin.*

TOOLS

Eight most common soldering errors

1. Not enough heat.

   The joint looks OK, but because you didn't apply quite enough heat, the solder didn't melt sufficiently to realign its internal molecular structure. It remained granular instead of becoming a solid, uniform blob, and you end up with a "dry joint," also known as a "cold joint," which will come apart when you pull the wires away from each other. Reheat the joint thoroughly and apply new solder.

   A leading cause of underheated solder is the temptation to use the soldering iron to carry solder to the joint. This results in the cold wires reducing the temperature of the solder. What you should do is touch the soldering iron to heat the wires first, and then apply the solder. This way, the wires are hot and help to melt the solder, which wants to stick to them.

   Because this is such a universal problem, I'll repeat myself: *Never melt solder on the tip of the iron and then use it to carry the solder to the joint.*

   You don't want to put hot solder on cold wires. You want to put cold solder on hot wires.

2. Too much heat.

   This may not hurt the joint, but can damage everything around it. Vinyl insulation will melt, exposing the wire and raising the risk of short circuits. You can easily damage semiconductors, and may even melt the internal plastic components of switches and connectors.

   Damaged components must be desoldered and replaced, which will take time and tends to be a big hassle (see "Tools: Desoldering" on page 109 for advice).

3. Not enough solder.

   A thin connection between two conductors may not be strong enough. When joining two wires, always check the underside of the joint to see whether the solder penetrated completely.

4. Moving the joint before the solder solidifies.

   You may create a fracture that you won't necessarily see. It may not stop your circuit from working, but at some point in the future, as a result of vibration or thermal stresses, the fracture can separate just enough to break electrical contact. Tracking it down will then be a chore. If you clamp components before you join them, or use perforated board to hold the components steady, you can avoid this problem.

5. Dirt or grease.

   Electrical solder contains rosin that cleans the metal that you're working with, but contaminants can still prevent solder from sticking. If any component looks dirty, clean it with fine sandpaper before joining it.

6. Carbon on the tip of your soldering iron.

   The iron gradually accumulates flecks of black carbon during use, and they can act as a barrier to heat transfer. Wipe the tip of the iron on the little sponge mounted in the base of your soldering iron stand or your helping hand.

7. Inappropriate materials.

   Electronic solder is designed for electronic components. It will not work with aluminum, stainless steel, or various other metals. You may be able to make it stick to chrome-plated items, but only with difficulty.

8. Failure to test the joint.

   Don't just assume that it's OK. Always test it, by applying manual force if you can (see Figures 3-38 and 3-39 for the ideal protocol) or, if you can't get a grip on the joint, slip a screwdriver blade under it and flex it just a little, or use small pliers to try to pull it apart. Don't be concerned about ruining your work. If your joint doesn't survive rough treatment, it wasn't a good joint.

Of the eight errors, dry/cold joints are by far the worst, because they are easy to make and can look OK.

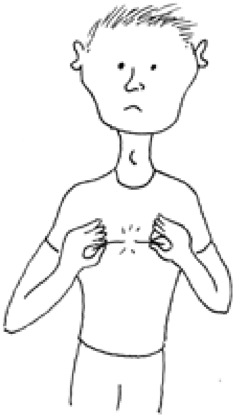

Figure 3-38. *Test result of a bad solder joint.*

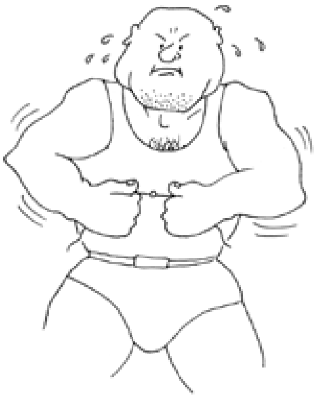

Figure 3-39. *Test result of a good solder joint.*

Your Second Solder Joint

Time now to try your pencil-style soldering iron. Once again, you must leave it plugged in for a good five minutes to make sure it's hot enough. In the meantime, don't forget to unplug your other soldering iron, and put it somewhere safe while it cools.

This time I'd like you to align the wires parallel with each other. Joining them this way is a little more difficult than joining them when they cross each other, but it's a necessary skill. Otherwise, you won't be able to slide heat-shrink tubing over the finished joint to insulate it.

Figures 3-40 through 3-44 show a successful joint of this type. The two wires do not have to make perfect contact with each other; the solder will fill any small gaps. But the wires must be hot enough for the solder to flow, and this can take an extra few seconds when you use the low-wattage pencil-style iron.

Be sure to feed the solder in as shown in the pictures. Remember: don't try to carry the solder to the joint on the tip of the iron. Heat the wires first, and then touch the solder to the wires and the tip of the iron, while keeping it in contact with the wires. Wait until the solder liquifies, and you will see it running eagerly into the joint. If this doesn't happen, be more patient and apply the heat for a little longer.

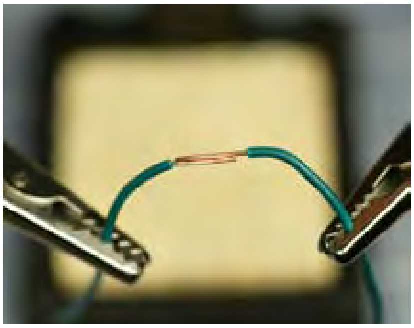

Figure 3-40

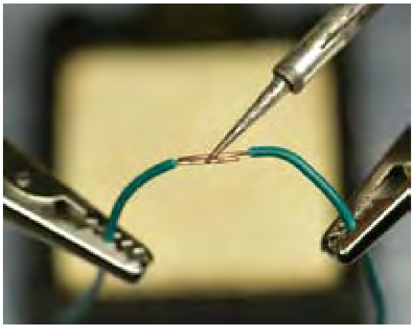

Figure 3-41

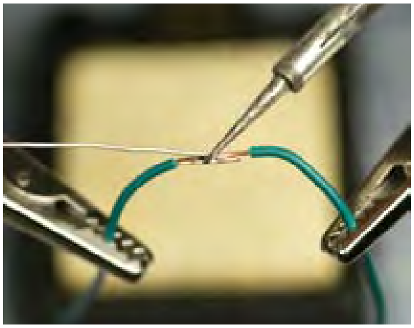

Figure 3-42

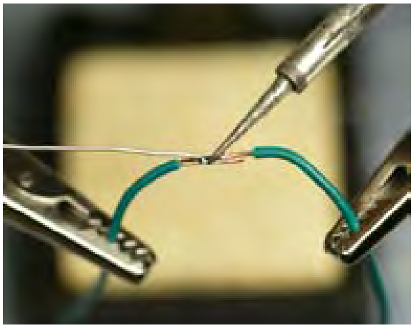

Figure 3-43. *This and the preceding three figures show how joining two wires that are parallel is more difficult, and the low-wattage, pencil-type soldering iron will require longer to heat them sufficiently for a good joint. Thinner solder can be used.*

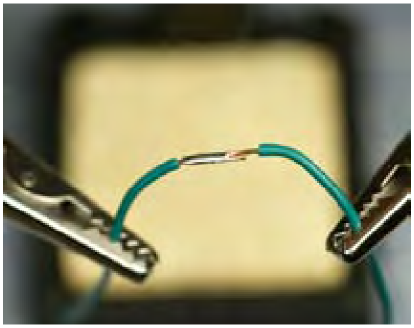

Figure 3-44. *The finished joint has enough solder for strength, but not so much solder that it will prevent heat-shrink tubing from sliding over it.*

THEORY

Soldering theory

The better you understand the process of soldering, the easier it should be for you to make good solder joints.

The tip of the soldering iron is hot, and you want to transfer that heat into the joint that you are trying to make. In this situation, you can think of the heat as being like a fluid. The larger the connection is between the soldering iron and the joint, the greater the quantity of heat, per second, that can flow through it.

For this reason, you should adjust the angle of the soldering iron so that it makes the widest possible contact. If it touches the wires only at a tiny point, you'll limit the amount of heat flow. Figures 3-45 and 3-46 illustrate this concept. Once the solder starts to melt, it broadens the area of contact, which helps to transfer more heat, so the process accelerates naturally. Initiating it is the tricky part.

The other aspect of heat flow that you should consider is that it can suck heat away from the places where you want it, and deliver it to places where you don't want it. If you're trying to solder a very heavy piece of copper wire, the joint may never get hot enough to melt the solder, because the heavy wire conducts heat away from the joint. You may find that even a 40-watt iron isn't powerful enough to overcome this problem, and if you are doing heavy work, you may need a more powerful iron.

As a general rule, if you can't complete a solder joint in 10 seconds, you aren't applying enough heat.

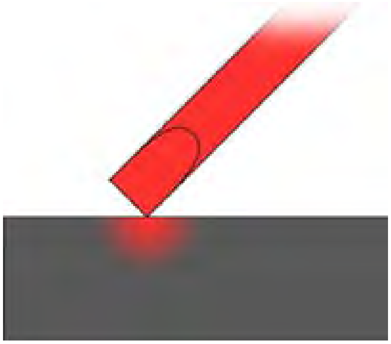

Figure 3-45. *With only a small surface area of contact between the iron and the working surface, an insufficient amount of heat is transferred.*

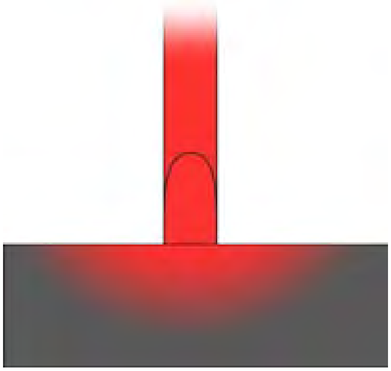

Figure 3-46. *A larger area of contact between the soldering iron and its target will greatly increase the heat transfer.*

TOOLS

Desoldering

Desoldering is much, much harder than soldering. Two simple tools are available:

- *Suction pump*. First, you apply the soldering iron to make the solder liquid. Then you use this simple gadget to try to suck up as much of the liquid as possible. Usually it won't remove enough metal to allow you to pull the joint apart, and you will have to try the next tool. Refer back to Figure 3-10.
- *Desoldering wick or braid*. Desoldering wick, also known as braid, is designed to soak up the solder from a joint, but again, it won't clean the joint entirely, and you will be in the awkward position of trying to use both hands to pull components apart while simultaneously applying heat to stop the solder from solidifying. Refer back to Figure 3-11.

I don't have much advice about desoldering. It's a frustrating experience (at least, I think so) and can damage components irrevocably.

Heat Guns Get Hot, Too!

Notice the chromed steel tube at the business end of your heat gun. Steel costs more than plastic, so the manufacturer must have put it there for a good reason—and the reason is that the air flowing through it becomes so hot that it would melt a plastic tube.

The metal tube stays hot enough to burn you for several minutes after you've used it. And, as in the case of soldering irons, other people (and pets) are vulnerable, because they won't necessarily know that the heat gun is hot. Most of all, make sure that no one in your home ever makes the mistake of using a heat gun as a hair dryer (Figure 3-47).

This tool is just a little more hazardous than it appears.

Adding Insulation

After you've succeeded in making a good inline solder connection between two wires, it's time for the easy part. Choose some heat-shrink tubing that is just big enough to slide over the joint with a little bit of room to spare.

Figure 3-47. *Other members of your family should understand that although a heat gun looks like a hair dryer, appearances may be deceptive.*

Slide the tubing along until the joint is centered under it, hold it in front of your heat gun, and switch on the gun (keeping your fingers away from the blast of superheated air). Turn the wire so that you heat both sides. The tubing should shrink tight around the joint within half a minute. If you overheat the tubing, it may shrink so much that it splits, at which point you must remove it and start over. As soon as the tubing is tight around the wire, your job is done, and there's no point in making it any hotter. Figures 3-48 through 3-50 show the desired result. I used white tubing because it shows up well in photographs. Different colors of heat-shrink tubing all perform the same way.

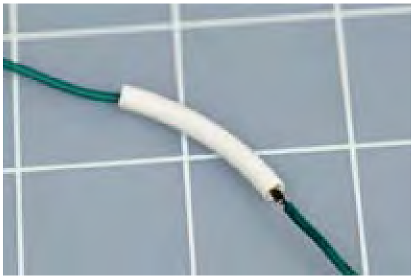

Figure 3-48. *Slip the tubing over your wire joint.*

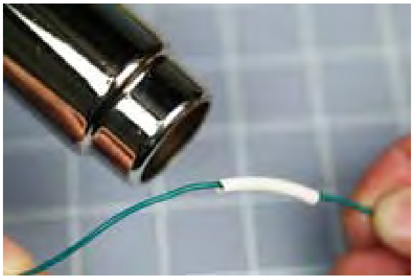

Figure 3-49. *Apply heat to the tubing.*

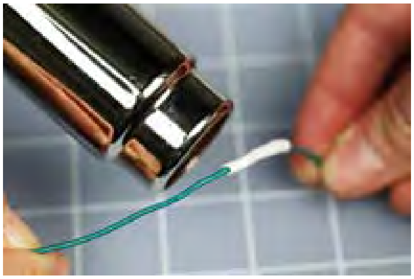

Figure 3-50. *Leave the heat on the tubing until it shrinks to firmly cover the joint.*

I suggest you next practice your soldering skills on a couple of practical projects. In the first one, you can add color-coded, solid-core wires to your AC adapter, and in the second one, you can shorten the power cord for a laptop power supply. You can use your larger soldering iron for both of these tasks, because neither of them involves any heat-sensitive components.

Modifying an AC Adapter

In the previous chapter, I mentioned the irritation of being unable to push the wires from your AC adapter into the holes of your breadboard. So, let's fix this right now:

1. Cut two pieces of solid-conductor 22-gauge wire—one of them red, the other black or blue. Each should be about 2 inches long. Strip a quarter-inch of insulation from both ends of each piece of wire.
2. Trim the wire from your AC adapter. You need to expose some fresh, clean copper to maximize your chance of getting the solder to stick.

   I suggest that you make one conductor longer than the other to minimize the chance of the bare ends touching and creating a short circuit. Use your meter, set to DC volts, if you have any doubt about which conductor is positive.

Solder the wires and add heat-shrink tubing as you did in the practice session. The result should look like Figure 3-51.

Choose the Right Tubing

If you use heat-shrink tubing on 110v AC cord, as is being done in this experiment, make sure you use tubing that's been rated for 110v use.

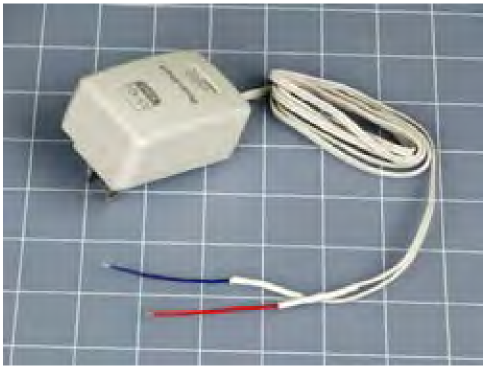

Figure 3-51. *Solid-core color-coded wires, soldered onto the wires from an AC adapter, provide a convenient way to feed power to a breadboard. Note that the wires are of differing lengths to reduce the risk of them touching each other.*

Shortening a Power Cord

When I travel, I like to minimize everything. It always annoys me that the power cord for the power supply of my laptop is 4 feet long. The thinner wire that connects the power supply to the computer is also 4 feet long, and I just don't need that much wire.

After searching exhaustively I couldn't find any laptop power cables shorter than 3 feet, so I decided to shorten one myself. If you feel no need to do this, you should try the following procedure on an old extension cord, just as an exercise. You do need to go through these steps to acquire some practice in soldering heavier, stranded wire and using heat-shrink tubing:

1. Use your wire cutters to chop the wire, and then a utility knife to split the two conductors, with one shorter than the other. When splicing a power cord or similar cable containing two or more conductors, it's good to avoid having the joints opposite each other. They fit more snugly if they are offset, and there's less risk of a short circuit if a joint fails.

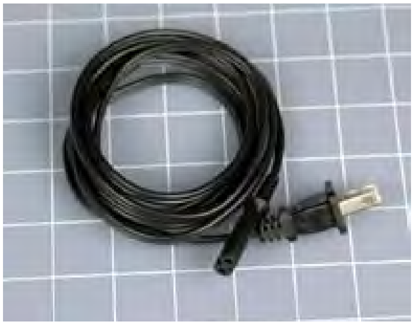

Figure 3-52

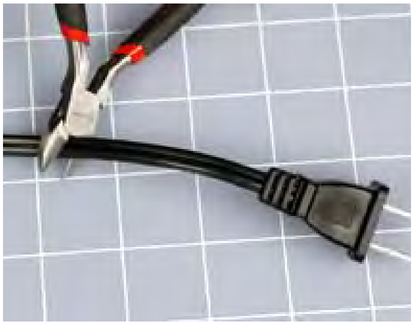

Figure 3-53

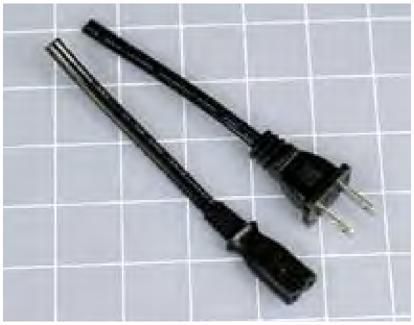

Figure 3-54

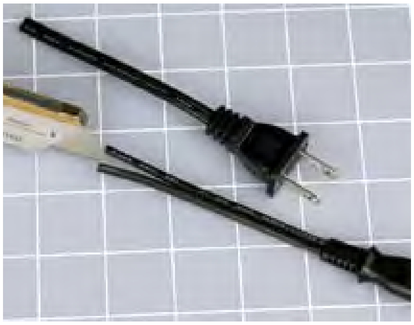

Figure 3-55

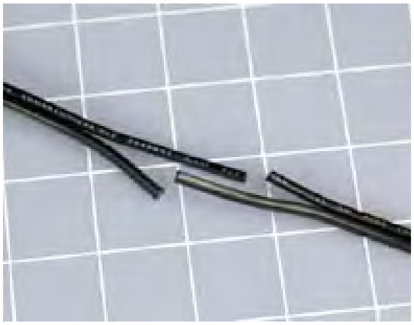

Figure 3-56

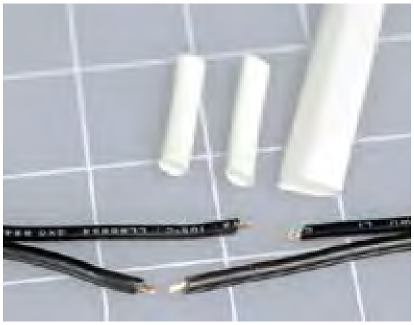

Figure 3-57

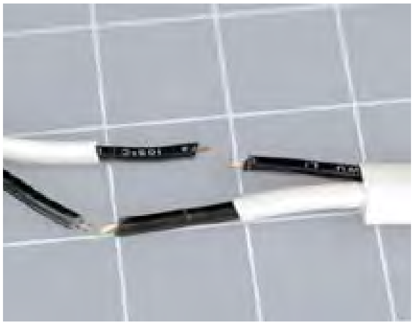

Figure 3-58. *Figures 3-52 through 3-58 illustrate the sequence of steps to prepare for making a shortened power cord for a laptop computer power supply.*

2. Strip off a minimal amount of insulation. One-eighth of an inch (3 mm) is sufficient. The automatic wire strippers that I mentioned in the shopping list in Chapter 1 are especially convenient, but regular wire strippers will do the job.
3. Cut two pieces of heat-shrink tubing, each 1 inch long, big enough to slide over the separate conductors in your cable. Cut a separate 2-inch piece of larger tubing that will slide over the entire joint when it's done. The steps described so far are illustrated in Figures 3-52 through 3-58.
4. Now for the most difficult part: activating your human memory. You have to remember to slide the tubing onto the wire *before* you make your solder joint, because the plugs on the ends of the wires will prevent you from adding any heat-shrink tubing later. If you're as impatient as I am, it's very difficult to remember to do this every time.

5. Use your helping hand to align the first joint. Push the two pieces of wire together so that the strands intermingle, and then squeeze them tight between finger and thumb, so that there are no little bits sticking out. A stray strand of wire can puncture heat-shrink tubing when the tubing is hot and soft and is shrinking around the joint.
6. The wire that you're joining is much heavier than the 22-gauge wire that you worked with previously, so it will suck up more heat, and you must touch the soldering iron to it for a longer time. Make sure that the solder flows all the way into the joint, and check the underside after the joint is cool. Most likely you'll find some bare copper strands there. The joint should become a nice solid, rounded, shiny blob. Keep the heat-shrink tubing as far away from the joint as possible while you're using the soldering iron, so that heat from the iron doesn't shrink the tubing prematurely, preventing you from sliding it over the joint later.

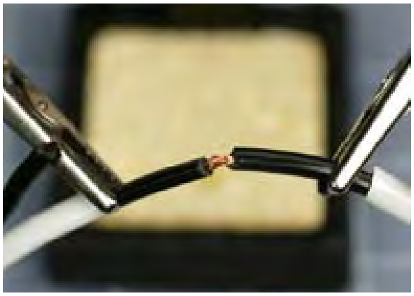

Figure 3-59

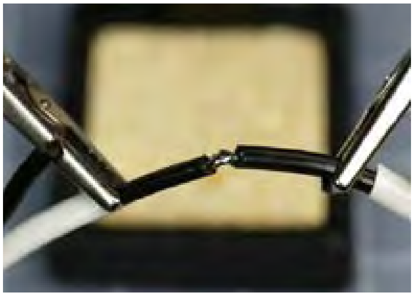

Figure 3-60

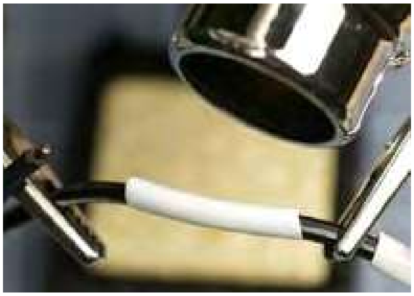

Figure 3-61

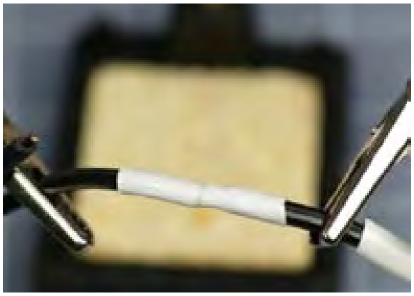

Figure 3-62

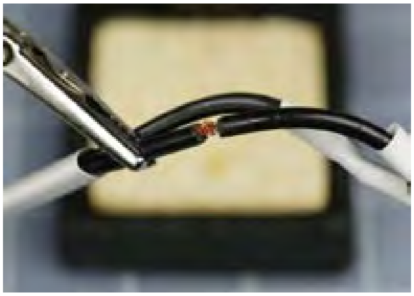

Figure 3-63

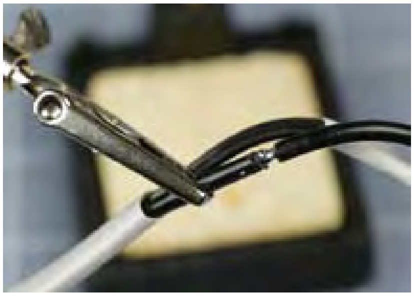

Figure 3-64

7. When the joint has cooled, slide the heat-shrink tubing over it, and apply the heat gun. Now repeat the process with the other conductor. Finally, slide the larger piece of tubing over the joint. You did remember to put the large tubing onto the wire at the beginning, didn't you?

Figures 3-59 through 3-65 show the steps all the way through to the end.

If you have completed the soldering exercises so far, you now have sufficient basic skills to solder your first electronic circuit. But first, I want you to verify the vulnerability of components to heat.

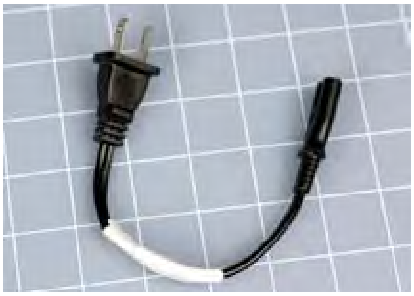

Figure 3-65. *Completion of the shortened power cord for a laptop power supply.*

Experiment 13: Broil an LED

In Chapter 1, you saw how an LED can be damaged if too much current flows through it. The electricity caused heat, which melted the LED. Unsurprisingly, you can just as easily melt it by applying too much heat to one of its leads with a soldering iron. The question is: how much heat is too much? Let's find out.

You will need:

- 30-watt or 40-watt soldering iron
- 15-watt pencil-type soldering iron
- A couple of LEDs (that are expendable)
- 680Ω resistor
- Wire cutters and sharp-nosed pliers
- "Helping hand" gadget to hold your work

I don't want you to use alligator clips to join the LED to a power supply, because the alligator clip will divert and absorb some of the heat from your soldering iron. Instead, please use some sharp-nosed pliers to bend each of the leads from an LED into little hooks, and do the same thing with the wires on a 680Ω load resistor. Finally bend the new wires on your AC adapter so that they, too, are tiny hooks. Now you can put the hooks together like links in a chain, as shown in Figure 3-66.

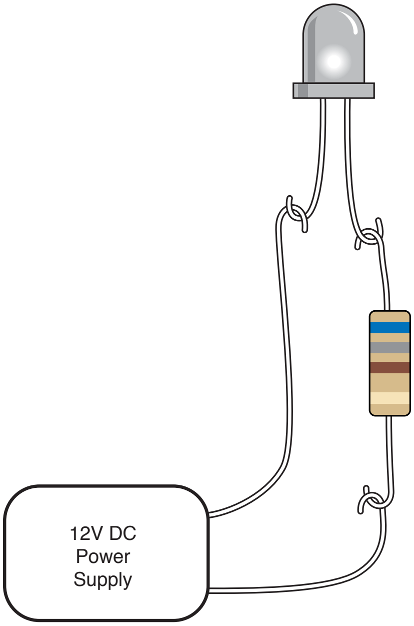

Figure 3-66. *By literally hooking together the leads from a resistor and a white-light LED, we minimize pathways for heat to escape during the subsequent test.*

Grip the plastic body of the LED in your helping hand. Plastic is not a good thermal conductor, so the helping hand shouldn't siphon too much heat away from our target. The resistor can dangle from one of the leads on the LED, and the wire from the AC adapter can hang from that, a little farther down. Gravity should be sufficient to make this work. Set your AC adapter to deliver 12 volts as before, plug it in, and your LED should be shining brightly. I used a white LED in this experiment, because it's easier to photograph.

Make sure your two soldering irons are really hot. They should have been plugged in for at least five minutes. Now take the pencil-style iron and hold its tip firmly against one of the leads on your glowing LED, while you check the time with a watch. Figure 3-67 shows the setup.

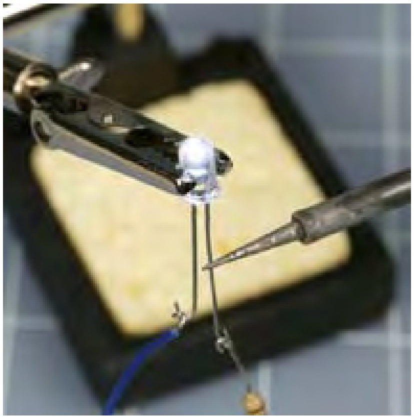

Figure 3-67. *Applying heat with a 15-watt soldering iron. A typical LED should withstand this treatment for two or three minutes, but if you substitute a 30-watt soldering iron, the LED is likely to burn out in under 15 seconds.*

I'm betting that you can sustain this contact for a full three minutes without burning out the LED. This is why you use a 15-watt soldering iron for delicate electronics work—it doesn't endanger the components.

Allow your LED wire to cool, and then apply your more powerful soldering iron to the same piece of wire as before. Again, make sure it is completely hot, and I think you'll find that the LED will go dark after as little as 10 seconds (note, some LEDs can survive higher temperatures than others). This is why you *don't* use a 30-watt soldering iron for delicate electronics work.

The large iron doesn't necessarily reach a higher temperature than the small one. It just has a larger heat capacity. In other words, a greater quantity of heat can flow out of it, at a faster rate.

Throw away your burned-out LED. Substitute a new one, connected as before, but add a full-size copper alligator clip to one of the leads up near the body of the LED, as shown in Figure 3-68. Press the tip of your 30-watt or 40-watt soldering iron against the lead just *below* the alligator clip. This time, you should be able to hold the powerful soldering iron in place for a full two minutes without burning out the LED.

Imagine the heat flowing out through the tip of your soldering iron, into the wire that leads to the LED—except that the heat meets the alligator clip along the way, as shown in Figure 3-69. The clip is like an empty vessel waiting to be filled. It offers much less resistance to heat than the remainder of the wire leading to the LED, so the heat prefers to flow into the copper clip, leaving the LED unharmed. At the end of your experiment, if you touch the clip, you'll find that it's hot, while the LED remains relatively cooler.

The alligator clip is known as a heat sink, and it should be made of copper, because copper is one of the best conductors of heat.

Because the 15-watt soldering iron failed to harm the LED, you may conclude that the 15-watt iron is completely safe, eliminating all need for a heat sink. Well, this may be true. The problem is, you don't really know whether some semiconductors may be more heat-sensitive than LEDs. Because the consequences of burning out a component are so exasperating, I suggest you should play it safe and use a heat sink in these circumstances:

- If you apply 15-watt iron extremely close to a semiconductor for 20 seconds or more.
- If you apply a 30-watt iron near resistors or capacitors for 10 seconds or more. (Never use it near semiconductors.)
- If you apply a 30-watt iron near anything meltable for 20 seconds or more. Meltable items include insulation on wires, plastic connectors, and plastic components inside switches.

Rules for Heat Sinking

1. Full-size copper alligator clips do work better.
2. Clamp the alligator clip as close as possible to the component and as far as possible from the joint. (You don't want to suck too much heat away from the joint.)
3. Make sure there is a metal-to-metal connection between the alligator clip and the wire to promote good heat transfer.

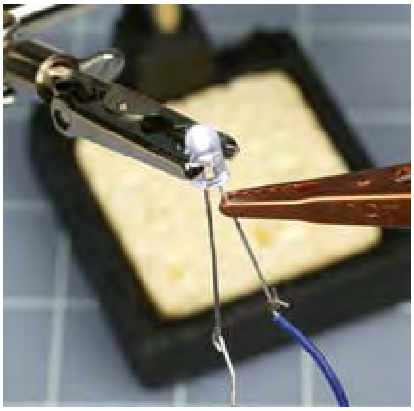

Figure 3-68. *When a copper alligator clip is used as a heat sink, you should be able to apply a 30-watt soldering iron (below the clip) without damaging the LED.*

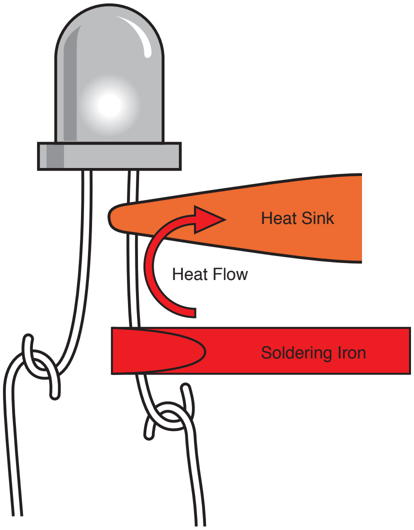

Figure 3-69. *The heat sink intercepts the heat, sucks it up, and protects the LED from damage.*

FUNDAMENTALS

All about perforated board

For the remainder of this book, you'll be using perforated board whenever you want to create permanent, soldered circuits. There are three ways to do this:

1. Point-to-point wiring. You use perforated board that has no connections behind the holes. Either the board has no copper traces on it at all, as in Figure 3-70, or you will find a little circular copper circle around each hole, as in Figure 3-71. These circles are not connected with each other and are used only to stabilize the components that you assemble.

   Point-to-point wiring allows you to place the components in a convenient, compact layout that can be very similar to a schematic. Under the board you bend the wires to link the components, and solder them together, adding extra lengths of wire if necessary. The advantage of this system is that it can be extremely compact. The disadvantage is that the layout can be confusing, leading to errors.

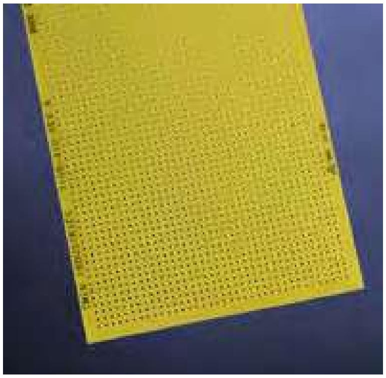

Figure 3-70

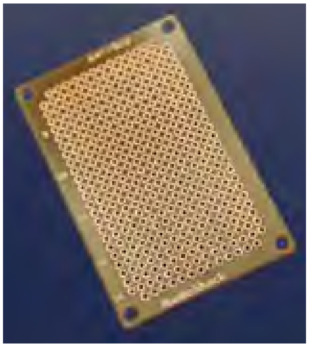

Figure 3-71. *Either this type of perforated board or the type in Figure 3-70 can be used for point-to-point wiring in Experiment 14.*

2. Breadboard-style wiring. Use perforated board that is printed with copper traces in exactly the same pattern as the conductors inside a breadboard. Once your circuit works on the breadboard, you move the components over to the perfboard one by one, maintaining their exact same positions relative to each other. You solder the "legs" of the components to the copper traces, which complete the circuit. Then you trim off the surplus wire. The advantage of this procedure is that it's quick, requires very little planning, and minimizes the possibility for errors. The disadvantage is that it tends to waste space. A cheap example is shown in Figure 3-72.
3. You can etch your own circuit board with customized copper traces that link your components in a point-to-point layout. This is the most professional way to complete a project, but it requires more time, trouble, and equipment than is practical in this book.

   Point-to-point wiring is like working with alligator clips, on a much smaller scale. The first soldered project will use this procedure.

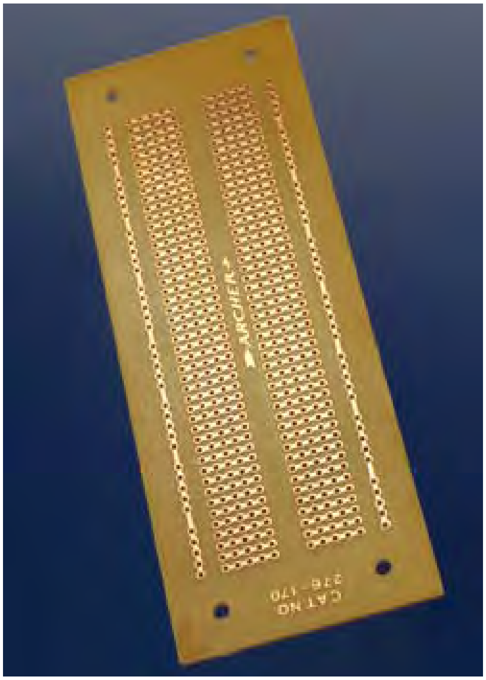

Figure 3-72. *Perforated board etched with copper in variants of a breadboard layout. This example is appropriate for Experiment 15.*

Experiment 14: A Pulsing Glow

You will need:

- Breadboard
- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Wire strippers and cutters
- Plain perforated board (no copper etching necessary)
- Small vise or clamp to hold your perforated board
- Resistors, various
- Capacitors, electrolytic, 100 µF and 220 µF, one of each
- Red LED, 5 mm, rated for 2 volts approximately
- 2N6027 programmable unijunction transistor

Your first circuit using a PUT was a slow-speed oscillator that made an LED flash about twice each second. The flashes looked very "electronic," by which I mean that the LED blinked on and off without a gradual transition between each state. I'm wondering if we can modify this circuit to make the LED pulse in a more gentle, interesting way, like the warning light on an Apple MacBook when it's in "sleep" mode. I'm thinking that something of this sort might be wearable as an ornament, if it's small enough and elegant enough.

I'm also thinking that this first soldering project will serve three purposes. It will test and refine your skill at joining wires together, will teach you point-to-point wiring with perfboard, and will give you some additional insight into the way that capacitors can be used to adjust timing.

Look back at the original schematic in Experiment 11, on page 82. Refresh your memory about the way it worked. The capacitor charges through a resistor until it has enough voltage to overcome the internal resistance in the PUT. Then the capacitor discharges through the PUT and flashes the LED.

If you drew a graph of the light coming out of the LED, it would be a thin, square-shaped pulse, as shown in Figure 3-73. How can we fill it out to make it more like the curve in Figure 3-74, so that the LED fades gently on and off, like a heartbeat?

One thing is obvious: the LED is going to be emitting a greater total amount of light in each cycle. Therefore, it's going to need more power. This means that C1, in Figure 3-75, must be a larger capacitor.

When we have a larger capacitor, it takes longer to charge. To keep the flashes reasonably frequent, we'll need a lower-value resistor for R1 to charge the capacitor quickly enough. In addition, reducing the values of R2 and R3 will program the PUT to allow a longer pulse.

Most important, I want to discharge the capacitor through a resistor to make the onset of the pulse gradual instead of sudden. Remember, when you have a resistor in series with a capacitor, the capacitor not only charges more slowly, but discharges more slowly.

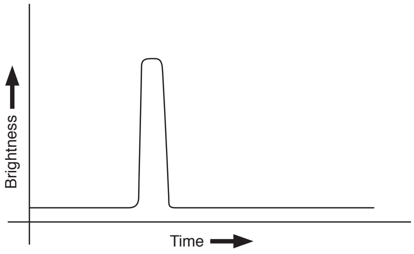

Figure 3-73

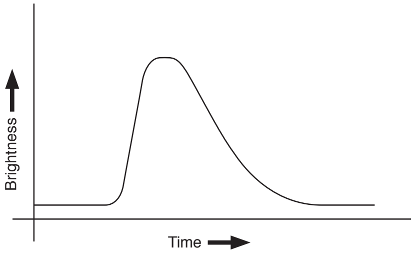

Figure 3-74. *The original PUT oscillator circuit in Experiment 11 made the LED emit sharp, short flashes. The upper graph shows what we might find if we measured light output over time. The second graph shows a gentler onset to each flash, followed by a slow fade-out. Capacitors can be used to create this effect.*

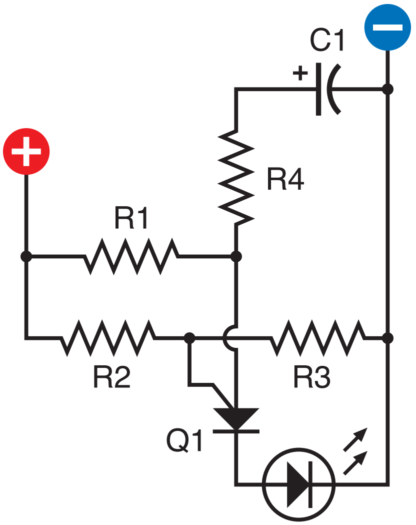

Figure 3-75. *The first step toward creating a gentler flashing effect is to use a larger capacitor for C1 and discharge it through a resistor, R4. Lower-value resistors are necessary to charge the capacitor rapidly enough.*

R1: 33K
R2: 1K
R3: 1K
R4: 1K
C1: 100 μF electrolytic
Q1: 2N6027

Figure 3-75 shows these features. Compare it with Figure 2-103 on page 85. R1 is now 33K instead of 470K. R2 and R3 are reduced to 1K. R4 also is 1K, to so that the capacitor takes longer to discharge through it. And C1 is now 100 µF instead of 2.2 µF.

Assemble this circuit on a breadboard, and compare the results when you include R4 or bypass it with a plain piece of jumper wire. It softens the pulse a bit, but we can work on it some more. On the output side of the PUT, we can add another capacitor. This will charge itself when the pulse comes out of the PUT, and then discharge itself gradually through another resistor, so that the light from the LED dies away more slowly.

Figure 3-76 shows the setup. C2 is large—220 µF—so it sucks up the pulse that comes out of the PUT, and then gradually releases it through 330Ω resistor R5 and the LED. You'll see that the LED behaves differently now, fading out inside of blinking off. But the resistances that I've added have dimmed the LED, and to brighten it, you should increase the power supply from 6 volts to 9 volts.

Remember that a capacitor imposes a smoothing effect only if one side of it is grounded to the negative side of the power supply. The presence of the negative charge on that side of the capacitor attracts the positive pulse to the other side.

I like the look of this heartbeat effect. I can imagine a piece of wearable electronic jewelry that pulses in this sensual way, very different from the hard-edged, sharp-on-and-off of a simple oscillator circuit. The only question is whether we can squeeze the components into a package that is small enough to wear.

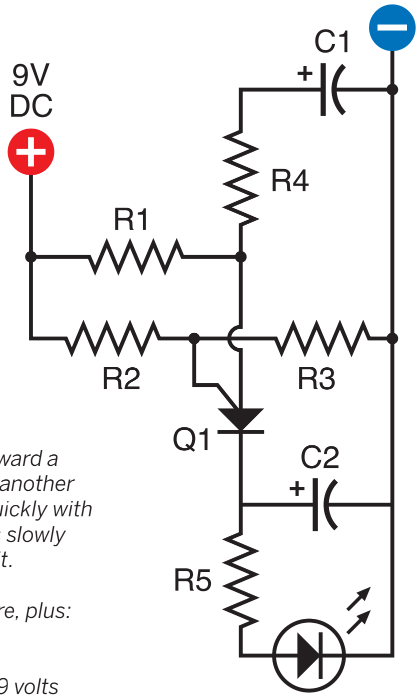

Figure 3-76. *The second step toward a gentler flashing effect is to add another capacitor, C2, which charges quickly with each pulse and then discharges slowly through R5 and the LED below it.*

Same components as before, plus:
R5: 330Ω
C2: 220 μF electrolytic
Power supply increased to 9 volts

Figure 3-77. *On a dark night in a rural area, the heartbeat flasher may be attractive in unexpected ways.*

Resizing the Circuit

The first step is to look at the physical components and imagine how to fit them into a small space. Figure 3-78 shows a 3D view of a compact arrangement. Check this carefully, tracing all the paths through the circuit, and you'll see that it's the same as the schematic. The trouble is that if we solder the components together like this, they won't have much strength. All the little wires can bend easily, and there's no easy way to mount the circuit in something or on something.

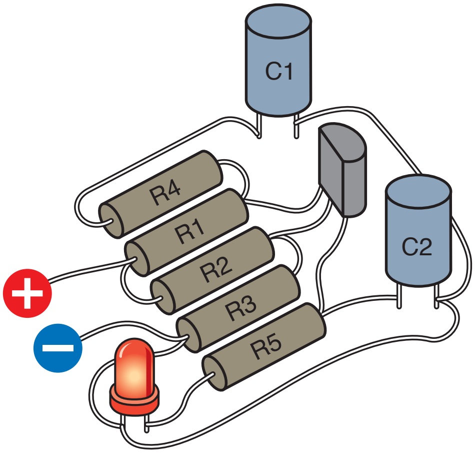

Figure 3-78. *This layout of components replicates their connections in the schematic diagram while squeezing them into a minimal amount of space.*

The answer is to put it on a substrate, which is one of those terms that people in the electronics field like to use, perhaps because it sounds more technical than "perfboard." But perforated board is what we need, and Figure 3-79 shows the components transferred onto a piece of board measuring just 1 inch by 0.8 inch.

The center version of this diagram uses dotted lines to show how the components will be connected with each other underneath the board. Mostly the leads that stick out from underneath the components will be long enough to make these connections.

Finally, the bottom version of the perfboard diagram shows the perfboard flipped left-to-right (notice the L and the R have been transposed to remind you, and I've used a darker color to indicate the underside of the board). Orange circles indicate where solder joints will be needed.

The LED should be unpluggable, because we may want to run it at some distance from the circuit. Likewise the power source should be unpluggable. Fortunately we can buy miniature connectors that fit right into the perforated board. You may have to go to large online retail suppliers such as Mouser.com for these. Some manufacturers call them "single inline sockets and headers," while others call them "boardmount sockets and pinstrip headers." Refer back to Figure 3-29 and check the shopping list for more details.

This is a very compact design that will require careful work with your pencil-style soldering iron. Because a piece of perforated board as small as this will tend to skitter around, I suggest that you apply your miniature vise to one end to anchor it with some weight while still allowing you to turn it easily.

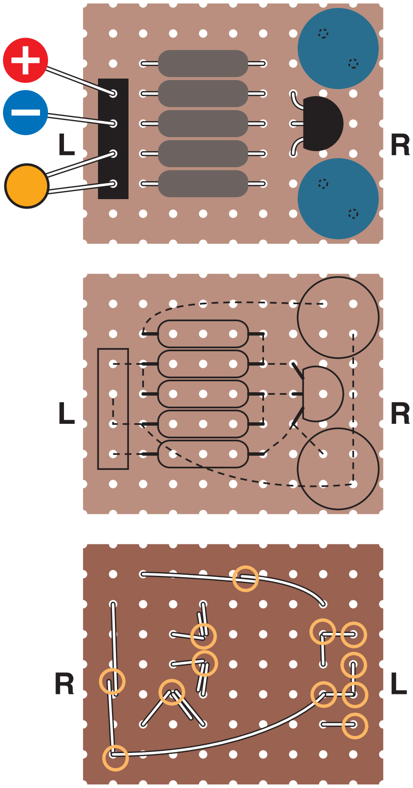

Figure 3-79. *Perforated board can be used to support the layout of components. Their leads are soldered together under the board to create the circuit. The middle diagram shows the wires under the board as dashed lines. The bottom diagram shows the board from underneath, flipped left to right. Orange circles indicate where solder joints will be necessary.*

When I'm working on this kind of project, I like to place it (with the vise attached) on a soft piece of polyurethane foam—the kind of slab that is normally used to make a chair cushion. The foam protects the components from damage when the board is upside-down, and again helps to prevent the work from sliding around unpredictably.

Step by Step

Here's the specific procedure for building this circuit:

1. Cut the small piece of perfboard out of a sheet that has no copper traces on it. You can cut the section using your miniature hobby saw, or you may be able to snap the board along its lines of holes, if you're careful. Alternatively, use a small ready-cut piece of perfboard with copper circles on it that are not connected to one another. You'll ignore the copper circles in this project. (In the next experiment, you'll deal with the additional challenge of making connections between components and copper traces on perforated board.)
2. Gather all the components and carefully insert them through holes in the board, counting the holes to make sure everything is in the right place. Flip the board over and bend the wires from the components to anchor them to the board and create connections as shown. If any of the wires isn't long enough, you'll have to supplement it with an extra piece of 22-gauge wire from your supply. You can remove all the insulation, as we'll be mounting the perfboard on a piece of insulating plastic.
3. Trim the wires approximately with your wire cutters.
4. Make the joints with your pencil soldering iron. Note that in this circuit, you are just joining wires to each other. The components are so close together that they'll prevent each other from wiggling around too much. If you are using board with copper pads (as I did), and some solder connects with them, that's OK—as long as it doesn't creep across to the neighboring component and create a short circuit.
5. Check each joint using a close-up magnifying glass, and wiggle it with pointed-nosed pliers. If there isn't enough solder for a really secure joint, reheat it and add more. If solder has created a connection that shouldn't be there, use a utility knife to make two parallel cuts in the solder, and scrape away the little section between them.

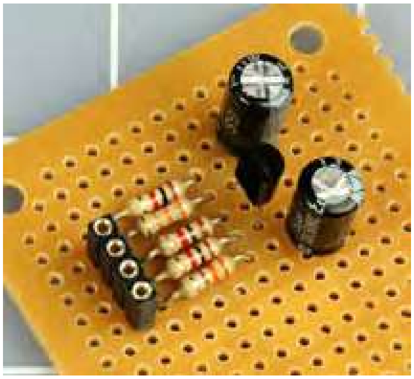

Figure 3-80. *Components mounted on a piece of perforated board.*

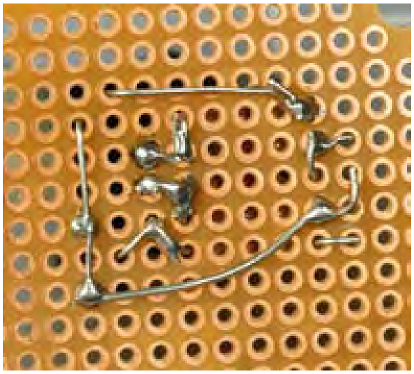

Figure 3-81. *The assembly seen from below. The copper circles around the holes are not necessary for this project. Some of them have picked up some solder, but this is irrelevant as long as no unintentional short circuits are created.*

Generally, I insert three or four components, trim the wires approximately, solder them, trim their wires finally, then pause to check the joints and the placement. If I solder too many components in succession, there's a greater risk of missing a bad joint, and if I make an error in placing a component, undoing it will be much more problematic if I have already added a whole lot more components around it.

Figures 3-80 and 3-81 show the version of this project that I constructed, before I trimmed the board to the minimum size.

Flying Wire Segments

The jaws of your wire cutters exert a powerful force that peaks and then is suddenly released when they cut through wire. This force can be translated into sudden motion of the snipped wire segment. Some wires are relatively soft, and don't pose a risk, but harder wires can fly in unpredictable directions at high speed, and may hit you in the eye. The leads of transistors are especially hazardous in this respect.

I think it's a good idea to wear safety glasses when trimming wires.

Finishing the Job

I always use bright illumination. This is not a luxury; it is a necessity. Buy a cheap desk lamp if you don't already have one. I use a daylight-spectrum fluorescent desk lamp, because it helps me identify the colored bands on resistors more reliably. Note that this type of fluorescent lamp emits quite a lot of ultraviolet light, which is not good for the lens in your eye. Avoid looking closely and directly at the tube in the lamp, and if you wear glasses, they will provide additional protection.

No matter how good your close-up vision is, you need to examine each joint with that close-up magnifier. You'll be surprised how imperfect some of them are. Hold the magnifier as close as possible to your eye, then pick up the thing that you want to examine and bring it closer until it comes into focus.

Finally, you should end up with a working circuit. You can insert the wires from your power supply into two of the tiny power sockets, and plug a red LED into the remaining two sockets. Remember that the two center sockets are negative, and the two outer sockets are positive, because it was easier to wire the circuit this way. You should color-code them to avoid mistakes.

So now you have a tiny circuit that pulses like a heartbeat. Or does it? If you have difficulty making it work, retrace every connection and compare it with the schematic. If you don't find an error, apply power to the circuit, attach the black lead from your meter to the negative side, and then go around the circuit with the red lead, checking the presence of voltage. Every part of this circuit should show at least some voltage while it's working. If you find a dead connection, you may have made a bad solder joint, or missed one entirely.

When you're done, now what? Well, now you can stop being an electronics hobbyist and become a crafts hobbyist. You can try to figure out a way to make this thing wearable.

First you have to consider the power supply. Because of the components that I used, we really need 9 volts to make this work well. How are you going to make this 9-volt circuit wearable, with a bulky 9-volt battery?

I can think of three answers:

1. You can put the battery in a pocket, and mount the flasher on the outside of the pocket, with a thin wire penetrating the fabric. Note that the tiny power connector on the perforated board will accept two 22-gauge wires if they are solid core, or if they are stranded (like the wires from a 9-volt battery connector) but have been thinly coated with solder.
2. You could mount the battery inside the crown of a baseball cap, with the flasher on the front.
3. You can put together three 3-volt button batteries in a stack, held in some kind of plastic clip. If you try this option, it may not be a good idea to try to solder wire to a battery. You will heat the liquid stuff inside the battery, which may not be good for it, and may not be good for you if the liquid starts boiling and the battery bursts open. Also, solder doesn't stick easily to the metallic finish on most battery terminals.

Most LEDs create a sharply defined beam of light, which you may want to diffuse to make it look nicer. One way to do this is to use a piece of transparent acrylic plastic, at least 1/4 inch thick, as shown in Figure 3-82. Sandpaper the front of the acrylic, ideally using an orbital sander that won't make an obvious pattern. Sanding will make the acrylic translucent rather than transparent.

Drill a hole slightly larger than the LED in the back of the acrylic. Don't drill all the way through the plastic. Remove all fragments and dust from the hole by blasting some compressed air into it, or by washing it if you don't have an air compressor. After the cavity is completely dry, get some transparent silicone caulking or mix some clear five-minute epoxy and put a drop in the bottom of the hole. Then insert the LED, pushing it in so that it forces the epoxy to ooze around it, making a tight seal. See Figure 3-82.

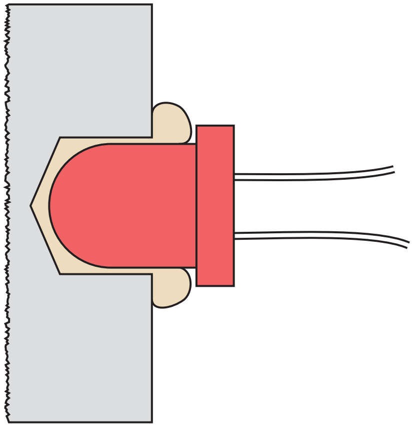

Figure 3-82. *This cross-sectional view shows a sheet of transparent acrylic in which a hole has been drilled part of the way from the back toward the front. Because a drill bit creates a hole with a conical shape at the bottom, and because the LED has rounded contours, transparent epoxy or silicone caulking can be injected into the hole before mounting the LED.*

Try illuminating the LED, and sand the acrylic some more if necessary. Finally, you can decide whether to mount the circuit on the back of the acrylic, or whether you want to run a wire to it elsewhere.

Because the LED will flash at about the speed of a human heart while the person is resting, it may look as if it's measuring your pulse, especially if you mount it on the center of your chest or in a strap around your wrist. If you enjoy hoaxing people, you can suggest that you're in such amazingly good shape, your pulse rate remains constant even when you're taking strenuous exercises.

To make a good-looking enclosure for the circuit, I can think of options ranging from embedding the whole thing in clear epoxy to finding a Victorian-style locket. I'll leave you to consider alternatives, because this is a book about electronics rather than handicrafts.

However, I will address one final issue: how long will this gadget continue flashing?

If you check the following section "Essentials: Battery life," you'll find that a regular alkaline 9-volt battery should keep the LED flashing for about 50 hours.

ESSENTIALS

Battery life

Any time you finish a circuit that you intend to run from a battery, you'll want to calculate the likely battery life. This is easily done, because manufacturers rate their batteries according to the "ampere hours" they can deliver. Keep the following in mind:

- The abbreviation for amp-hours is Ah, sometimes printed as AH. Milliampere-hours are abbreviated mAh.
- The rating of a battery in amp-hours is equal to the current, in amps, multiplied by the number of hours that the battery can deliver it.

Thus, in theory 1 amp-hour can mean 1 amp for 1 hour, or 0.1 amp for 10 hours, or 0.01 amp for 100 hours—and so on. In reality, it's not as simple as this, because the chemicals inside a battery become depleted more quickly when you draw a heavy current, especially if the battery gets hot. You have to stay within limits that are appropriate to the size of the battery.

For instance, if a small battery is rated for 0.5 amp-hours, you can't expect to draw 30 amperes from it for 1 minute. But you should be able to get 0.005 amps (i.e., 5 milliamps) for 100 hours without any trouble. Remember, though, that the voltage delivered by a battery will be greater than its rated voltage when the battery is fresh, and will diminish below its rated voltage while the battery is delivering power.

According to some test data that I trust (I think they are a little more realistic than the estimates supplied by battery manufacturers), here are some numbers for typical batteries:

- Typical 9 volt alkaline battery: 0.3 amp-hours, while delivering 100 mA.
- Typical AA size, 1.5-volt alkaline battery: 2.2 amp-hours, while delivering 100 mA.
- Rechargeable nickel-metal hydride battery: about twice the endurance of a comparably sized alkaline battery.
- Lithium battery: maybe three times the endurance of an alkaline battery.

BACKGROUND

Maddened by measurement

Throughout most of this book, I've mostly used measurements in inches, although sometimes I've digressed into the metric system, as when referring to "5-mm LEDs." This isn't inconsistency on my part; it reflects the conflicted state of the electronics industry, where you'll find inches and millimeters both in daily use, often in the very same data sheet.

The United States is the only major nation still using the old system of units that originated in England. (The other two holdouts are Liberia and Myanmar, according to the CIA's *World Factbook*.) Still, the United States has led many advances in electronics, especially the development of silicon chips, which have contacts spaced 1/10 inch apart. These standards became firmly established, and show no sign of disappearing.

To complicate matters further, even in the United States, you can encounter two incompatible systems for expressing fractions of an inch. Drill bits, for instance, are measured in multiples of 1/64 inch, while metal thicknesses may be measured in decimals such as 0.06 inch (which is approximately 1/16 inch).

The metric system is not necessarily more rational than the U.S. system. Originally, when the metric system was formally introduced in 1875, the meter was defined as being 1/10,000,000 of the distance between the North Pole and the equator, along a line passing through Paris—a quixotic, Francocentric conceit. Since then, the meter has been redefined three times, in a series of efforts to achieve greater accuracy in scientific applications.

As for the usefulness of a 10-based system, moving a decimal point is certainly simpler than doing calculations in 64ths of an inch, but the only reason we count in tens is because we happen to have evolved with that number of digits on our hands. A 12-based system would really be more convenient, as numbers would be evenly divisible by 2 and 3.

As we're stuck with the whimsical aspects of length measurement, I've created the charts in Figures 3-83 and 3-84 to assist you in going from one system to another. From these you will see that when you need to drill a hole for a 5 mm LED, a 3/16-inch drill bit is about right. (In fact, it results in a better, tighter fit than if you drill an actual 5 mm hole.)

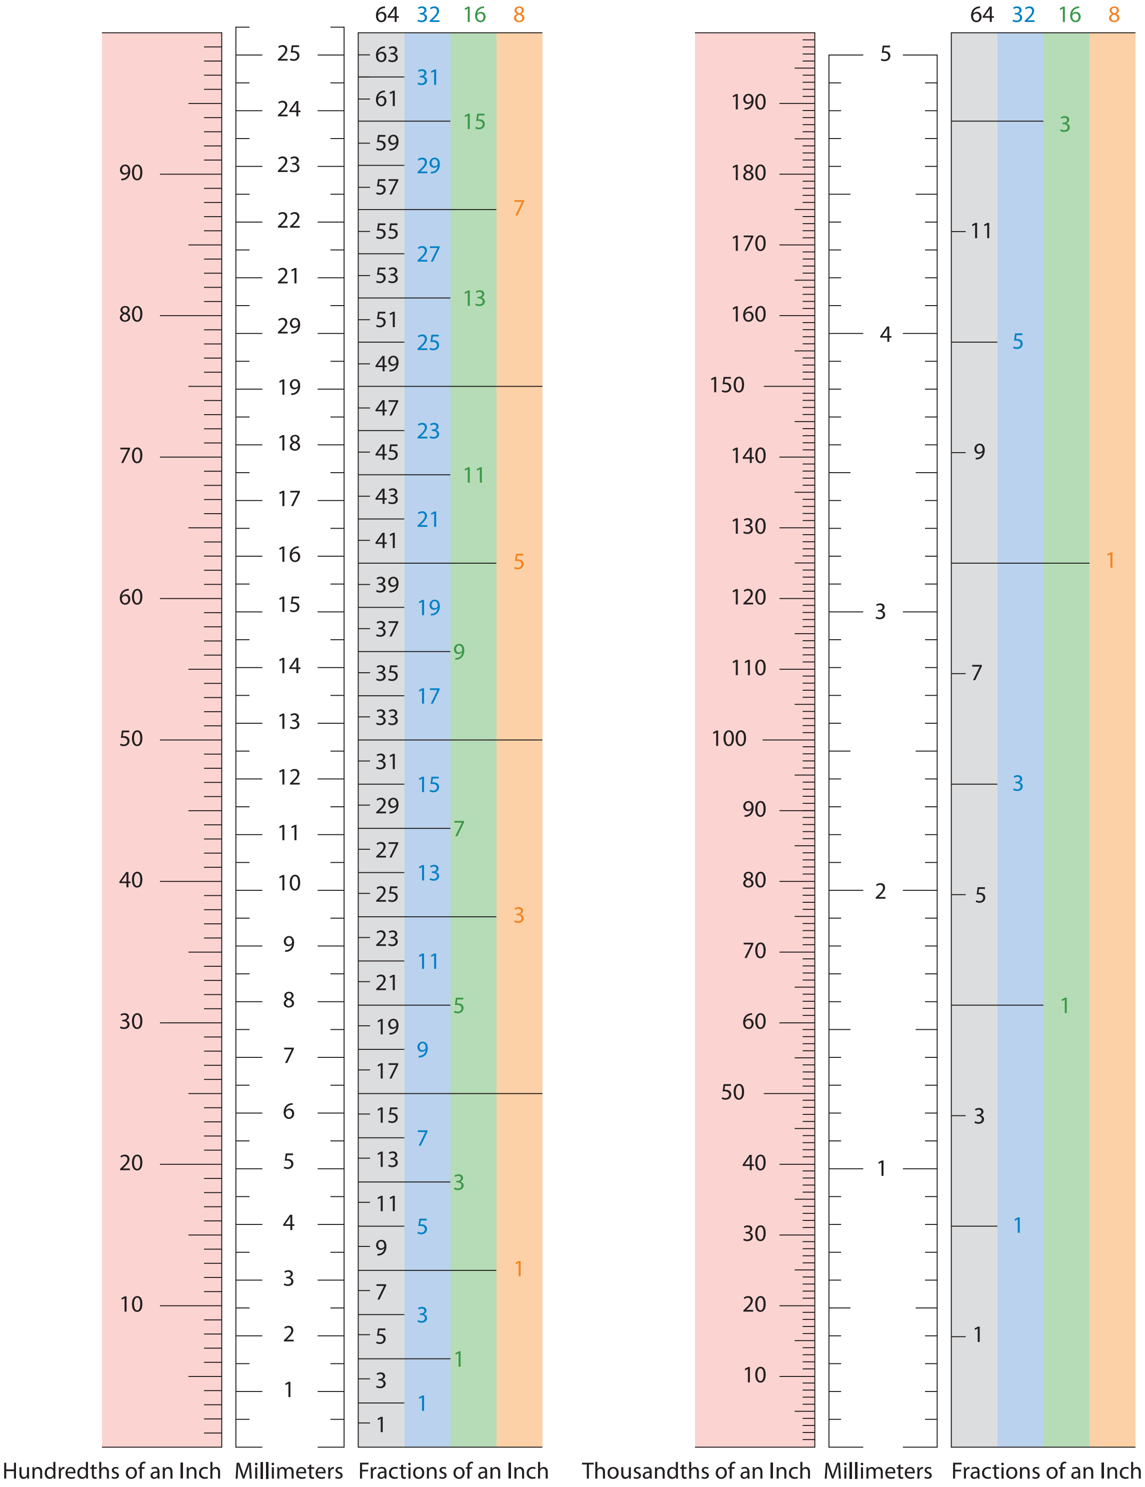

Figure 3-83. *Because units of measurement are not standardized in electronics, conversion is often necessary. The chart on the right is a 5x magnification of the bottom section of the chart on the left.*

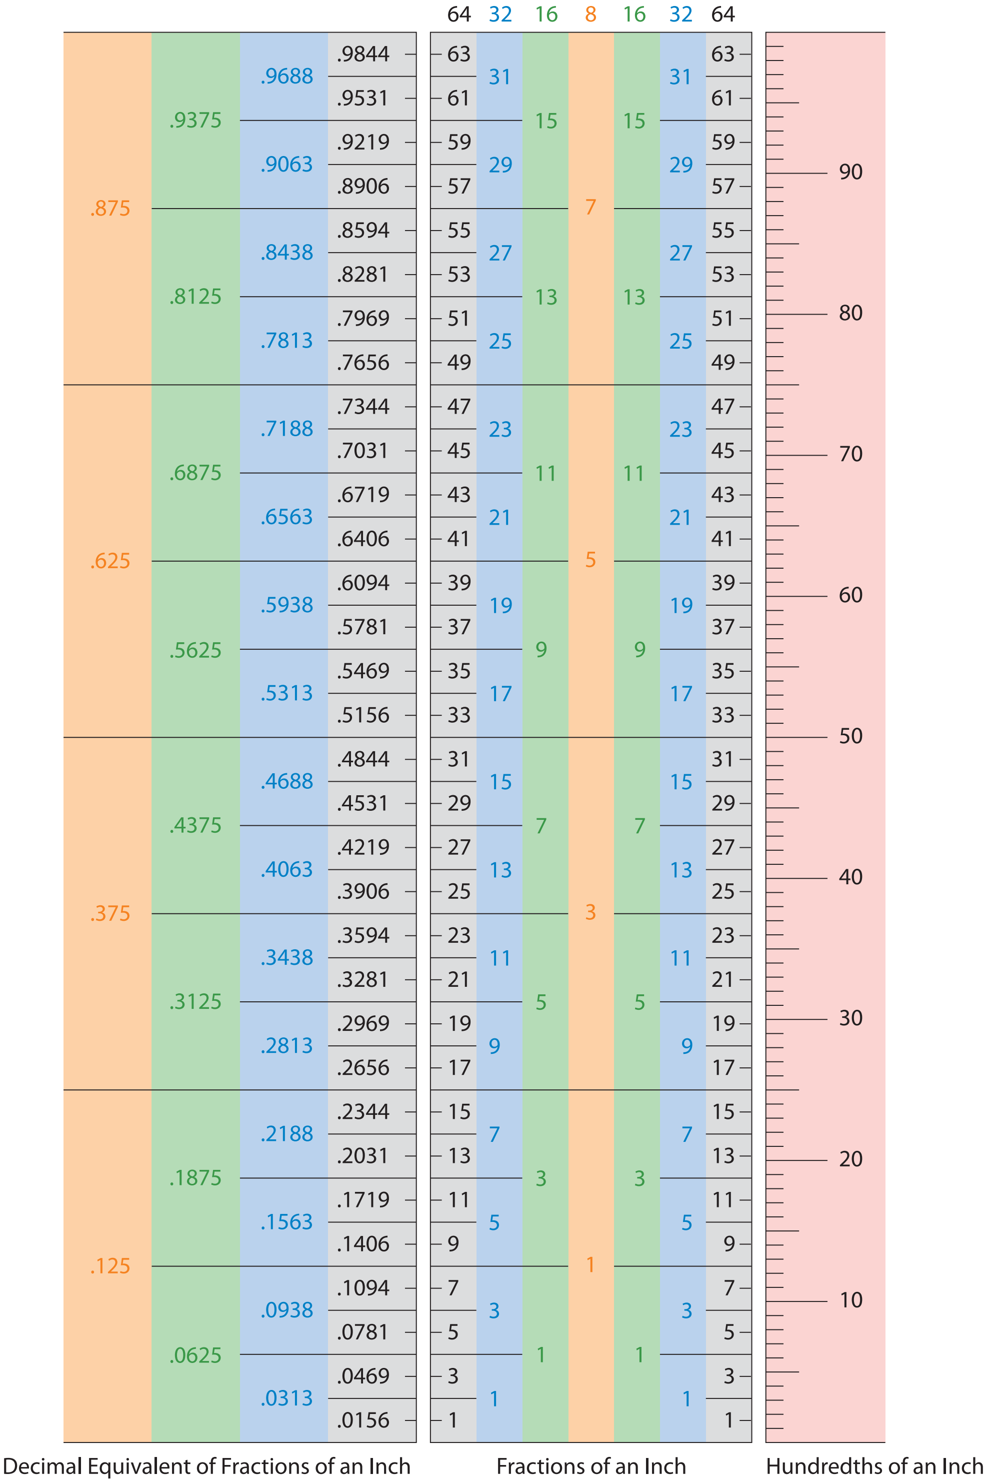

Figure 3-84. *This chart allows conversion between hundredths of an inch, conventional U. S. fractions of an inch, and fractions expressed in thousandths of an inch.*

Experiment 15: Intrusion Alarm Revisited

Time now to add some of the enhancements to the intrusion alarm that I discussed at the end of Experiment 11. I'm going to show you how the alarm can be triggered if you install various detectors on windows and doors in your home. I'll also show how the alarm can be wired so that it locks itself on and continues to make noise even after a door or window is reclosed.

This experiment will demonstrate the procedure for transferring a project from a breadboard to a piece of perforated board that has copper connections laid out identically to the ones inside the breadboard, as shown earlier in Figure 3-72. And you'll mount the finished circuit in a project box with switches and connectors on the front.

When all is said and done, you'll be ready for wholesale circuit building. The explanations in the rest of this book will get gradually briefer, and the pace will increase.

You will need:

- 15-watt pencil-type soldering iron
- Thin solder (0.022 inches or similar)
- Wire strippers and cutters
- Perforated board etched with copper in a breadboard layout
- Small vise or clamp to hold your perforated board
- The same components that you used in Experiment 11, plus:
  - 2N2222 NPN transistor. Quantity: 1.
  - DPDT relay. Quantity: 1.
  - SPDT toggle switch. Quantity: 1.
  - 1N4001 diode. Quantity: 1.
  - Red and green 5mm LEDs. Quantity: 1 each.
  - Project box, 6 × 3 × 2 inches.
  - Power jack, type N, and matching power socket, type N.
  - Binding posts.
  - Stranded 22-gauge wire, three different colors.
  - Magnetic sensor switches, sufficient for your home.
  - Alarm network wiring, sufficient for your home.

Magnetic Sensor Switches

A typical alarm sensor switch consists of two modules: the magnetic module and the switch module, as shown in Figures 3-85 and 3-86. The magnetic module contains a permanent magnet, and nothing else. The switch module contains a "reed switch," which makes or breaks a connection (like a contact inside a relay) under the influence of the magnet. When you bring the magnetic module close to the switch module, you may faintly hear the reed switch click as it flips from one state to the other.

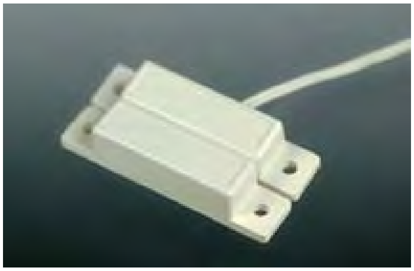

Figure 3-85. *In this simple alarm sensor switch, the lower module contains a magnet, which opens and closes a reed switch sealed into the upper module.*

Like all switches, reed switches can be normally open or normally closed. For this project, you want the kind of switch that is normally open, and closes when the magnetic module is close to it.

Attach the magnetic module to the moving part of a door or window, and attach the switch module to the window frame or door frame. When the window or door is closed, the magnetic module is almost touching the switch module. The magnet keeps the switch closed until the door or window is opened, at which point the switch opens.

The only question is: how do we use this component to trigger our alarm? As long as a small current flows through all our magnetic sensor switches, the alarm should be off, but if the flow of current stops, the alarm should switch on.

We could use a relay that is "always on" while the alarm is armed. When the circuit is interrupted, the relay relaxes and its other pair of contacts closes, which could power up the alarm noisemaker.

But I don't like this idea. Relays take significant power, and they can get hot. Most of them are not designed to be kept "always-on." I'd prefer to handle the task using a transistor.

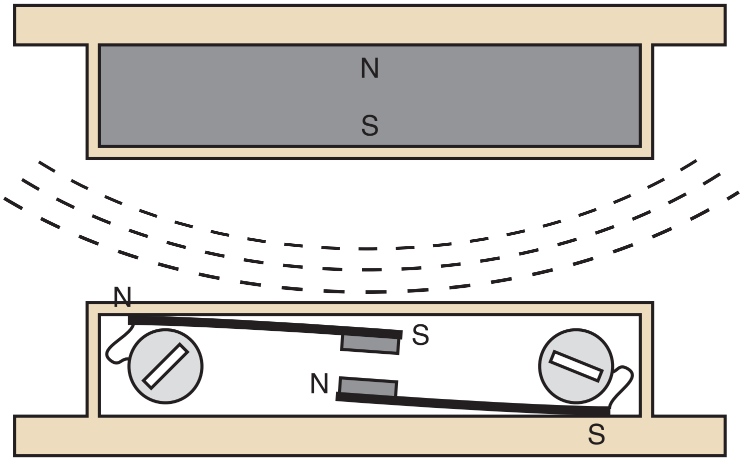

Figure 3-86. *This cutaway diagram shows a reed switch (bottom) and the magnet that activates it (top), inside an alarm sensor. The switch contains two flexible magnetized strips, the upper one with its south pole adjacent to an electrical contact, the lower one with its north pole adjacent to an electrical contact. When the south pole of the magnet approaches the switch, the magnetic force (shown as dashed lines) repels the south contact and attracts the north contact, causing them to snap together. Two screws on the outside of the casing are connected with the strips inside.*

A Break-to-Make Transistor Circuit

First, recall how an NPN transistor works. When the base is not sufficiently positive, the transistor blocks current between its collector and emitter, but when the base is relatively positive, the transistor passes current.

Take a look at the schematic in Figure 3-87, which is built around our old friend the 2N2222 NPN transistor. When the switch is closed, it connects the base of the transistor to the negative side of the power supply through a 1K resistor. At the same time, the base is connected with the positive side of the power supply through a 10K resistor. Because of the difference in resistances and the relatively high turn-on voltage for the LED, the base is forced below its turn-on threshold, and as a result, the transistor will not pass much current. The LED will glow dimly at best.

Now what happens when the switch is opened? The base of the transistor loses its negative power supply and has only its positive power supply. It becomes much more positive, above the turn-on threshold for the transistor, which tells the transistor to lower its resistance and pass more current. The LED now glows brightly. Thus, when the switch is turned off and breaks the connection, the LED is turned on.

This seems to be what we want. Imagine a whole series of switches instead of just one switch, as shown in Figure 3-88. The circuit will still work the same way, even if the switches are scattered all over your home, because the resistance in the wires connecting the switches will be trivial compared with the resistance of the 1K resistor.

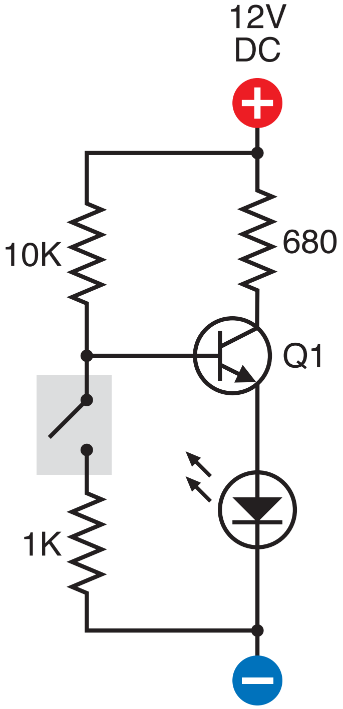

Figure 3-87. *In this demonstration circuit, when the switch is opened, it interrupts negative voltage to the base of the transistor, causing the transistor to lower its resistance, allowing current to reach the LED. Thus, when the switch is turned off, it turns on the LED.*

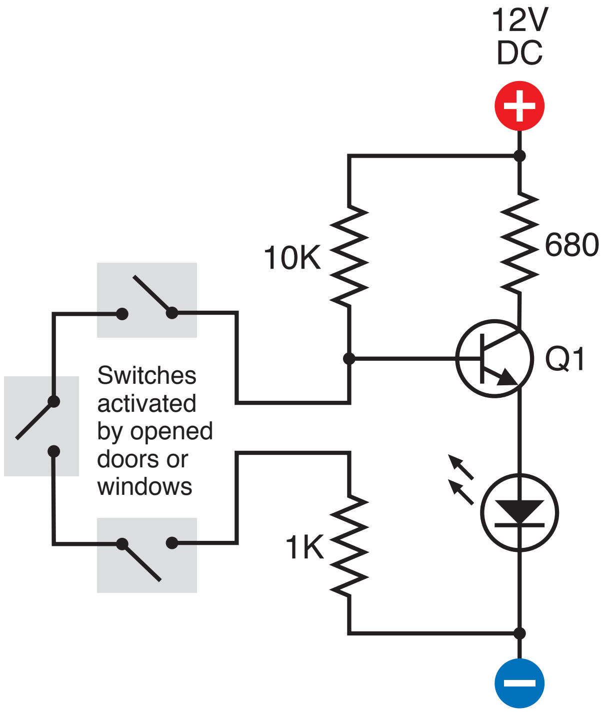

Figure 3-88. *A network of switches, wired in series, can be substituted for the single switch in Figure 3-87. Now any one switch will break continuity and trigger the transistor.*

I have shown the switches open, because that's the way the schematic for a switch is drawn, but imagine them all closed. The base of the transistor will now be supplied through the long piece of wire connecting all the closed switches, and the LED will stay dark. Now if just one switch is opened, or if anyone tampers with the wire linking them, the base of the transistor loses its connection to negative power, at which point the transistor conducts power and the LED lights up.

While all the switches remain closed, the circuit is drawing very little current—probably about 1.1 mA. So you could run it from a typical 12-volt alarm battery.

Now suppose we swap out the LED and put a relay in there instead, as shown in Figure 3-89. I don't mind using a relay in this location, because the relay will not be "always on." It will normally be off, and will draw power only when the alarm is triggered.

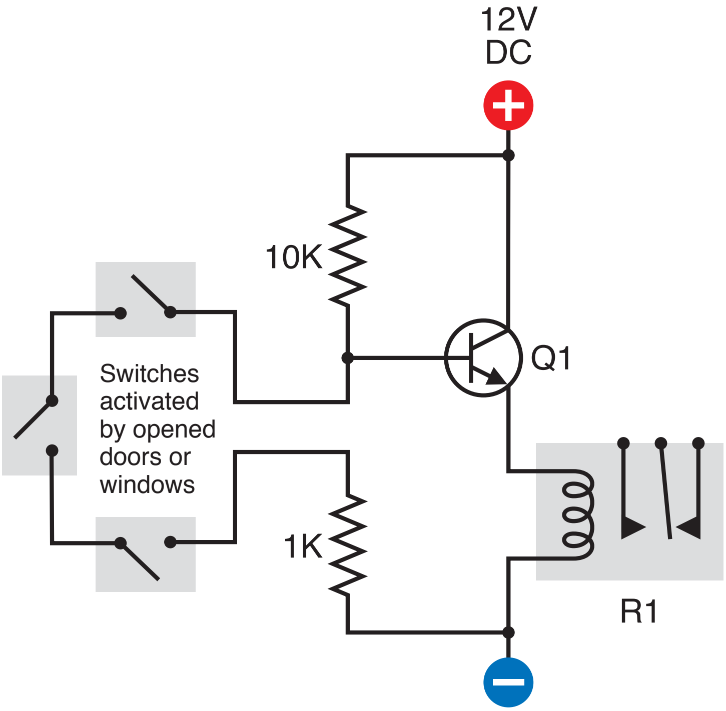

Figure 3-89. *If the LED and 680Ω resistor shown in are removed, and a relay takes their place, the relay will be activated when any switch in the sensor network is opened.*

Try one of the 12-volt relays that you used previously. You should find that when you open the switch, the relay is energized. When you close the switch, the relay goes back to sleep. Note that I eliminated the 680Ω resistor from the circuit, because the relay doesn't need any protection from the 12-volt power supply.

Self-Locking Relay

There's only one remaining problem: we want the alarm to continue making noise even after someone who has opened a door or window closes it again quickly. In other words, when the relay is activated, it must lock itself on.

One way to do this would be by using a latching relay. The only problem is that we would then need another piece of circuitry to unlatch it. I prefer to show you how you can make any relay keep itself switched on after it has received just one jolt of power. This idea will be useful to you later in the book as well.

The secret is to supply power to the relay coil through the two contacts inside the relay that are normally open. (Note that this is exactly opposite to the relay oscillator, which supplied power to its coil through the contacts that were normally closed. That setup caused the relay to switch itself off almost as soon as it switched itself on. This setup causes the relay to keep itself switched on, as soon as it has been activated.)

In Figure 3-90, the four schematics illustrate this. You can imagine them as being like frames in a movie, photographed microseconds apart. In the first picture, the switch is open, the relay is not energized, and nothing is happening. In the second, the switch has been closed to energize the coil. In the third, the coil has pulled the contact inside the relay, so that power now reaches the coil via two paths. In the fourth, the switch has been opened, but the relay is still powering its own coil through its contacts. It will remain locked in this state until the power is disconnected.

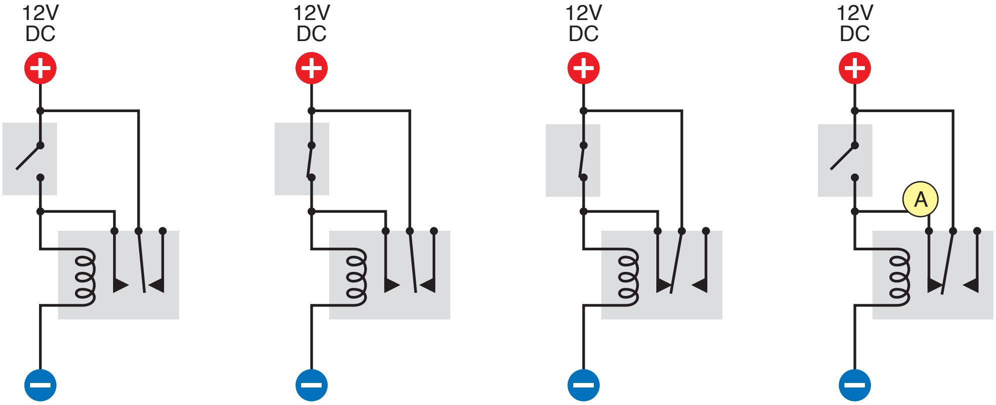

Figure 3-90. *This sequence of schematics shows the events that occur when a relay is energized. Initially, the switch is open. Then the switch is closed, activating the relay. The relay then powers itself through its own internal contacts. The relay remains energized even after the switch is opened again. Power switched by the relay can be taken from the circuit at point A.*

All we need to do, to make use of this idea, is to substitute the transistor for the on/off switch, and tap into the circuit at point A, running a wire from there to the noisemaking module.

Figure 3-91 shows how that would work. When the transistor is activated by any of the network of sensor switches, as previously explained, the transistor conducts power to the relay. The relay locks itself on, and the transistor becomes irrelevant.

Figure 3-92. *This block diagram previously shown in Figure 2-112 on page 90 has been updated to include the magnetic-switch network and locking-relay control system.*

Because I've been adding pieces to the original alarm noisemaker circuit, I've updated the block diagram from Figure 2-112 to show that we can still break this down into modules with simple functions. The revised diagram is shown in Figure 3-92.

Blocking Bad Voltage

One little problem remains: in the new version of the circuit, if the transistor goes off while the relay is still on, current from the relay can flow back up the wire to the emitter of the transistor, where it will try to flow backward through the transistor to the base, which is "more negative," as it is linked through all the magnetic switches and the 1K resistor to the negative side of the power supply.

Applying power backward through a transistor is not a nice thing to do. Therefore the final schematic in this series shows one more component, which you have not seen before: a diode, labeled D1. See Figure 3-93. The diode looks like the heart of an LED, and indeed, that's pretty much what it is, although some diodes are much more robust. It allows electricity to flow in only one direction, from positive to negative, as shown by its arrow symbol. If current tries to flow in the opposite direction, the diode blocks it. The only price you pay for this service is that the diode imposes a small voltage drop on electricity flowing in the "OK" direction.

So now, positive flow can pass from the transistor, through the diode, to the relay coil, to get things started. The relay then supplies itself with power, but the diode prevents the positive voltage from getting back into the transistor the wrong way.

Perhaps a more elegant solution to the problem is to connect the NO leg of the relay via a 10k resistor to the base connection. When the relay is not energized, the NO leg is inert and simply behaves as a parasitic capacitance on the node. When the relay becomes energized, the NO leg shunts +12V through the common terminal via a 10k resistor into the base of the transistor. In this circuit configuration, the transistor is never exposed to a potentially harmful voltage and you are not depending on leakage currents of non-ideal elements to protect devices.

However, I needed an opportunity to introduce you to the concept of diodes. You can check the following section "Essentials: All about diodes" to learn more.

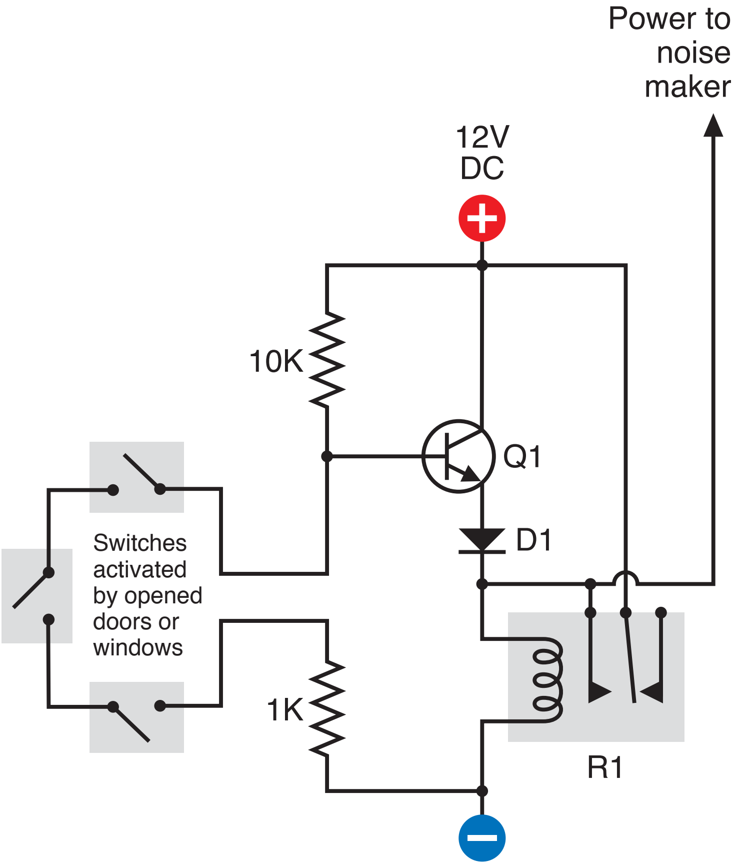

Figure 3-93. *Diode D1 has been added to protect the emitter of Q1 from positive voltage when the relay is energized.*

ESSENTIALS

All about diodes

A diode is a very early type of semiconductor. It allows electricity to flow in one direction, but blocks it in the opposite direction. (A light-emitting diode is a much more recent invention.) Like an LED, a diode can be damaged by reversing the voltage and applying excessive power, but most diodes generally have a much greater tolerance for this than LEDs. The end of the diode that blocks positive voltage is always marked, usually with a circular band, while the other end remains unmarked. Diodes are especially useful in logic circuits, and can also convert alternating current (AC) into direct current (DC).

A Zener diode is a special type that we won't be using in this book. It blocks current completely in one direction, and also blocks it in the other direction until a threshold voltage is reached—much like a PUT.

Signal diodes are available for various different voltages and wattages. The 1N4001 diode that I recommend for the alarm activation circuit is capable of handling a much greater load at a much higher voltage, but I used it because it has a low internal resistance. I wanted the diode to impose a minimal voltage drop, so that the relay would receive as much voltage as possible.

It's good practice to use diodes at less than their rated capacity. Like any semiconductor, they can overheat and burn out if they are subjected to mistreatment.

The schematic symbol for a diode has only one significant variant: sometimes the triangle is outlined instead of filled solid black (see Figure 3-94).

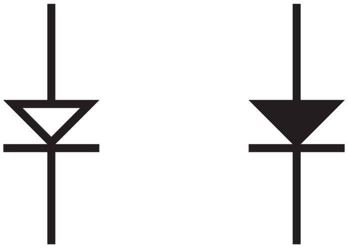

Figure 3-94. *Either of these schematic symbols may be used to represent a diode, but the one on the right is more common than the one on the left.*

Completing the Breadboard Alarm Circuit

It's time now to breadboard the control circuit for your alarm noisemaker. Figure 3-95 shows how this can be done. I am assuming that you still have the noisemaker, which functions as before. I'm assuming that you still have its relevant components mounted on the top half of the breadboard. To save space, I'm just going to show the additional components mounted on the bottom half of the same breadboard.

It's important to remember that you are not supplying power directly to the left and right "rails" on the breadboard anymore; you are supplying power to the relay-transistor section, and when the relay closes its contacts, the *relay* supplies power to the rails. These then feed the power up to the top half of the breadboard. So disconnect your power supply from the breadboard rails and reconnect it as shown in Figure 3-95.

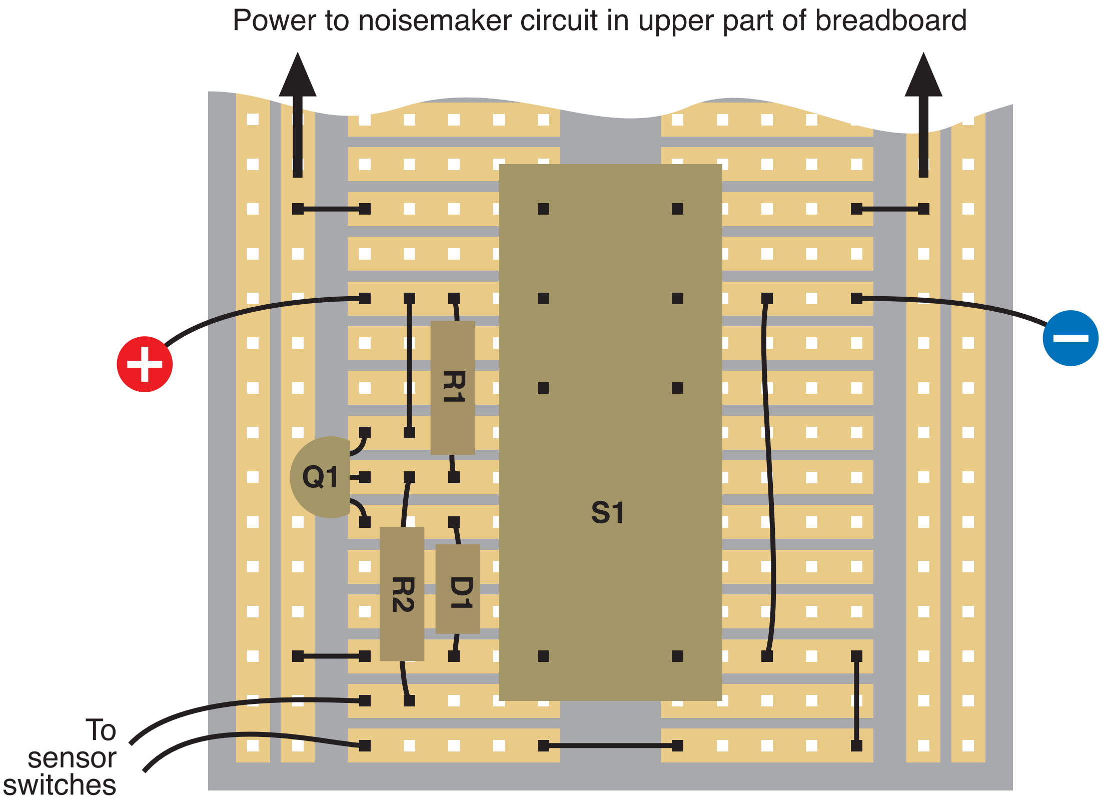

Figure 3-95. *The schematic that was developed in the previous pages can be emulated with components on a breadboard, as shown here. S1 is a DPDT relay. Wires to the sensor switch network and to the power supply must be added where shown.*

Because it's a double-pole relay, I am using it to switch negative as well as positive. This means that when the relay contacts are open, the noisemaking section of the circuit is completely isolated from the rest of the world.

The breadboarded relay circuit is exactly the same as the schematic in Figure 3-93. The components have just been rearranged and squeezed together so that they will fit alongside the relay. Two wires at the lower-left corner go to the network of magnetic sensor switches that will trip the alarm; for testing purposes, you can just hold the stripped ends of these two wires together to simulate all the switches being closed, and separate the wires to simulate a switch opening.

Two more wires bring power to the breadboard on either side of the relay. This is where you should connect your power supply during testing. The output from the relay, through its top pair of contacts, is connected with the rails of the breadboard by a little jumper wire at top left, and another at top right. Don't forget to include them! One more little wire at the lower-left corner (easily overlooked) connects the lefthand side rail to the lefthand coil terminal of the relay, so that when the relay is powering the noisemaker circuit, it powers itself as well.

When you mount the diode, remember that the end of it that is marked with a band around it is the end that blocks positive current. In this circuit, that's the lower end of the diode.

Try it to make sure that it works. Short the sensor wires together and then apply power. The alarm should remain silent. You can use your meter to check that no voltage exists between the side rails. Now separate the sensor wires, and the relay should click, supplying power to the side rails, which activates the noisemaker. Even if you bring the sensor wires back together, the relay should remain locked on. The only way to unlock it is to disconnect the power supply.

When the circuit is active, the transistor followed by the diode drops the voltage slightly, but the 12-volt relay should still work.

In my test circuit, trying three different relays, they drew between 27 and 40 milliamps at 9.6 volts. Some current still leaked through the transistor when it was in its "off" mode, but only a couple of milliamps at 0.5 volts. This low voltage was far below the threshold required to trip the relay.

Ready for Perfboarding

If the circuit works, the next step is to immortalize it on perforated board. Use the type of board that has a breadboard contact pattern etched on it in copper, as shown in Figure 3-72 on page 116. Check the following section, "Essentials: Perfboard procedure," for guidance on the best way to make this particular kind of solder joint—and the subsequent section for the most common problems.

ESSENTIALS

Perfboard soldering procedure

Carefully note the position of a component on your breadboard, and then move it to the same relative position on the perfboard, poking its wires through the little holes.

Turn the perfboard upside down, make sure that it's stable, and examine the hole where the wire is poking through, as shown in Figure 3-96. A copper trace surrounds this hole and links it with others. Your task is to melt solder so that it sticks to the copper and also to the wire, forming a solid, reliable connection between the two of them.

Take your pencil-style soldering iron in one hand and some solder in your other hand. Hold the tip of the iron against the wire and the copper, and feed some thin solder to their intersection. After two to four seconds, the solder should start flowing.

Allow enough solder to form a rounded bump sealing the wire and the copper, as shown in Figure 3-97. Wait for the solder to harden thoroughly, and then grab the wire with pointed-nosed pliers and wiggle it to make sure you have a strong connection. If all is well, snip the protruding wire with your cutters. See Figure 3-98.

Because solder joints are difficult to photograph, I'm using drawings to show the wire before and after making a reasonably good joint, which is shown in pure white, outlined with a black line.

Actual soldered perfboard is shown in the photographs in Figures 3-99 and 3-100.

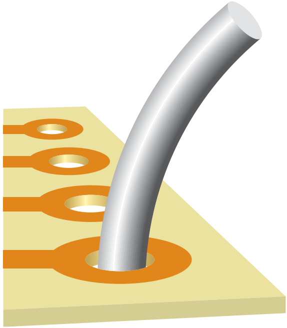

Figure 3-96

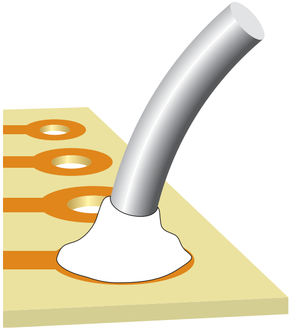

Figure 3-97

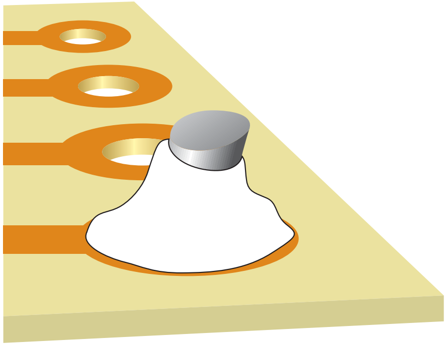

Figure 3-98. *To establish a connection between a section of wire and a copper trace on perforated board, the wire is pushed through the hole, and solder (shown in pure white for illustrative purposes) completes the connection. The wire can then be snipped short.*

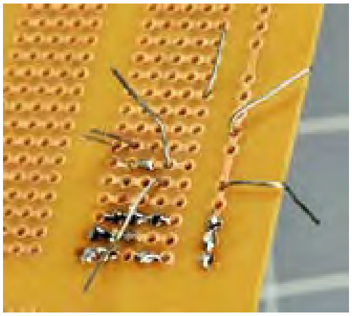

Figure 3-99. *This photograph was taken during the process of transferring components from breadboard to perforated board. Two or three components at a time are inserted from the other side of the board, and their leads are bent over to prevent them from falling out.*

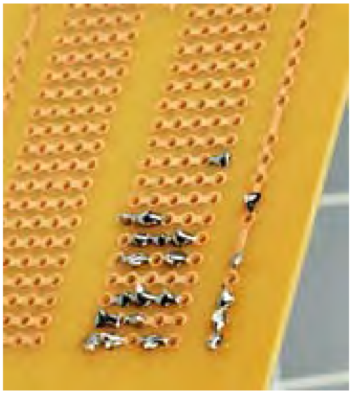

Figure 3-100. *After soldering, the leads are snipped short and the joints are inspected under a magnifying glass. Another two or three components can now be inserted, and the process can be repeated.*

TOOLS

Four most common perfboarding errors

1. Too much solder

Before you know it, solder creeps across the board, touches the next copper trace, and sticks to it, as depicted in Figure 3-101. When this happens, you have to wait for it to cool, and then cut it with a utility knife. You can also try to remove it with a rubber bulb and solder wick, but some of it will tend to remain.

Even a microscopic trace of solder is enough to create a short circuit. Check the wiring under a magnifying glass while turning the perfboard so that the light strikes it from different angles (or use your solder wick to suck it away).

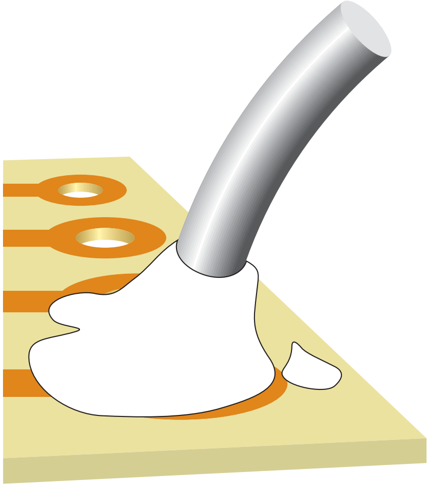

Figure 3-101. *If too much solder is used, it makes a mess and can create an unwanted connection with another conductor.*

2. Not enough solder

If the joint is thin, the wire can break free from the solder as it cools. Even a microscopic crack is sufficient to stop the circuit from working. In extreme cases, the solder sticks to the wire, and sticks to the copper trace around the wire, yet doesn't make a solid bridge connecting the two, leaving the wire encircled by solder yet untouched by it, as shown in Figure 3-102. You may find this undetectable unless you observe it with magnification.

You can add more solder to any joint that may have insufficient solder, but be sure to reheat the joint thoroughly.

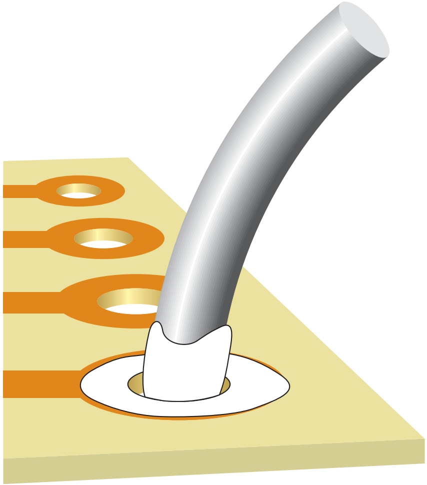

Figure 3-102. *Too little solder (or insufficient heat) can allow a soldered wire to remain separate from the soldered copper on the perforated board. Even a hair-thin gap is sufficient to prevent an electrical connection.*

3. Components incorrectly placed

It's very easy to put a component one hole away from the position where it should be. It's also easy to forget to make a connection.

I suggest that you print a copy of the schematic, and each time you make a connection on the perforated board, you eliminate that wire on your hardcopy, using a highlighter.

4. Debris

When you're trimming wires, the little fragments that you cut don't disappear. They start to clutter your work area, and one of them can easily get trapped under your perforated board, creating an electrical connection where you don't want it.

This is another reason for working with something soft, such as polyurethane foam, under your project. It tends to absorb or hold little pieces of debris, reducing the risk of you picking them up in your wiring.

Clean the underside of your board with an old (dry) toothbrush before you apply power to it, and keep your work area as neat as possible. The more meticulous you are, the fewer problems you'll have later.

Once again, be sure to check every joint with a magnifying glass.

Transferring components from the breadboard to the perforated board should be fairly simple, as long as you don't try to move too many at once. Follow the suggestions described in previous section "Essentials: Perfboard procedure," and pause frequently to check your connections. Impatience is almost always the cause of errors in this kind of work.

Figure 3-103 shows the noisemaker section of the circuit on perfboard, with the components positioned to minimize wasted space. Figure 3-104 shows the perfboard with the relay and its associated components added. The two black wires will go to the loudspeaker, the black-and-red pair of wires will bring power to the board, and the green wires will go to the magnetic sensor switches. Each wire penetrates the board, and its stripped end is soldered to the copper beneath.

Test it now, in the same way that you tested the same circuit on the breadboard. If it doesn't work, check the following section, "Essentials: Real-world fault tracing." If it does work, you're ready to trim the board and mount it in a project box.

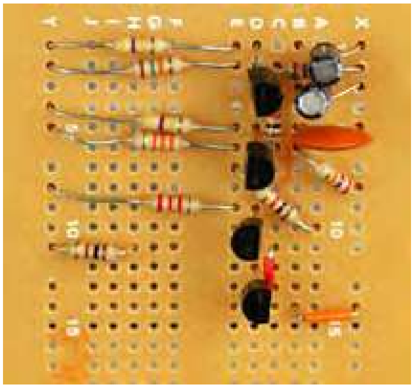

Figure 3-103. *The noisemaker circuit has been transplanted from breadboard to perforated board, with no additions or changes.*

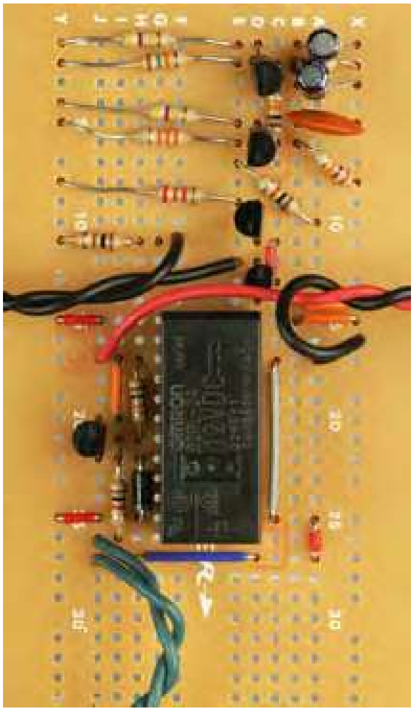

Figure 3-104. *The relay-transistor control circuit has been added. Wires to external devices have been stripped and poked into the perforated board, where they are soldered in place. The green wires connect with the sensor network, the black wires go to the loudspeaker, and the red-and-black wires supply power.*

ESSENTIALS

Real-world fault tracing

Here's a real-life description of the procedure for tracing a fault.

After I assembled the perfboard version of the combined noisemaker and relay circuit, I checked my work, applied power—and although the relay clicked, no sound came out of the loudspeaker. Of course, everything had worked fine on the breadboard.

First I looked at component placement, because this is the easiest thing to verify. I found no errors. Then I flexed the board gently while applying power—and the loudspeaker made a brief "beep." Any time this happens, you can be virtually certain that a solder joint has a tiny crack in it.

The next step was to anchor the black lead of my meter to the negative side of the power supply, and then switch on the power and go through the circuit point by point, from top to bottom, checking the voltage at each point with the red lead of the meter. In a simple circuit like this, every part should show at least some voltage.

But when I got to the second 2N2222 transistor, which powers the loudspeaker, its output was completely dead. Either I had melted the transistor while soldering it (unlikely), or there was a bad joint. I checked the perfboard beneath the transistor with the magnifying glass, and found that solder had flowed around one of the leads of the transistor without actually sticking to it. The gap must have been less than one-thousandth of an inch, but still, that was enough. Probably, the problem had been caused by dirt or grease.

This is the kind of patient inquiry you need to follow when a circuit doesn't work. Check whether your components are placed correctly, check your power supply, check the power on the board, check the voltage at each stage, and if you are persistent, you'll find the fault.

Switches and Inputs for the Alarm

Now you need to make the system easy to use. The block diagram in Figure 3-105 shows one additional box near the top of the sequence: User Controls. These will consist of switches, LEDs, and connections to the outside world. To plan this part of the job, first I have to summarize the way in which our alarm system works at this point in its evolution.

A full-featured home alarm system normally has two modes: in-home and away-from-home:

- Using the in-home mode, you switch on the alarm while you are at home so that it will alert you if an intruder opens a door or window.
- Using the away-from-home mode, typically you enter a code number, after which you have 30 seconds to leave and close the door behind you. When you return, you trigger the alarm by opening the door, but now you have 30 seconds to go to the control panel and enter your code number again to stop the alarm from sounding.

So far, the alarm system that you've been building has only an in-home mode. Still, many people find this function useful and reassuring. Later in the book I'll suggest a way in which you can modify it to incorporate an away-from-home mode, but for now, making it practical for in-home use is enough of a challenge.

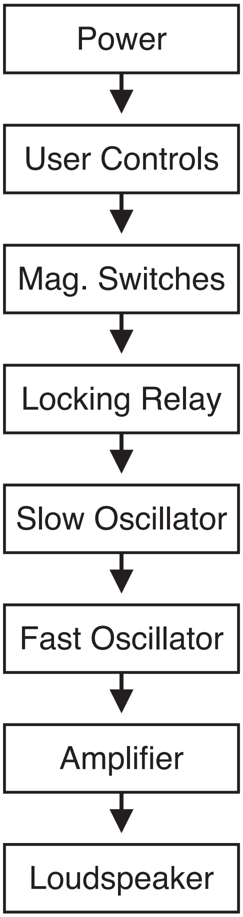

Figure 3-105. *The final block diagram for this phase of the project shows where user controls fit in the series of functions.*

Consider how it should be used on an everyday basis. It should have an on/off switch, naturally. When it's on, any of the magnetic sensor switches should trigger the alarm. But what if you switch it on without realizing that you've left a window open? At that time it won't be appropriate for the alarm to sound. What you really need is a circuit-test feature, to tell you if all the doors and windows are closed. Then you can switch on the alarm.

I think a pushbutton would be useful to test the alarm circuit. When you press it, a green LED should light up to indicate that the circuit is good. After you see the green light, you let go of the pushbutton and turn on the power switch, which illuminates a red LED, to remind you that the alarm is now armed and ready.

One additional feature would be useful: an alarm noisemaker test feature, so that you can be sure that the system is capable of sounding its alert when required to do so.

The circuit shown in Figure 3-106 incorporates all of these features. S1 is a SPDT switch; S2 is a DPDT momentary pushbutton of ON-(ON) type. The schematic shows it in its "relaxed" mode, when the button is not being pressed.

D1 is a red LED, D2 is a green LED, J1 is a power input jack (to be connected with an external 12-volt supply), and R1 is a 680Ω resistor to protect the LEDs. Note that J1 follows the usual practice of supplying positive voltage in its center contact, and negative in the circular shell around the center.

When S1 is in its Off position, it still supplies positive power through its upper contact to S2, the pushbutton. When the pushbutton is pressed, so that it goes into its "Test" position, the pole of S2 connects with the power and sends it out through the sensor switches on doors and windows. The wires to these switches will be attached via a couple of binding posts, shown here as two circles. If the sensor switches are all closed, power returns through the second binding post, passes through the lower set of contacts in S2, and lights D2, the green LED. Because S1 is not supplying power to the alarm circuit board, the alarm does not sound at this time.

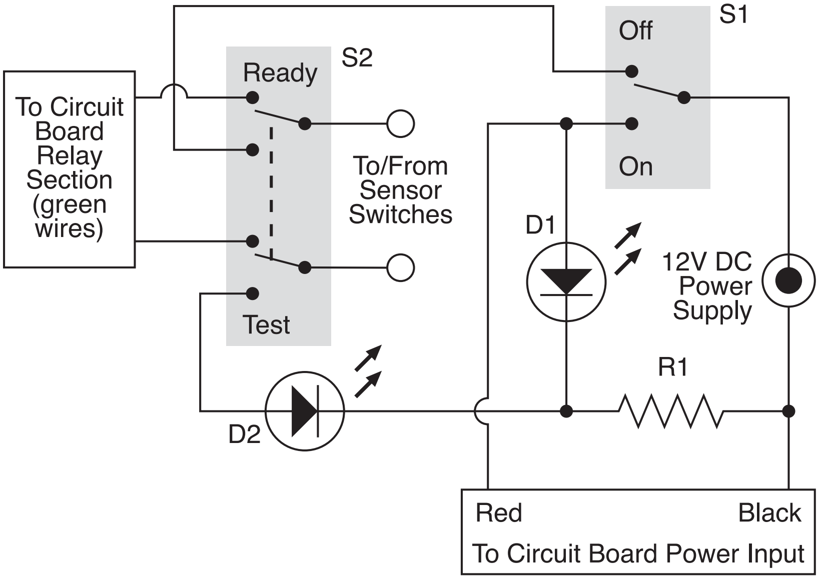

Figure 3-108. *This schematic suggests a convenient way to add an on/off switch, a continuity testing feature, and a noisemaker testing feature to the alarm.*

Now if S1 is turned to its On position, it sends power to the components on the perforated board. The transistor circuit sends power out along the green wires to S2, and as long as the button is not being pressed, the power goes out through the switch network and back through S2, to the transistor, keeping its base relatively negative. So the alarm remains silent. But as soon as a sensor switch is opened, the circuit is broken and the alarm sounds. The only way to stop it will be by switching S1 into its Off position.

Finally, if you press S2, the pushbutton, while S1 is in its On mode, you interrupt the network of switches and activate the noisemaker. In this way, S2 does dual duty: when S1 is off, pushbutton S2 tests the sensor switches for continuity. When S1 is on, S2 tests the noisemaker to make sure it creates a noise. I think this is the simplest possible way to implement these features.

Installing the Switches

If you bought a project box from RadioShack, it may have come with two optional top panels: one made of metal, the other made of plastic. I'll assume that you'll use the plastic one, as you'll have more trouble drilling holes in metal. The type of plastic used by RadioShack is ABS, which is very easy to shape with the tools that I have recommended.

You have to choose a layout for the switches and other components that will share the top panel of the project box. I like a layout to be neat, so I take the trouble to draw it using illustration software, but a full-size pencil sketch is almost as good. Just make sure there's room for the components to fit together, and try to place them similarly to the schematic, to minimize the risk of confusion.

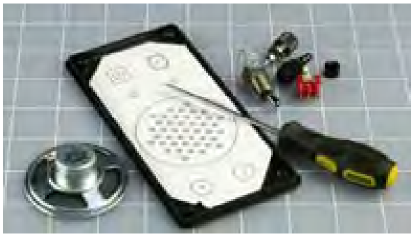

Figure 3-107. *A printed layout for the switches, LEDs, and other components has been taped to the underside of the lid of the project box. An awl is pressed through the paper to mark the center of each hole to be drilled in the lid.*

Tape your sketch to the inside of the top panel, as shown in Figure 3-107, and then use a sharp pointed tool, such as a pick, to press through and mark the plastic at the center of each hole. The indentations will help to center your bit when you drill the holes. Remember that you'll need to make multiple holes to vent the sound from the loudspeaker, which will be beneath the top panel of the box. The result is shown in Figure 3-108.

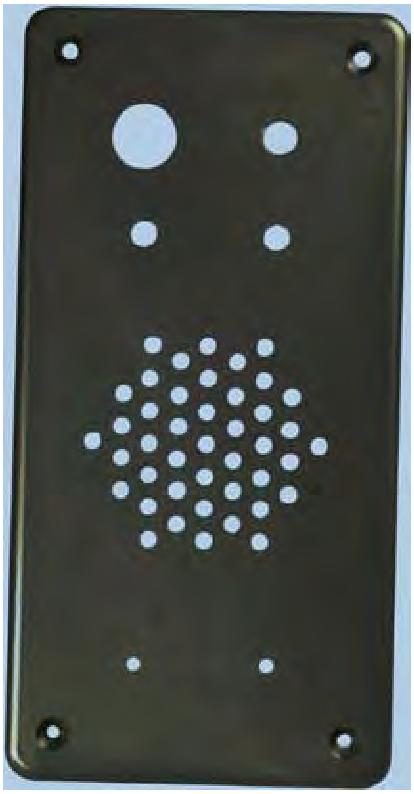

Figure 3-108. *The exterior of the panel after drilling. A small handheld cordless drill can create a neat result if the holes were marked carefully.*

I placed all the components on the top panel, with the exception of the power input jack, which I positioned at one end of the box. Naturally, each hole has to be sized to fit its component, and if you have calipers, they'll be very useful for taking measurements and selecting the right drill bit. Otherwise, make your best guess, too small being better than too large. A deburring tool is ideal for slightly enlarging a hole so that a component fits snugly. This may be necessary if you drill 3/16-inch holes for your 5-inch mm LEDs. Fractionally enlarge each hole, and the LEDs should push in very snugly.

If your loudspeaker lacks mounting holes, you'll have to glue it in place. I used five-minute epoxy to do this. Be careful not to use too much. You don't want any of the glue to touch the speaker cone.

Drilling large holes in the thin, soft plastic of a project box can be a problem. The drill bit tends to dig in and create a mess. You can approach this problem in one of three ways:

1. Use a Forstner drill bit if you have one. It creates a very clean hole.
2. Drill a series of holes of increasing size.
3. Drill a smaller hole than you need, and enlarge it with a deburring tool.

Regardless of which approach you use, you'll need to clamp or hold the top panel of the project box with its outside surface face-down on a piece of scrap wood. Then drill from the inside, so that your bit will pass through the plastic and into the wood.

Finally, mount the components in the panel, as shown in Figure 3-109, and turn your attention to the underneath part of the box.

The circuit board will sit on the bottom, held in place with four #4-size machine screws (bolts) with washers and nylon-insert locknuts. You need to use locknuts to eliminate the risk of a nut working loose and falling among components where it can cause a short circuit.

You'll have to cut the perfboard to fit, taking care not to damage any of the components on it. Also check the underside the board for loose fragments of copper traces after you finish cutting.

Drill bolt holes in the board, if necessary, taking care again not to damage any components. Then mark through the holes to the plastic bottom of the box, and drill the box. Countersink the holes (i.e., bevel the edges of a hole so that a flat-headed screw will fit into it flush with the surrounding surface), push the little bolts up from underneath, and install the circuit board. Be extremely careful not to attach the circuit board too tightly to the project box. This can impose bending stresses, which may break a joint or a copper trace on the board.

I like to include a soft piece of plastic under the board to absorb any stresses. Because you're using locknuts, which will not loosen, there's no need to make them especially tight.

Test the circuit again after mounting the circuit board, just in case.

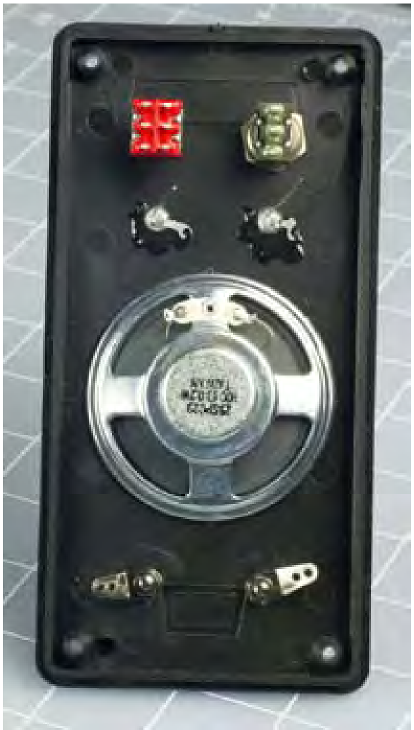

Figure 3-109. *Components have been added to the control panel of the project box (seen from the underside). The loudspeaker has been glued in place. Spare glue was dabbed onto the LEDs, just in case. The SPDT on/off switch is at the top right, the DPDT pushbutton is at top left, and the binding posts, which will connect with the network of magnetic sensor switches, are at the bottom.*

Soldering the Switches

Figure 3-110 shows how the physical switches should be wired together. Remember that S1 is a toggle switch and S2 is a DPDT pushbutton. Your first step is to decide which way up they should be. Use your meter to find out which terminals are connected when the switch is flipped, and when the button is pressed. You'll probably want the switch to be on when the toggle is flipped upward. Be especially careful with the orientation of the pushbutton, because if you wire it upside-down, it will constantly have the alarm in "test" mode, which is not what you want.

Remember, the center terminal of any double-throw switch is almost always the pole of the switch, connecting with the terminals immediately above it and below it.

Stranded wire is appropriate to connect the circuit board with the components in the top panel, because the strands flex easily and impose less stress on solder joints. Twisting each pair of wires together helps to minimize the mess.

Remember to install the LEDs with their short, negative wires connected with the resistor. This will entail some wire-to-wire soldering. You may want to protect some of these bare leads and joints with thin heat-shrink tubing, to minimize the risk of short circuits when you push all the parts into the box.

When you connect wires or components with the lugs on the switches, your pencil-style soldering iron probably won't deliver enough heat to make good joints. You can use your higher-powered soldering iron in these locations, but you absolutely must apply a good heat sink to protect the LEDs when you attach them, and don't allow the iron to remain in contact with anything for more than 10 seconds. It will quickly melt insulation, and may even damage the internal parts of the switches.

In projects that are more complex than this one, it would be good practice to link the top panel with the circuit board more neatly. Multicolored ribbon cable is ideal for this purpose, with plug-and-socket connectors that attach to the board. For this introductory project, I didn't bother. The wires just straggle around, as shown in Figure 3-111.

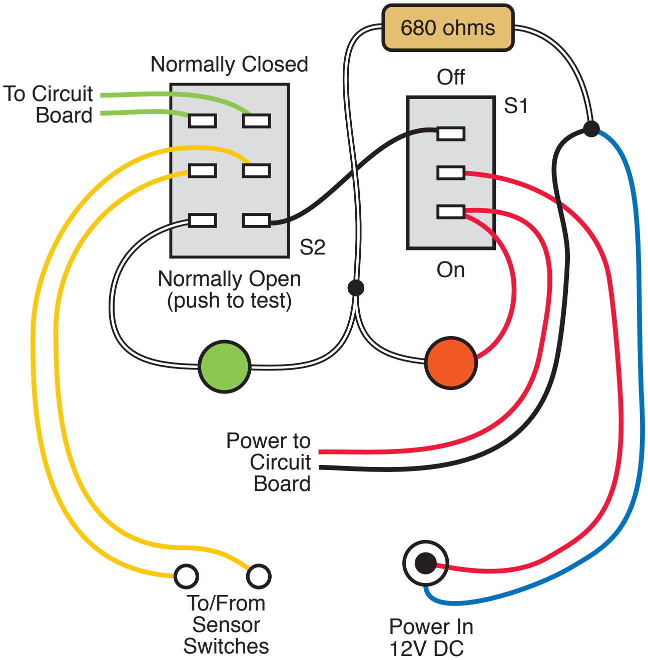

Figure 3-110. *The components can be wired together like this to replicate the circuit shown in The red and green circles are LEDs. Small, solid black circles indicate wire-to-wire solder joints.*

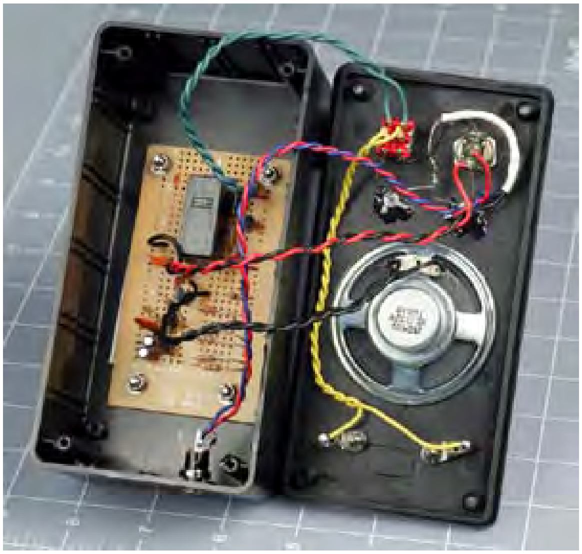

Figure 3-111. *The circuit board has been installed in the base of the project box, and the power input jack has been screwed into the end of the box. Twisted wire-pairs have been connected on a point-to-point basis, without much concern over neatness, as this is a relatively small project. The white insulation at the top-right corner of the front panel is heat-shrink tube that encloses a solder joint and the 680Ω load resistor. Soldering wires to the pushbutton switch requires care and precision, as the contacts are closely spaced.*

Final Test

When you've completed the circuit, test it! If you don't have your network of magnetic sensor switches set up yet, you can just use a piece of wire to connect the two binding posts. Make sure that S1 is in its Off position, then solder the appropriate plug to your 12-volt power source, and plug it into the power jack. When you press the button, the green LED should light up to show continuity between the two binding posts. Now disconnect the wire between the binding posts, press the button again, and the green LED should remain dark.

Reconnect the binding posts, flip S1 to its On position, and the red LED should light up. Press the button, and the alarm should start. Reset it by turning S1 off and then on again; then disconnect the wire between the binding posts. Again, the alarm should start, and it should continue even if you reconnect the wire.

If everything works the way it should, it's time to screw the top of the box in place, pushing the wires inside. Because you're using a large box, you should have no risk of metal parts touching each other accidentally, but still, proceed carefully.

Alarm Installation

Before you install your magnetic sensor switches, you should test each one by moving the magnetic module near the switch module and then away from it, while you use your meter to test continuity between the switch terminals. The switch should close when it's next to the magnet, and open when the magnet is removed.

Now draw a sketch of how you'll wire your switches together. Always remember that they have to be in series, not in parallel! Figure 3-112 shows the concept in theory. The two terminals are the binding posts on top of your control box (which is shown in green), and the dark red rectangles are the magnetic sensor switches on windows and doors. Because the wire for this kind of installation usually has two conductors, you can lay it as I've indicated but cut and solder it to create branches. The solder joints are shown as orange dots. Note how current flows through all the switches in series before it gets back to the control box.

Figure 3-113 shows the same network as you might actually install it in a situation where you have two windows and a door. The blue rectangles are the magnetic modules that activate the switch modules.

You'll need a large quantity of wire, obviously. The type of white, stranded wire that is sold for doorbells or furnace thermostats is good. Typically, it is 20-gauge or larger.

After you install all the switches, clip your meter leads to the wires that would normally attach to the alarm box. Set your meter to test continuity, and open each window or door, one at a time, to check whether you're breaking the continuity. If everything is OK, attach the alarm wires to the binding posts on your project box.

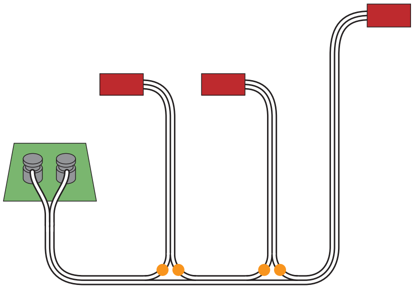

Figure 3-112. *Dual-conductor, white insulated wire can be used to connect the terminals on the alarm control box with magnetic sensors (shown in dark red). Because the sensors must be in series, the wire is cut and joined at positions marked with orange dots.*

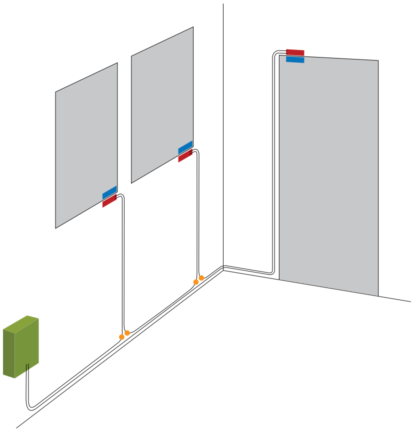

Figure 3-113. *In an installation involving two windows and a door, the magnetic components of the sensors (blue rectangles) could be placed as shown, while the switches (dark red) are located alongside them.*

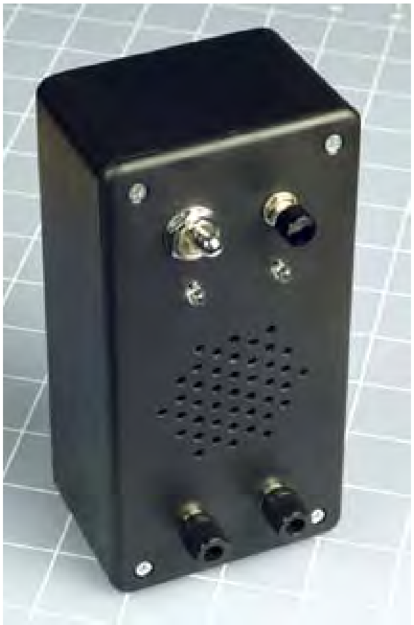

Figure 3-114. *The intrusion alarm completed and in its project box.*

Now deal with the power supply. Use your AC adapter, set to 12 volts, hooked up to your type N power plug, or attach the power plug to a 12-volt alarm battery.

If you use a battery, be especially careful that the wire leading to the center terminal of your power plug is positive! A 12-volt battery can deliver substantial current, which can fry your components if you connect it the wrong way around. It would be a shame to destroy your entire project at the very last step.

The only remaining task is to label the switch, button, power socket, and binding posts on the alarm box. You know that the switch turns the power on and off, and the button tests the circuit and the noisemaker, but no one else knows, and you might want to allow a guest to use your alarm while you're away. For that matter, months or years from now, you may forget some details. Will you remember that the power source for this unit should be 12 volts?

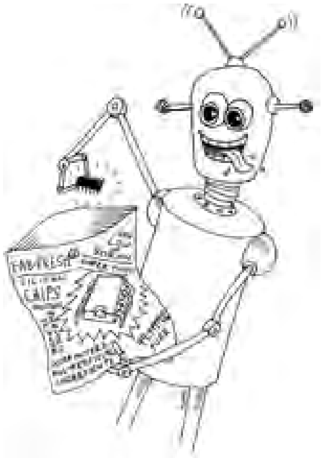
Labeling really is a good idea. But as you can see in Figure 3-114, I haven't quite gotten around to it for the box that I built.

Conclusion

The alarm project has taken you through the basic steps that you will usually follow any time you develop something:

1. Draw a schematic and make sure that you understand it.
2. Modify it to fit the pattern of conductors on a breadboard.
3. Install components on the breadboard and test the basic functions.
4. Modify or enhance the circuit, and retest.
5. Transfer to perforated board, test, and trace faults if necessary.
6. Add switches, buttons, power jack, and plugs or sockets to connect the circuit with the outside world.
7. Mount everything in a box (and add labeling).

While going through this sequence, I hope you've learned the basics of electricity, along with some simple electrical theory, and fundamentals about electronic components. This knowledge should enable you to move on to the much more powerful realm of integrated circuit—which I'll cover in Chapter 4.



4

Chips, Ahoy!

IN THIS CHAPTER

Shopping List: Experiments 16 Through 24
Experiment 16: Emitting a Pulse
Experiment 17: Set Your Tone
Experiment 18: Reaction Timer
Experiment 19: Learning Logic
Experiment 20: A Powerful Combination
Experiment 21: Race to Place
Experiment 22: Flipping and Bouncing
Experiment 23: Nice Dice
Experiment 24: Intrusion Alarm Completed

Before I get into the fascinating topic of integrated circuit (IC) chips, I have to make a confession: some of the things I asked you to do in Chapter 3 could have been done a bit more simply. Does this mean you have been wasting your time? No, I firmly believe that by building circuits with old-fashioned components—capacitors, resistors, and transistors—you acquire the best possible understanding of the principles of electronics. Still, you are going to find that integrated circuit chips, containing dozens, hundreds, or even thousands of transistor junctions, will enable some shortcuts.

Shopping List: Experiments 16 Through 24

Tools

The only new tool that I recommend using in conjunction with chips is a logic probe. This tells you whether a single pin on a chip has a high or low voltage, which can be helpful in figuring out what your circuit is doing. The probe has a memory function so that it will light its LED, and keep it lit, in response to a pulse that may have been too quick for the eye to see.

Search online and buy the cheapest logic probe you can find. I don't have any specific brand recommendations. The one shown in Figure 4-1 is fairly typical.

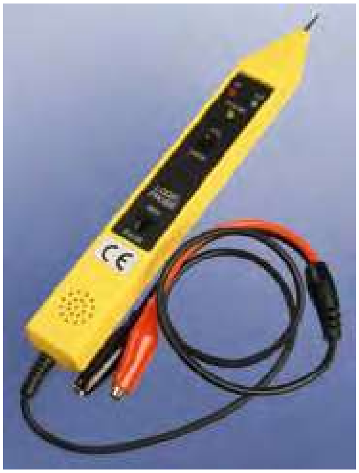


Figure 4-1. *A logic probe detects the high or low voltage on each pin of a chip, and reveals pulses that may occur too quickly for you to perceive them with the unaided eye.*

Supplies

Integrated circuit chips

If you buy everything on this shopping list, and you bought basic parts such as resistors and capacitors that were listed previously, you should have everything you need for all the projects in this chapter.

As chips are quite cheap (currently around 50 cents apiece), I suggest you buy extras. This way, if you damage one, you'll have some in reserve. You'll also have a stock for future projects.

Please read the next section, "Fundamentals: Choosing chips," before you begin chip-shopping. Chips should be easily obtainable from all the major electronics retail suppliers, and sometimes are found on eBay shops. Look in the appendix for a complete list of URLs.

FUNDAMENTALS

Choosing chips

Figure 4-2 shows what is often referred to as an integrated circuit (IC). The circuit is actually etched onto a tiny wafer or "chip" of silicon, embedded in a black plastic body, which is properly referred to as the "package." Tiny wires inside the package link the circuit with the two rows of pins on either side. Throughout this book, I will use the word "chip" to refer to the whole object, including its pins, as this is the most common usage.

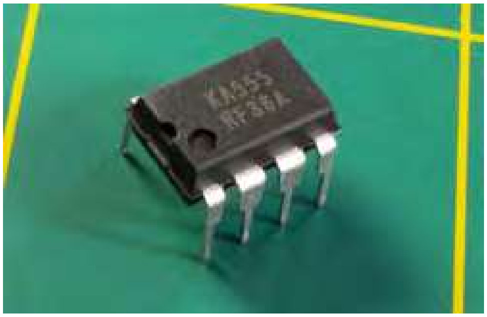

Figure 4-2. *An integrated circuit chip in Plastic Dual-Inline Pin package, abbreviated PDIP, or, more often, DIP.*

The pins are mounted at intervals of 1/10 inch in two rows spaced 3/10 inch apart. This format is known as a Plastic Dual Inline Package, abbreviated PDIP, or, more often, just DIP. The chip in the photograph has four pins in each row; others may have many more. The first thing you need to know, when shopping for chips, is that you'll only be using the DIP package. This book will not be featuring the more modern type, known as "surface-mount," because they're much smaller, more difficult to handle, and require special tools that are relatively expensive. Figure 4-3 shows a size comparison between a 14-pin DIP package and a 14-pin surface-mount package. Many surface-mount chips are even smaller than the one shown.

Just about every chip has a part number printed on it. In Figure 4-2, the part number is KA555. In Figure 4-3, the DIP chip's part number is M74HC00B1, and the surface-mount chip is a 74LVC07AD. You can ignore the second line of numbers and/or letters on each chip, as they are not part of the part number.

Notice in Figure 4-3 that even though the chips look quite different from each other, they both have "74" in their part numbers. This is because both of them are members of the "7400" family of logic chips, which originally had part numbers from 7400 and upward (7400, 7401, 7402, 7403, and so on). Often they are now referred to as "74xx" chips, where "xx" includes all the members of the family. I'll be using this family a lot, so you need to know how to buy them. I'll give you some advice on that without going into details yet about what the chips actually do.

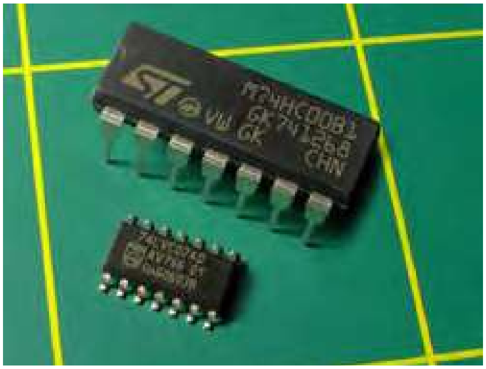

Figure 4-3. *The DIP chip, at the rear, has pins spaced 1/10 inch apart, suitable for insertion in a breadboard or perforated board. It can be soldered without special tools. The small-outline integrated circuit (SOIC) surface-mount chip (foreground) has solder tabs spaced at 1/20 inch. Other surface-mount chips have pins spaced at 1/40 inch or even less (these dimensions are often expressed in millimeters). Surface-mount chips are designed primarily for automated assembly and are difficult to work with manually. In this photo, the yellow lines are 1 inch apart to give you an idea of the scale.*

Take a look at Figure 4-4, which shows how to interpret a typical part number in a 74xx family member. The initial letters identify the manufacturer (which you can ignore, as it really makes no difference for our purposes). Skip the letters until you get to the "74." After that, you find two more letters, which are important. The 74xx family has evolved through many generations, and the letter(s) inserted after the "74" tell you which generation you're dealing with. Some generations have included:

- 74L
- 74LS
- 74C
- 74HC
- 74AHC

And there are more. Generally speaking, subsequent generations tend to be faster or more versatile than previous generations. In this book, for reasons I'll explain later, we are mostly using the HC generation.

FUNDAMENTALS

Choosing chips (continued)

After the letters identifying the generation, you'll find two (sometimes more) numerals. These identify the specific function of the chip. You can ignore any remaining letters and numerals. Looking back at Figure 4-3, the DIP chip part number, M74HC00B1 tells you that it is a chip in the 74xx family, HC generation, with its function identified by numerals 00. The surface-mount chip number, 74LVC07AD, tells you that it is in the 74xx family, LVC generation, with function identified by numerals 07. For convenience we could refer to the first chip as a "74HC00" and the second chip as a "74HC07" because, regardless of their different manufacturers and package sizes, the fundamental behavior of the circuit inside remains the same.

The purpose of this long explanation is to enable you to interpret catalog listings when you go chip shopping. You can search for "74HC00" and the online vendors are usually smart enough to show you appropriate chips from multiple manufacturers, even though there are letters preceding and following the term that you're searched for.

Suppose a circuit requires a 74HC04 chip. If you search for "74HC04" on the website of a parts supplier, you may find versions such as the CD74HC04M96 by Texas Instruments, the 74HC04N by NXP Semiconductors, or MM74HC04N by Fairchild Semiconductor. Because they all have "74HC04" in the middle, any of them will work.

Just be careful that you buy the larger DIP-style package, not the surface-mount package. If the part number has an "N" on the end, you can be sure that it's a DIP package. If there is no "N" on the end, it may or may not be a DIP package, and you will have to check a photo or additional description to make sure. If the part number begins with SS, SO, or TSS, it's absolutely definitely surface-mount, and you don't want it. Many catalogs show photographs of the chips to assist you in buying the right package style.

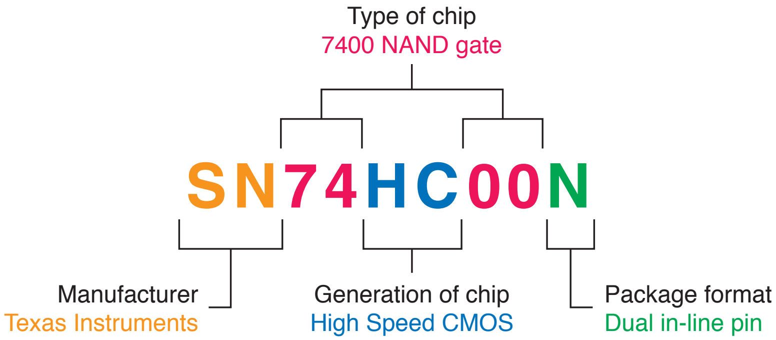

Figure 4-4. *Look for the chip family (74xx, in this case) with the correct generation (HC, in this case) embedded in the number. Make sure you buy the DIP version, not the surface-mount version. The manufacturer is unimportant.*

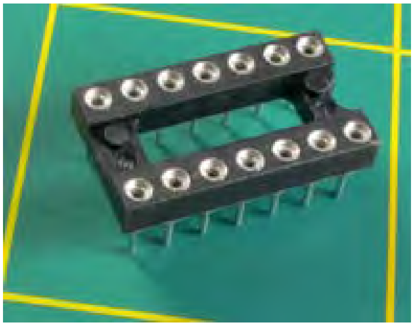

Figure 4-5. *When you're soldering a circuit onto perforated board, sockets eliminate the risk of overheating integrated circuit chips and reduce the risk of zapping them with static electricity, and enable easy replacement.*

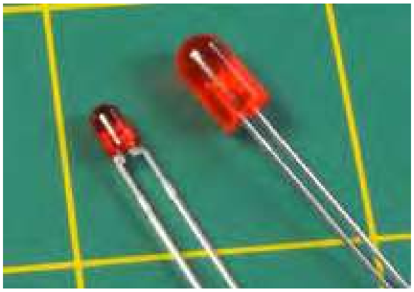

Figure 4-6. *An HC series logic chip is rated to deliver only 4mA at each pin. This is inadequate to drive a typical 5 mm LED (right), which is rated for 20mA forward current. Miniature, low-current LEDs (left) will use as little as 1mA in series with a suitable resistor, and are ideal for test circuits in which you want to see the output with a minimum of hassle.*

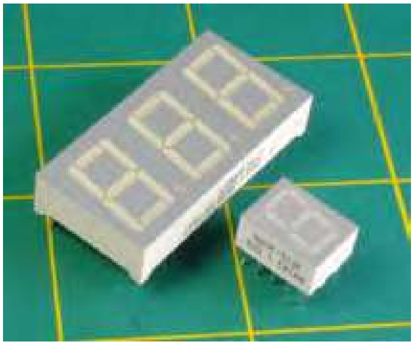

Figure 4-7. *Seven-segment displays are the simplest way to show a numeric output and can be driven directly by some CMOS chips. For finished projects, they are typically mounted behind transparent red acrylic plastic panels.*

Here's your chip list:

- 555 Timer. STMicroelectronics SA555N, Fairchild NE555D, RadioShack TLC555, or similar. Do not get the "CMOS" version of this chip, or any fancy versions such as those of high precision. Buy the cheapest you can find. Quantity: 10. The chip in Figure 4-2 is a 555 timer.
- Logic chips types 74HC00, 74HC02, 74HC04, 74HC08, 74HC32, and 74HC86. Actual part numbers could be M74HC00B1, M74HC02B1, M74HC04B1, and so on, by STMicroelectronics, or SN74HC00N, SN74HC02N, SN74HC04N, and so on, by Texas Instruments. Any other manufacturers are acceptable.
- Remember, each part number should have "HC" in the middle of it, and you want the DIP or PDIP package, not surface-mount. Quantity of each: At least 4.
- 4026 Decade Counter (a chip that counts in tens). Texas Instruments CD-4026BE or similar. Quantity: 4 (you'll need 3, but because this is a CMOS chip sensitive to static electricity, you should have at least one in reserve). Any chip with "4026" in its part number should be OK.
- 74LS92 counter chip, 74LS06 open-collector inverter chip, and 74LS27 triple-input NOR chip. Quantity: 2 of each. Note the "LS" in these part numbers! There will be one experiment in which I want you to use the LS generation instead of the HC generation.

IC sockets

I suggest that you avoid soldering chips directly onto perforated board. If you damage them, they're difficult to remove. Buy some DIP sockets, solder the sockets onto the board, and then plug the chips into the sockets. You can use the cheapest sockets you can find (you don't need gold-plated contacts for our purposes). You will need 8-pin, 14-pin, and 16-pin DIP sockets, such as parts 276-1995, 276-1999, and 276-1998 from RadioShack. See Figure 4-5. Quantity of each: 5 minimum.

Low-power LEDs

The logic chips that you'll be using are not designed to deliver significant power. You'll need to add transistors to amplify their output if you want to drive bright LEDs or relays. Because adding transistors is a hassle, I suggest an alternative: Special low-power LEDs that will draw as little as 1mA, such as the Everlight model T-100 Low Current Red, part number HLMPK150. Figure 4-6 shows a size comparison with a regular 5mm LED. Quantity: 10 (at a minimum).

LED numeric displays

In at least one of our projects, you'll want to illuminate some seven-segment LED numerals. You'll need either three individual numerals, or one package containing three numerals, such as the Kingbright High Efficiency Red Diffused, part number BC56-11EWA, which will be specifically referred to in schematics in this book. If you buy a different seven-segment display, it must be an LED with a "common cathode." (Don't buy liquid-crystal LCD numerals; they require different electronics to drive them.) If you have a choice of power consumption, buy whichever product consumes the least current. See Figure 4-7.

Latching relays

You're going to need a 5-volt latching relay that has two coils, instead of one. The first coil flips the relay one way; the second coil flips it back. The relay consumes no additional power while remaining passively in each state. I suggest the Panasonic DS2E-SL2-DC5V relay. If you buy a different relay, it must be dual-coil latching to run off 5 volts DC, switching at least 1 amp, in a "2 form C" package, to fit your breadboard.

Potentiometers

You'll need 5K, 10K, and 100K linear potentiometers (one of each). Also, a 10K trimmer potentiometer (which you may find described just as a "trimmer"). The manufacturer is unimportant.

Voltage regulators

Because many logic chips require precisely 5 volts DC, you need a voltage regulator to deliver this. The LM7805 does the job. Here again, the chip number will be preceded or followed with an abbreviation identifying the manufacturer and package style, as in the LM7805CT from Fairchild. Any manufacturer will do, but the package should look like the one in Figure 4-8, and if you have a choice, buy a regulator that can deliver at least 1 amp.

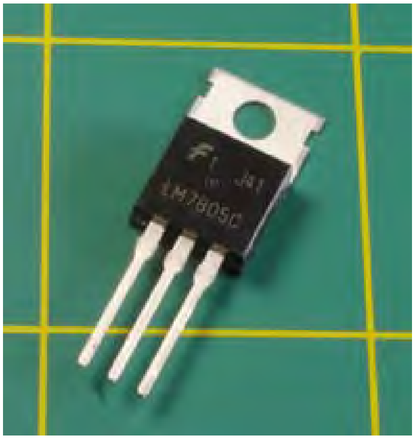

Figure 4-8. *Many integrated circuit chips require a controlled power supply of 5 volts, which can be delivered by this regulator when you apply 7.5 to 9 volts to it. The lefthand pin is for positive input, the center pin is a common ground, and the righthand pin is the 5V output. For currents exceeding 250mA, you should bolt the regulator to a metal heat sink using the hole at the top.*

Tactile switches

These are SPST pushbuttons (momentary switches), usually with four legs. Look for the ALPS part number SKHHAKA010 or any similar item that has pins to fit your breadboard or perforated board. See Figure 4-9.

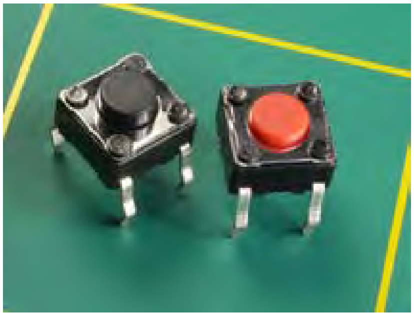

Figure 4-9. *A tactile switch delivers tactile feedback through your fingertip when you press it. They are almost always SPST pushbuttons designed for mounting in circuit boards with standard 1/10-inch hole spacing.*

12-key numeric keypad

Velleman "12 keys keyboard with common output" (no part number, but has been available through All Electronics under catalog code KP-12). Quantity: 1.

This type of keypad has the same layout as an old-fashioned touchtone phone. It should have at least 13 pins or contacts, 12 of which connect with individual pushbuttons, the thirteenth connecting with the other side of all the pushbuttons. In other words, the last pin is "common" to all of them, and this type of keypad is often described as having a "common output." The type of keypad that you don't want is "matrix-encoded," with fewer than 13 contacts, requiring additional external circuitry. See Figures 4-10 and 4-11. If you can't find the Velleman keypad that I suggest, look carefully at keypad descriptions and photographs to make sure that the one you buy is not matrix-encoded and has a common terminal.

Alternatively, you may substitute 12 cheap SPST NO pushbuttons and mount them in a small project box.

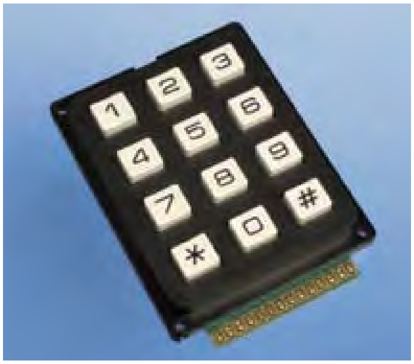

Figure 4-10. *When shopping for a numeric keypad, it should have 12 keys in "touch-tone phone" layout, and should have at least 13 contacts for input/output. The contacts are visible here along the front edge.*

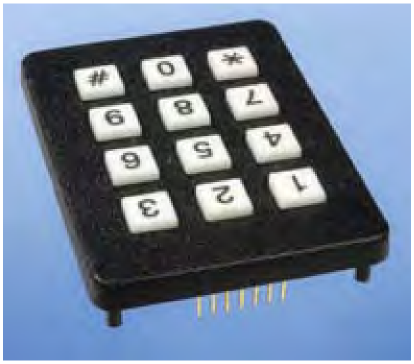

Figure 4-11. *This keypad has insufficient pins and will not work in the circuit in this book.*

BACKGROUND

How chips came to be

The concept of integrating solid-state components into one little package originated with British radar scientist Geoffrey W. A. Dummer, who talked about it for years before he attempted, unsuccessfully, to build one in 1956. The first true integrated circuit wasn't fabricated until 1958 by Jack Kilby, working at Texas Instruments. Kilby's version used germanium, as this element was already in use as a semiconductor. (You'll encounter a germanium diode when I deal with crystal radios in the next chapter of this book.) But Robert Noyce, pictured in Figure 4-12, had a better idea.

Born in 1927 in Iowa, in the 1950s Noyce moved to California, where he found a job working for William Shockley. This was shortly after Shockley had set up a business based around the transistor, which he had coinvented at Bell Labs.

Noyce was one of eight employees who became frustrated with Shockley's management and left to establish Fairchild Semiconductor. While he was the general manager of Fairchild, Noyce invented a silicon-based integrated circuit that avoided the manufacturing problems associated with germanium. He is generally credited as the man who made integrated circuits possible.

Early applications were for military use, as Minuteman missiles required small, light components in their guidance systems. These applications consumed almost all chips produced from 1960 through 1963, during which time the unit price fell from around $1,000 to $25 each, in 1963 dollars.

In the late 1960s, medium-scale integration chips emerged, each containing hundreds of transistors. Large-scale integration enabled tens of thousands of transistors on one chip by the mid-1970s, and today's chips can contain as many as several billion transistors.

Robert Noyce eventually cofounded Intel with Gordon Moore, but died unexpectedly of a heart attack in 1990. You can learn more about the fascinating early history of chip design and fabrication at *http://www.siliconvalleyhistorical.org*.

Figure 4-12. *This picture of Robert Noyce, late in his career, is from the Wikimedia Commons.*

Experiment 16: Emitting a Pulse

I'm going to introduce you to the most successful chip ever made: the 555 timer. As you can find numerous guides to it online, you might question the need to discuss it here, but I have three reasons for doing so:

1. It's unavoidable. You simply have to know about this chip. Some sources estimate that more than 1 billion are still being manufactured annually. It will be used in one way or another in most of the remaining circuits in this book.
2. It provides a perfect introduction to integrated circuits, because it's robust, versatile, and illustrates two functions that we'll be dealing with later: comparators and a flip-flop.
3. After reading all the guides to the 555 that I could find, beginning with the original Fairchild Semiconductor data sheet and making my way through various hobby texts, I concluded that its inner workings are seldom explained very clearly. I want to give you a graphic understanding of what's happening inside it, because if you don't have this, you won't be in a good position to use the chip creatively.

You will need:

- 9-volt power supply.
- Breadboard, jumper wires, and multimeter.
- 5K linear potentiometer. Quantity: 1.
- 555 timer chip. Quantity: 1.
- Assorted resistors and capacitors.
- SPST tactile switches. Quantity: 2.
- LED (any type). Quantity: 1.

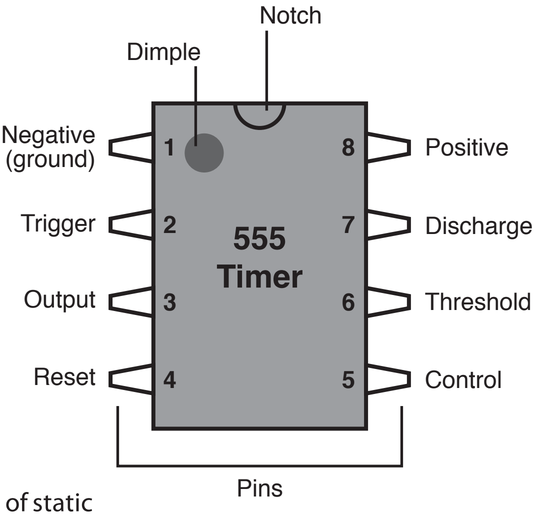

Figure 4-13. *The 555 timer chip, seen from above. Pins on chips are always numbered counterclockwise, from the top-left corner, with a notch in the body of the chip uppermost, or a circular indentation at top-left, to remind you which end is up.*

Procedure

The 555 chip is very robust, but still, in theory, you can zap it with a jolt of static electricity and kill it. Therefore, to be on the safe side, you should ground yourself before handling it. See the "Grounding yourself" warning on page 172 for details. Although this warning primarily refers to the type of chips known as CMOS, which are especially vulnerable, grounding yourself is always a sensible precaution.

Look for a small circular indentation, called the *dimple*, molded into the body of the chip, and turn the chip so that the indentation is at the top-left corner with the pins pointing down. Alternatively, if your chip is of the type with a notch at one end, turn the chip so that the notch is at the top.

The pins on chips are always numbered counterclockwise, starting from the top-left pin (next to the dimple). See Figure 4-13, which also shows the names of the pins on the 555 timer, although you don't need to know most of them just yet.

Insert the chip in your breadboard so that its pins straddle the channel down the center. Now you can easily feed voltages to the pins on either side, and read signals out of them. See Figure 4-14 for a precise guide to placement, in the first project. The timer is identified as "IC1," because "IC" is the customary abbreviation for "Integrated Circuit."

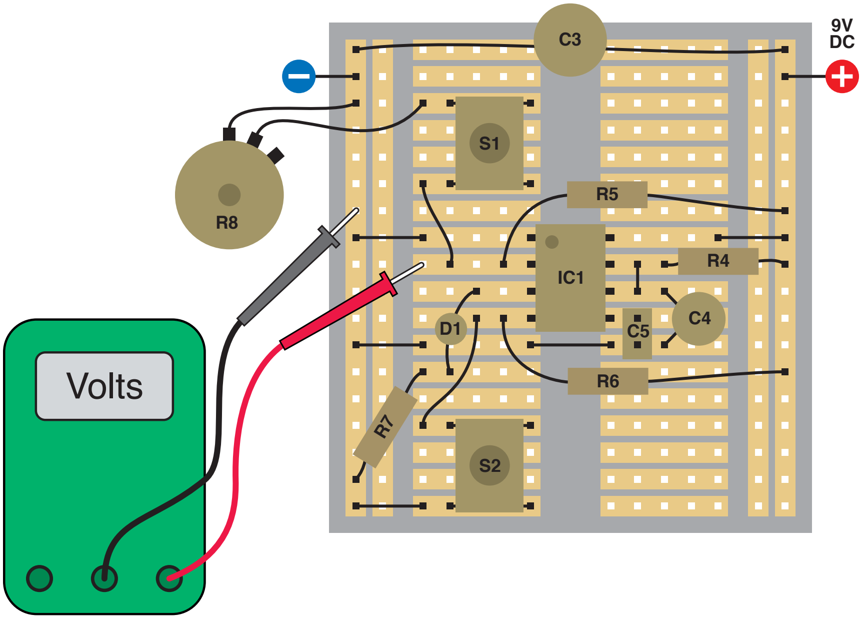

Figure 4-14. *This circuit allows you to explore the behavior of the 555 timer chip. Use your meter to monitor the voltage on pin 2 as shown. There are no resistors labeled R1, R2, or R3 and no capacitors labeled C1 or C2, because they'll be added in a later schematic. Component values in this schematic:*

R4: 100K
R5: 2K2
R6: 10K
R7: 1K
R8: 5K linear potentiometer
C3: 100 μF electrolytic
C4: 47 μF electrolytic
C5: 0.1 μF ceramic
IC1: 555 timer
S1, S2: SPST tactile switches (pushbuttons)
D1: Generic LED

R5 holds the trigger (pin 2) positive until S1 is pressed, which lowers the voltage depending on the setting of potentiometer R8. When the trigger voltage falls below 1/3 of the power supply, the chip's output (pin 3) goes high for a period determined by the values of R4 and C4. S2 resets (zeros) the timer, by reducing the voltage to pin 4, the Reset. C3 smoothes the power supply, and C5 isolates pin 5, the control, so that it won't interfere with the functioning of this test circuit. (We'll use the control pin in a future experiment.)

All integrated circuit chips require a power supply. The 555 is powered with negative voltage applied to pin 1 and positive to pin 8. If you reverse the voltage accidentally, this can permanently damage the chip, so place your jumper wires carefully.

Set your power supply to deliver 9 volts. It will be convenient for this experiment if you supply positive down the righthand side and negative down the lefthand side of the breadboard, as suggested in Figure 4-14. C3 is a large capacitor, at least 100 µF, which is placed across the power supply to smooth it out and provide a local store of charge to fuel fast-switching circuits, as well as to guard against other transient dips in voltage. Although the 555 isn't especially fast-switching, other chips are, and you should get into the habit of protecting them.

Begin with the potentiometer turned all the way counterclockwise to maximize the resistance between the two terminals that we're using, and when you apply the probe from your meter to pin 2, you should measure about 6 volts when you press S1.

Now rotate the potentiometer clockwise and press S1 again. If the LED doesn't light up, keep turning the potentiometer and pressing and releasing the button. When you've turned the potentiometer about two-thirds of the way, you should see the LED light up for just over 5 seconds when you press and release the button. Here are some facts that you should check for yourself:

- The LED will keep glowing after you release the button.
- You can press the button for any length of time (less than the timer's cycle time) and the LED always emits the same length of pulse.
- The timer is triggered by a fall in voltage on pin 2. You can verify this with your meter.
- The LED is either fully on or fully off. You can't see a faint glow when it's off, and the transition from off to on and on to off is very clean and precise.

Check Figure 4-16 to see how the components should look on your breadboard, and then look at the schematic in Figure 4-15 to understand what's happening. I will be adding more components later, which I will be labeling R1, R2, C1, and C2 to be consistent with data sheets that you may see for the 555 timer. Therefore, in this initial circuit the resistors are labeled R4 and up, and capacitors C3 and up.

When S1 (the tactile switch) is open, pin 2 of the 555 timer receives positive power through R5, which is 2K2. Because the input resistance of the timer is very high, the voltage on pin 2 is almost the full 9 volts.

When you press the button, it connects negative voltage through R8, the 5K potentiometer to pin 2. Thus, R8 and R5 form a voltage divider with pin 2 in the middle. You may remember this concept from when you were testing transistors. The voltage between the resistances will change, depending on the values of the resistances.

If R8 is turned up about halfway, it is approximately equal to R5, so the midpoint, connected to pin 2, has about half the 9-volt power supply. But when you turn the potentiometer so that its resistance falls farther, the negative voltage outweighs the positive voltage, so the voltage on pin 2 gradually drops.

If you have clips on your meter leads, you can hook them onto the nearest jumper wires and then watch the meter while you turn the potentiometer up and down and press the button.

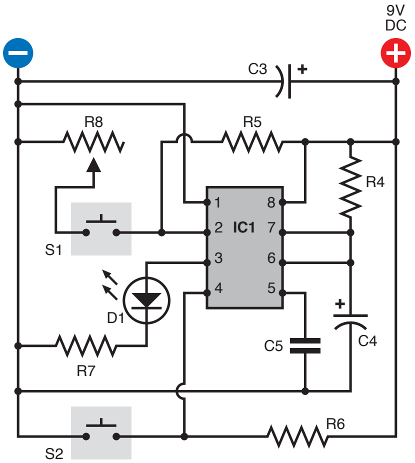

Figure 4-15. *A schematic view of the circuit shown in Figure 4-14. Throughout this chapter, the schematics will be laid out to emulate the most likely placement of components on a breadboard. This is not always the simplest layout, but will be easiest for you to build. Refer to Figure 4-14 for the values of the components.*

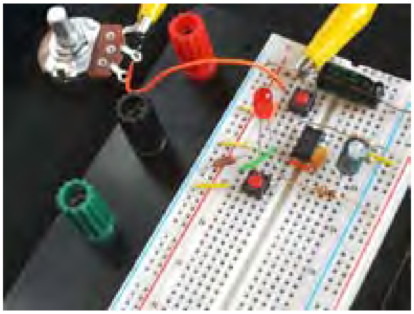

Figure 4-16. *This is how the components look when installed on the breadboard. The alligator clips are attached to a patch cord that links the 100 µF capacitor to the potentiometer. The power supply input is not shown.*

The graphs in Figure 4-17 illustrate what is happening. The upper graph shows the voltage applied to pin 2 by random button-presses, with the potentiometer turned to various values. The lower graph shows that the 555 is triggered if, and only if, the voltage on pin 2 actively drops from above 3 volts to below 3 volts. What's so special about 3 volts? It's one-third of our 9-volt power supply.

Here's the take-home message:

- The output of the 555 (pin 3) emits a *positive* pulse when the trigger (pin 2) drops *below* one-third of the supply voltage.
- The 555 delivers the *same duration* of positive pulse every time (so long as you don't supply a prolonged low voltage on pin 2).
- A *larger* value for R4 or for C4 will *lengthen* the pulse.
- When the output (pin 3) is high, the voltage is almost equal to the supply voltage. When the output goes low, it's almost zero.

The 555 converts the imperfect world around it into a precise and dependable output. It doesn't switch on and off absolutely instantly, but is fast enough to *appear* instant.

Now here's another thing to try. Trigger the timer so that the LED lights up. While it is illuminated, press S2, the second button, which grounds pin 4, the reset. The LED should go out immediately.

When the reset voltage is pulled *low*, the output goes *low*, regardless of what voltage you apply to the trigger.

There's one other thing I want you to notice before we start using the timer for more interesting purposes. I included R5 and R6 so that when you first switch on the timer, it is not emitting a pulse—but is ready to do so. These resistors apply a positive voltage to the trigger and the reset pin, to make sure that the 555 timer is ready to run when you first apply power to it.

As long as the *trigger* voltage is *high*, the timer *will not* emit a pulse. (It emits a pulse when the trigger voltage drops.)

As long as the *reset* voltage is *high*, the timer is *able* to emit a pulse. (It shuts down when the reset voltage drops.)

R5 and R6 are known as "pull-up resistors" because they pull the voltage up. You can easily overwhelm them by adding a direct connection to the negative side of the power supply. A typical pull-up resistor for the 555 timer is 10K. With a 9-volt power supply, it only passes 0.9mA (by Ohm's Law).

Finally, you may be wondering about the purpose of C5, attached to pin 5. This pin is known the "control" pin, which means that if you apply a voltage to it, you can control the sensitivity of the timer. I'll get to this in more detail a little later. Because we are not using this function right now, it's good practice to put a capacitor on pin 5 to protect it from voltage fluctuations and prevent it from interfering with normal functioning.

Make sure you become familiar with the basic functioning of the 555 timer before you continue.

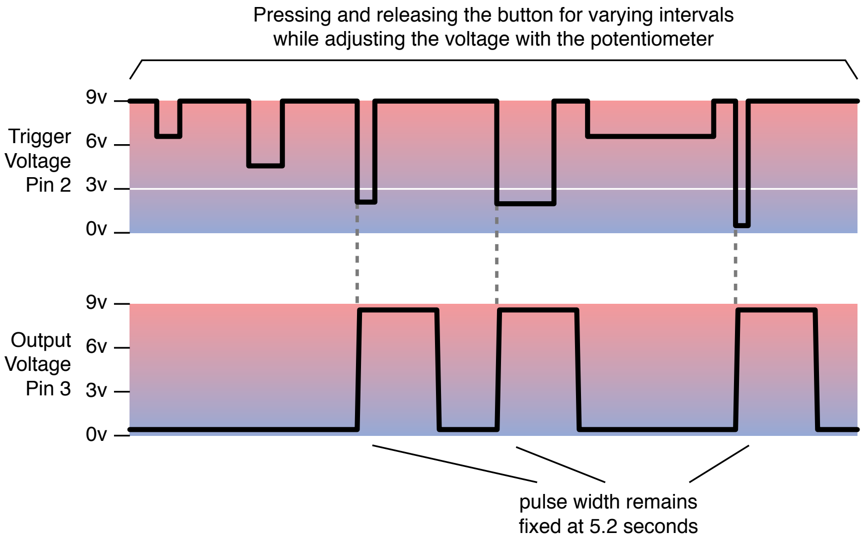

Figure 4-17. *The top graph shows voltage on the trigger (pin 2) when the pushbutton is pressed, for different intervals, at different settings of the potentiometer. The lower graph shows the output (pin 3), which rises until it is almost equal to the power supply, when the voltage on pin 2 drops below 1/3 the full supply voltage.*

FUNDAMENTALS

The following table shows 555 pulse duration in monostable mode:

- Duration is in seconds, rounded to two figures.
- The horizontal scale shows common resistor values between pin 7 and positive supply voltage.
- The vertical scale shows common capacitor values between pin 6 and negative supply voltage.

To calculate a different pulse duration, multiply resistance × capacitance × 0.0011 where resistance is in kilohms, capacitance is in microfarads, and duration is in seconds.

THEORY

Inside the 555 timer: monostable mode

The plastic body of the 555 timer contains a wafer of silicon on which are etched dozens of transistor junctions in a pattern that is far too complex to be explained here. However, I can summarize their function by dividing them into groups, as shown in Figure 4-18. An external resistor and two external capacitors are also shown, labeled the same way as in Figure 4-15.

The negative and positive symbols inside the chip are power sources which actually come from pins 1 and 8, respectively. I omitted the internal connections to those pins for the sake of clarity.

The two yellow triangles are "comparators." Each comparator compares two inputs (at the base of the triangle) and delivers an output (from the apex of the triangle) depending on whether the inputs are similar or different. We'll be using comparators for other purposes later in this book.

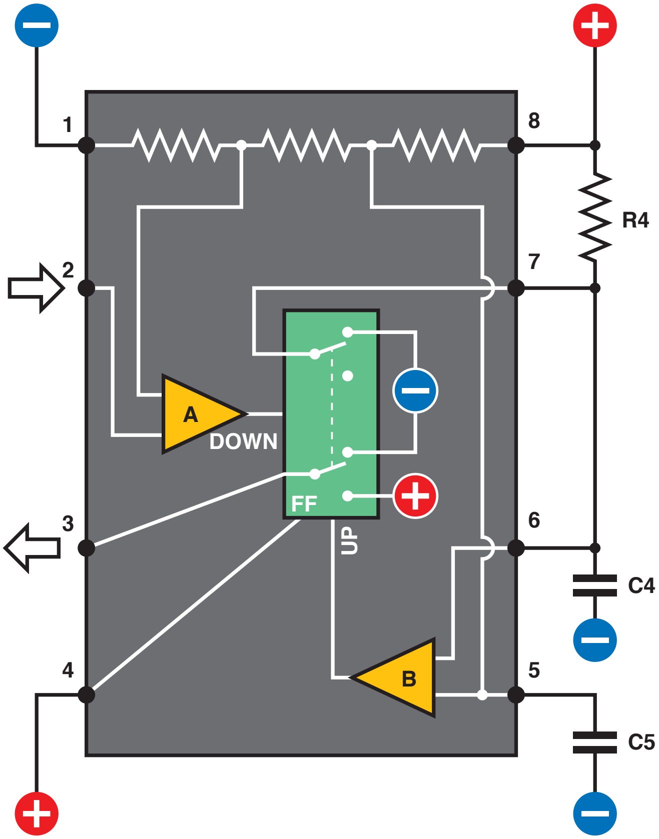

Figure 4-18. *Inside the 555 timer. White lines indicate connections inside the chip. A and B are comparators. FF is a flip-flop which can rest in one state or the other, like a double-throw switch. A drop in voltage on pin 2 is detected by comparator A, which triggers the flip-flop into its "down" position and sends a positive pulse out of pin 3. When C4 charges to 2/3 of supply voltage, this is detected by comparator B, which resets the flip-flop to its "up" position. This discharges C4 through pin 7.*

THEORY

Inside the 555 timer: monostable mode (continued)

The green rectangle, identified as "FF," is a "flip-flop." I have depicted it as a DPDT switch, because that's how it functions here, although of course it is really solid-state.

Initially when you power up the chip, the flip-flop is in its "up" position which delivers low voltage through the output, pin 3. If the flip-flop receives a signal from comparator A, it flips to its "down" state, and flops there. When it receives a signal from comparator B, it flips back to its "up" state, and flops there. The "UP" and "DOWN" labels on the comparators will remind you what each one does when it is activated.

Flip-flops are a fundamental concept in digital electronics. Computers couldn't function without them.

Notice the external wire that connects pin 7 with capacitor C4. As long as the flip-flop is "up," it sinks the positive voltage coming through R4 and prevents the capacitor from charging positively.

If the voltage on pin 2 drops to 1/3 of the supply, comparator A notices this, and flips the flip-flop. This sends a positive pulse out of pin 3, and also disconnects the negative power through pin 7. So now C4 can start charging through R4. While this is happening, the positive output from the timer continues.

As the voltage increases on the capacitor, comparator B monitors it through pin 6, known as the threshold. When the capacitor accumulates 2/3 of the supply voltage, comparator B sends a pulse to the flip-flop, flipping it back into its original state. This discharges the capacitor through pin 7, appropriately known as the discharge pin. Also, the flip-flop ends the positive output through pin 3 and replaces it with a negative voltage. This way, the 555 returns to its original state.

I'll sum up this sequence of events very simply:

1. Initially, the flip-flop grounds the capacitor and grounds the output (pin 3).
2. A drop in voltage on pin 2 to 1/3 the supply voltage or less makes the output (pin 3) positive and allows capacitor C4 to start charging through R4.
3. When the capacitor reaches 2/3 of supply voltage, the chip discharges the capacitor, and the output at pin 3 goes low again.

In this mode, the 555 timer is "monostable," meaning that it just gives one pulse, and you have to trigger it again to get another.

You adjust the length of each pulse by changing the values of R4 and C4. How do you know which values to choose? Check the table on page 157, which gives an approximate idea and also includes a formula so that you can calculate values of your own.

I didn't bother to include pulses shorter than 0.01 second in the table, because a single pulse of this length is usually not very useful. Also I rounded the numbers in the table to 2 significant figures, because capacitor values are seldom more accurate than that.

BACKGROUND

How the timer was born

Back in 1970, when barely a half-dozen corporate seedlings had taken root in the fertile ground of Silicon Valley, a company named Signetics bought an idea from an engineer named Hans Camenzind. It wasn't a huge breakthrough concept—just 23 transistors and a bunch of resistors that would function as a programmable timer. The timer would be versatile, stable, and simple, but these virtues paled in comparison to its primary selling point. Using the emerging technology of integrated circuits, Signetics could reproduce the whole thing on a silicon chip.

This entailed some trial and error. Camenzind worked alone, building the whole thing initially on a large scale, using off-the-shelf transistors, resistors, and diodes on a breadboard. It worked, so then he started substituting slightly different values for the various components to see whether the circuit would tolerate variations during production and other factors such as changes in temperature when the chip was in use. He made at least 10 different versions of the circuit. It took months.

Next came the crafts work. Camenzind sat at a drafting table and used a specially mounted X-Acto knife to scribe his circuit into a large sheet of plastic. Signetics then reduced this image photographically by a ratio of about 300:1. They etched it into tiny wafers, and embedded each of them in a half-inch rectangle of black plastic with the product number printed on top. Thus, the 555 timer was born.

It turned out to be the most successful chip in history, both in the number of units sold (tens of billions and counting) and the longevity of its design (unchanged in almost 40 years). The 555 has been used in everything from toys to spacecraft. It can make lights flash, activate alarm systems, put spaces between beeps, and create the beeps themselves.

Today, chips are designed by large teams and tested by simulating their behavior using computer software. Thus, chips inside a computer enable the design of more chips. The heyday of solo designers such as Hans Camenzind is long gone, but his genius lives inside every 555 timer that emerges from a fabrication facility. (If you'd like to know more about chip history, see *http://www.semiconductormuseum.com/Museum_Index.htm*.)

FUNDAMENTALS

Why the 555 is useful

In its monostable mode (which is what you just saw), the 555 will emit a single pulse of fixed (but programmable) length. Can you imagine some applications? Think in terms of the pulse from the 555 controlling some other component. A motion sensor on an outdoor light, perhaps. When an infra-red detector "sees" something moving, the light comes on for a specific period—which can be controlled by a 555.

Another application could be a toaster. When someone lowers a slice of bread, a switch will close that triggers the toasting cycle. To change the length of the cycle, you could use a potentiometer instead of R4 and attach it to the external lever that determines how dark you want your toast. At the end of the toasting cycle, the output from the 555 would pass through a power transistor, to activate a solenoid (which is like a relay, except that it has no switch contacts) to release the toast.

Intermittent windshield wipers could be controlled by a 555 timer—and on earlier models of cars, they actually were.

And what about the burglar alarm that was described at the end of Chapter 3? One of the features that I listed, which has not been implemented yet, is that it should shut itself off after a fixed interval. We can use the change of output from a 555 timer to do that.

The experiment that you just performed seemed trivial, but really it implies all kinds of possibilities.

555 timer limits

1. The timer can run from a stable voltage source ranging from 5 to 15 volts.
2. Most manufacturers recommend a range from 1K to 1M for the resistor attached to pin 7.
3. The capacitor value can go as high as you like, if you want to time really long intervals, but the accuracy of the timer will diminish.
4. The output can deliver as much as 100mA at 9 volts. This is sufficient for a small relay or miniature loudspeaker, as you'll see in the next experiment.

Beware of Pin-Shuffling!

In all of the schematics in this book, I'll show chips as you'd see them from above, with pin 1 at top left. Other schematics that you may see, on websites or in other books, may do things differently. For convenience in drawing circuits, people shuffle the pin numbers on a chip so that pin 1 isn't necessarily shown adjacent to pin 2.

Look at the schematic in Figure 4-20 and compare it with the one in Figure 4-15. The connections are the same, but the one in Figure 4-20 groups pins to reduce the apparent complexity of the wiring.

"Pin shuffling" is common because circuit-drawing software tends to do it, and on larger chips, it is necessary for functional clarity of the schematic (i.e., logical groupings of pin names versus physical groupings on memory chips, for example). When you're first learning to use chips, I think it's easier to understand a schematic that shows the pins in their actual positions. So that's the practice I will be using here.

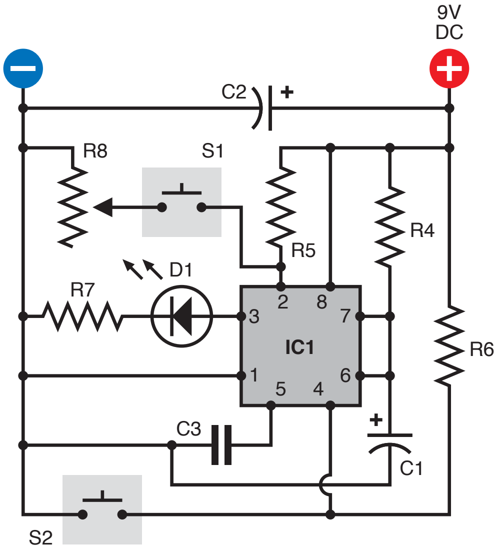

Figure 4-20. *Many people draw schematics in which the pin numbers on a chip are shuffled around to make the schematic smaller or simpler. This is not helpful when you try to build the circuit. The schematic here is for the same circuit as in Figure 4-15. This version would be harder to recreate on a breadboard.*

Experiment 17: Set Your Tone

I'm going to show you two other ways in which the 555 timer can be used.

You will need the same items as in Experiment 16, plus:

- Additional 555 timer chip. Quantity: 1.
- Miniature loudspeaker. Quantity: 1.
- 100K linear potentiometer. Quantity: 1.

Procedure

Leave the components from Experiment 16 where they are on the breadboard, and add the next section below them, as shown in Figures 4-21 and 4-22. Resistor R2 is inserted between pins 6 and 7, instead of the jumper wire that shorted the pins together in the previous circuit, and there's no external input to pin 2 anymore. Instead, pin 2 is connected via a jumper wire to pin 6. The easiest way to do this is by running the wire across the top of the chip.

I have omitted the smoothing capacitor from the schematic in Figure 4-22, because I'm assuming that you're running this circuit on the same breadboard as the first, where the previous smoothing capacitor is still active.

A loudspeaker in series with a 100Ω resistor (R3) has been substituted for the LED to show the output from the chip. Pin 4, the reset, is disabled by connecting it to the positive voltage supply, as I'm not expecting to use the reset function in this circuit.

Now what happens when you apply power? Immediately, you should hear noise through the loudspeaker. If you don't hear anything, you almost certainly made a wiring error.

Notice that you don't have to trigger the chip with a pushbutton anymore. The reason is that when C1 charges and discharges, its fluctuating voltage is connected via a jumper wire across the top of the chip to pin 2, the trigger. In this way, the 555 timer now triggers itself. I'll describe this in more detail in the next section "Theory: Inside the 555 timer: astable mode," if you want to see exactly what is going on.

In this mode, the chip is "astable," meaning that it is not stable, because it flips to and fro endlessly, sending a stream of pulses for as long as the power is connected. The pulses are so rapid that the loudspeaker reproduces them as noise.

In fact, with the component values that I specified for R1, R2, and C1, the 555 chip is emitting about 1,500 pulses per second. In other words, it creates a 1.5 KHz tone.

Check the table on page 166 to see how different values for R2 and C1 can create different pulse frequencies with the chip in this astable mode. Note that the table assumes a fixed value of 1K for R1!

THEORY

Inside the 555 timer: astable mode

Here's what is happening now, illustrated in Figure 4-23. Initially, the flip-flop grounds C1 as before. But now the low voltage on the capacitor is connected from pin 7 to pin 2 through an external wire. The low voltage tells the chip to trigger itself. The flip-flop obediently flips to its "on" position and sends a positive pulse to the loudspeaker, while removing the negative voltage from pin 7.

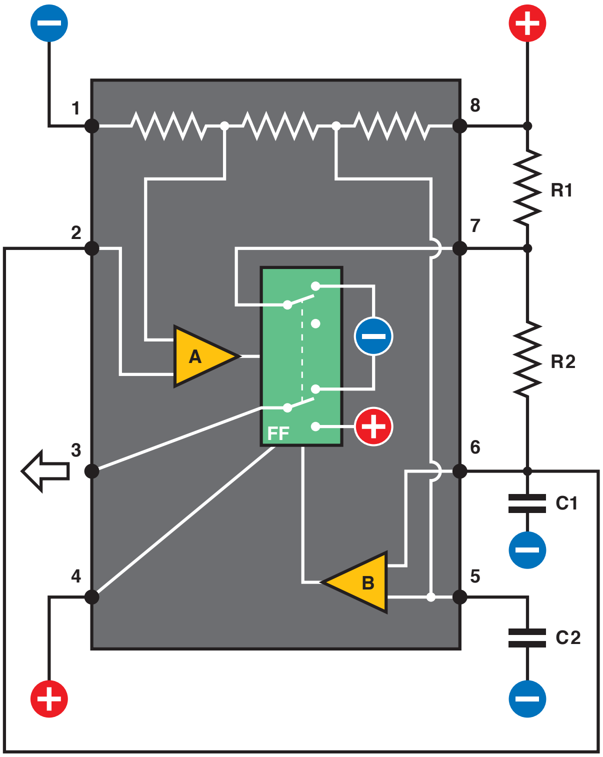

Figure 4-23. *When the 555 timer is used in astable mode, resistor R2 is placed between pin 6 and pin 7, and pin 6 is connected via an external wire to pin 2, so that the timer triggers itself.*

Now C1 starts charging, as it did when the timer was in monostable mode, except that it is being charged through R1 + R2 in series. Because the resistors have low values, and C1 is also small, C1 charges quickly. When it reaches 2/3 full voltage, comparator B takes action as before, discharging the capacitor and ending the output pulse from pin 3.

The capacitor takes longer to discharge than before, because R2 has been inserted between it and pin 7, the discharge pin. While the capacitor is discharging, its voltage diminishes, and is still linked to pin 2. When the voltage drops to 1/3 of full power or less, comparator A kicks in and sends another pulse to the flip-flop, starting the process all over again.

Summing up:

1. In astable mode, as soon as power is connected, the flip-flop pulls down the voltage on pin 2, triggering comparator A, which flips the flip-flop to its "down" position.
2. Pin 3, the output, goes high. The capacitor charges through R1 and R2 in series.
3. When the capacitor reaches 2/3 of supply voltage, the flip-flop goes "up" and the output at pin 3 goes low. The capacitor starts to discharge through R2.
4. When the charge on the capacitor diminishes to 1/3 of full voltage, the pull-down on pin 2 flips the flip-flop again and the cycle repeats.

Unequal on/off cycles

When the timer is running in astable mode, C1 charges through R1 and R2 in series. But when C1 discharges, it dumps its voltage through R2 only. This means that the capacitor charges more slowly than it discharges. While it is charging, the output on pin 3 is high; while it is discharging, the output on pin 3 is low. Consequently the "on" cycle is always longer than the "off" cycle. Figure 4-24 shows this as a simple graph.

If you want the on and off cycles to be equal, or if you want to adjust the on and off cycles independently (for example, because you want to send a very brief pulse to another chip, followed by a longer gap until the next pulse), all you need to do is add a diode, as shown in Figure 4-25.

Now when C1 charges, the electricity flows through R1 as before but takes a shortcut around R2, through diode D1. When C1 discharges, the diode blocks the flow of electricity in that direction, and so the discharge goes back through R2.

THEORY

Inside the 555 timer: astable mode (continued)

R1 now controls the charge time on its own, while R2 controls the discharge time. The formula for calculating the frequency is now:

Frequency = 1440 / ((R1 + R2) × C1)

If you set R1 = R2, you should get almost equal on/off cycles ("almost" because the diode itself imposes a small internal voltage drop of about 0.6V). The exact value depends primarily on the manufacturing process used to make the diode.

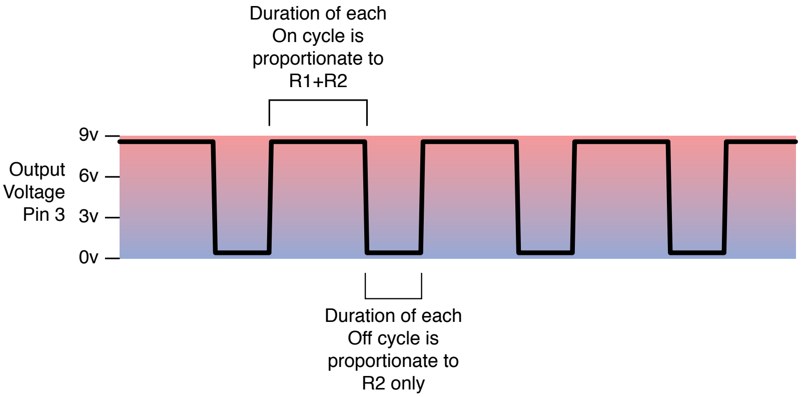

Figure 4-24. *In its usual astable configuration, the timer charges a capacitor through R1+R2 and discharges the capacitor through R2 only. Therefore its output on cycles are longer than its output off cycles.*

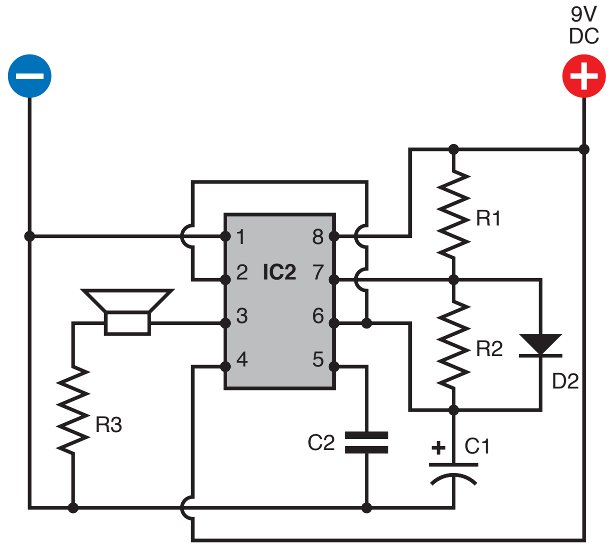

Figure 4-25. *This is a modification of the schematic shown in Figure 4-22. By adding a diode to a 555 timer running in astable mode, we eliminate R2 from the charging cycle of capacitor C1. Now we can adjust the output on cycle with the value of R1, and the output off cycle with the value of R2, so that the on and off durations are independent of each other.*

FUNDAMENTALS

The following table shows 555 timer frequency in astable mode:

- Frequency is in pulses per second, rounded to two figures.
- The horizontal scale shows common resistor values for R2.
- The vertical scale shows common capacitor values for C1. Resistor R1 is assumed to be 1K.
- Resistor R1 is assumed to be 1K.

To calculate a different frequency: double R2, add the product to R1, multiply the sum by C1, and divide the result into 1440. Like this:

Frequency = 1440 / ((R1 + 2R2) × C1) cycles per second

In this formula, R1 and R2 are in kilohms, C1 is in microfarads, and the frequency is in hertz (cycles per second). Note that the frequency is measured from the start of one pulse to the start of the next. The duration of each pulse is not the same as the length of time between each pulse. This issue is discussed in the previous section.

Astable Modifications

In the circuits shown in Figures 4-22 or 4-25, if you substitute a 100K potentiometer for R2, you can adjust the frequency up and down by turning the shaft.

Another option is to “tune” the timer by using pin 5, the control, as shown in the Figure 4-26. Disconnect the capacitor that was attached to that pin and substitute the series of resistors shown. R9 and R11 are both 1K resistors, either side of R10, which is a 100K potentiometer. They ensure that pin 5 always has at least 1K between it and the positive and negative sides of the power supply. Connecting it directly to the power supply won’t damage the timer, but will prevent it from generating audible tones. As you turn the potentiometer to and fro, the frequency will vary over a wide range. If you want to generate a very specific frequency, a trimmer potentiometer can be used instead.

A primary advantage of using pin 5 to adjust frequency is that you can control it remotely. Take the output from pin 3 of another 555 timer running slowly in astable mode, and pipe it through a 2K2 resistor to pin 5. Now you get a two-tone siren effect, as one timer controls the other. If, in addition, you add a 100 µF capacitor between pin 5 and ground, the charging and discharging of the capacitor will make the tone slide up and down instead of switching abruptly. I'll describe this in more detail shortly. This leads me to the whole topic of one chip controlling another chip, which will be our last variation on this experiment.

Chaining Chips

Generally speaking, chips are designed so that they can talk to each other. The 555 couldn't be easier in this respect:

- Pin 3, the output, from one 555 can be connected directly to pin 2, the trigger, of a second 555.
- Alternatively, the output can be sufficient to provide power to pin 8 of a second 555.
- The output is appropriate to control or power other types of chips too.

Figure 4-27 shows these options.

When the output from the first 555 goes high, it is about 70 to 80% of its supply voltage. In other words, when you're using a 9V supply, the high output voltage is at least 6 volts. This is still above the minimum of 5V that the second chip needs to trigger its comparator, so there's no problem.

Figure 4-27. *Three ways to chain 555 timers together. The output of IC1 can power a second timer, or adjust its control voltage, or activate its trigger pin.*

You can chain together the two 555 timers that you already have on your breadboard. Figure 4-28 shows how to connect the two circuits that were shown previously in Figures 4-15 and 4-22. Run a wire from pin 3 (the output) of the first chip to pin 8 (the positive power supply) of the second chip, and disconnect the existing wire connecting pin 8 to your power supply. The new wire is shown in red. Now when you press the button to activate the first chip, its output powers the second chip.

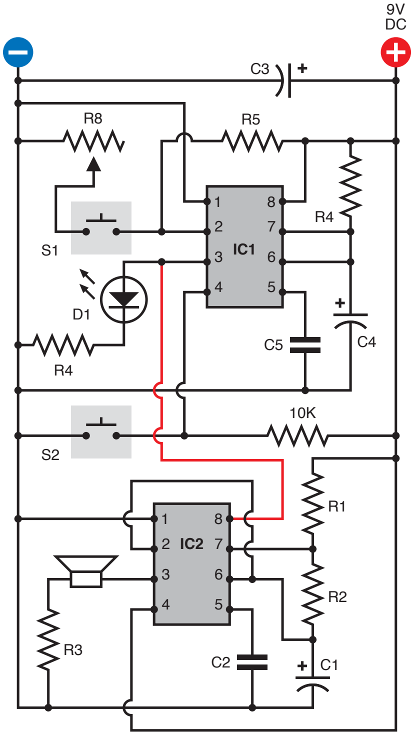

Figure 4-28. *You can combine the two circuits shown in Figures 4-15 and 4-22 simply by disconnecting the wire that provides power to pin 8 of the second timer, and running a substitute wire (shown in red).*

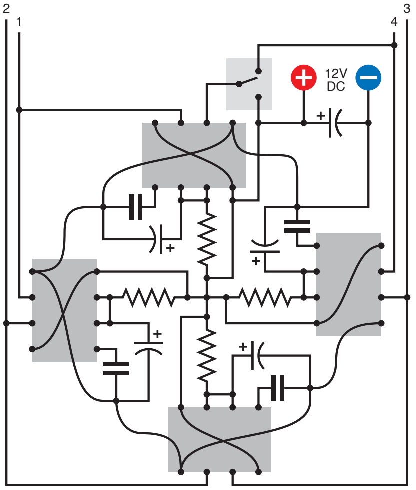

Figure 4-29. *Four 555 timers, chained together in a circle, can flash a series of four sets of LEDs in sequence, like Christmas lights or a movie marquee.*

You can also use the output from one chip to trigger another (i.e., you can connect pin 3 from the first chip to pin 2 of the second). When the output from the first chip is low, it's less than half a volt. This is well below the threshold that the second chip requires to be activated. Why would you want to do this? Well, you might want to have both timers running in monostable mode, so that the end of a high pulse from the first one triggers the start of a high pulse in the second one. In fact, you could chain together as many timers as you like in this way, with the last one feeding back and triggering the first one, and they could flash a series of LEDs in sequence, like Christmas lights. Figure 4-29 shows how four timers could be linked this way, in a configuration that would occupy minimal space (and would be wired point-to-point on perforated board, not on breadboard-format board). Each of the outputs numbered 1 through 4 would have about enough power to run maybe 10 LEDs, if you used relatively high load resistors to limit their current.

Incidentally, you can reduce the chip count (the number of chips) by using two 556 timers instead of four 555 timers. The 556 contains a pair of 555 timers in one package. But because you have to make the same number of external connections (other than the power supply), I haven't bothered to use this variant.

You can even get a 558 timer that contains four 555 circuits, all preset to function in astable mode. I decided not to use this chip, because its output behaves differently from a normal 555 timer. But you can buy a 558 timer and play with it if you wish. It is ideal for doing the "chain of four timers" that I suggested previously. The data sheet even suggests this.

Lastly, going back to the idea of modifying the frequency of a 555 timer in astable mode, you can chain two timers, as shown in Figure 4-30. The red wire shows the connection from the output of the first timer to the control pin of the second. The first timer has now been rewired in astable mode, so that it creates an oscillating on/off output around four times per second. This output flashes the LED (to give you a visual check of what's going on) and feeds through R7 to the control pin of the second timer.

But C2 is a large capacitor, which takes time to charge through R7. While this happens, the voltage detected by pin 5 slowly rises, so that the tone generated by IC2 gradually rises in pitch. Then IC1 reaches the end of its on cycle and switches itself off, at which point C2 discharges and the pitch of the sound generated by IC2 falls again.

You can tweak this circuit to create all kinds of sounds, much more controllably then when you were using PUT transistors to do the same kind of thing. Here are some options to try:

- Double or halve the value of C2.
- Omit C2 completely, and experiment with the value of R7.
- Substitute a 10K potentiometer for R7.
- Change C4 to increase or decrease the cycle time of IC1.

- Halve the value of R5 while doubling the value of C4, so that the cycle time of IC1 stays about the same, but the On time becomes significantly longer than the Off time.
- Change the supply voltage in the circuit from 9 volts to 6 volts or 12 volts.

Remember, you can't damage a 555 timer by making changes of this kind. Just make sure that the negative side of your power supply goes to pin 1 and the positive side to pin 8.

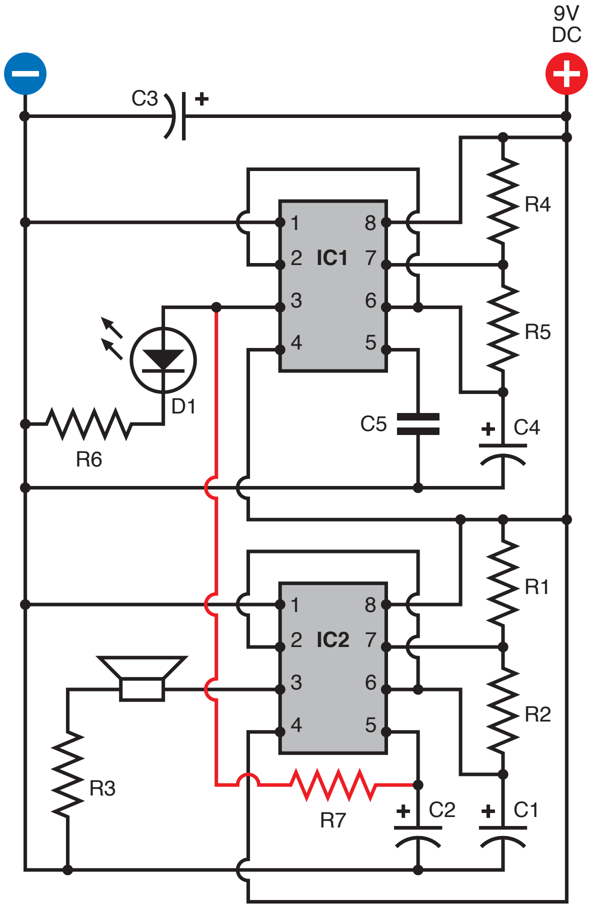

Figure 4-30. *When both timers are astable, but IC1 runs much more slowly than IC2, the output from IC1 can be used to modulate the tone generated by IC2. Note that as this is a substantial modification to the previous schematics, several components have been relabeled. To avoid errors, you may need to remove the old circuit from your breadboard and build this version from scratch. Try these values initially:*

R1, R4, R6, R7: 1K
R2, R5: 10K
R3: 100 ohms
C1: 0.047 µF
C2, C3: 100 µF
C4: 68 µF
C5: 0.1 µF

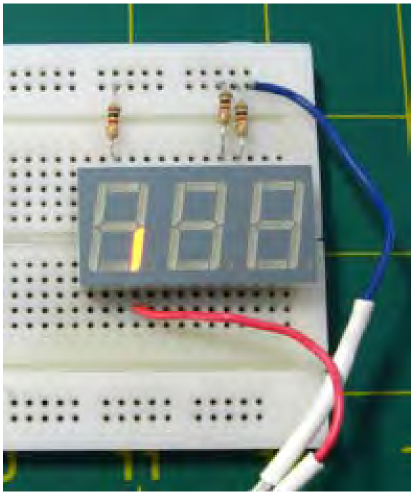

Figure 4-31. *After putting a 1K resistor between the common cathode of the display and the negative supply voltage, you can use the positive supply voltage to illuminate each segment in turn.*

Experiment 18: Reaction Timer

Because the 555 can easily run at thousands of cycles per second, we can use it to measure human reactions. You can compete with friends to see who has the fastest response—and note how your response changes depending on your mood, the time of day, or how much sleep you got last night.

Before going any further, I have to warn you that this circuit will have more connections than others you've tackled so far. It's not conceptually difficult, but requires a lot of wiring, and will only just fit on a breadboard that has 63 rows of holes. Still, we can build it in a series of phases, which should help you to detect any wiring errors as you go.

You will need:

- 4026 chip. Quantity: 4 (really you need only 3, but get another one in case you damage the others).
- 555 timers. Quantity: 3.
- Tactile switches (SPST momentary switches). Quantity: 3.
- Three numeric LEDs, or one 3-digit LED display (see the shopping list at the beginning of this chapter). Quantity: 1.
- Breadboard, resistors, capacitors, and meter, as usual.

Step 1: Display

You can use three separate LED numerals for this project, but I suggest that you buy the Kingbright BC56-11EWA on the shopping list at the beginning of this chapter. It contains three numerals in one big package.

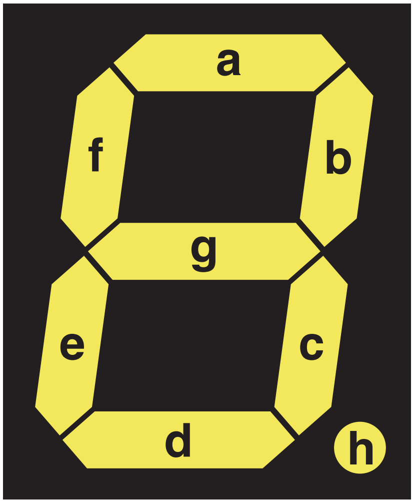

Figure 4-32. *The most basic and common digital numeral consists of seven LED segments identified by letters, as shown here, plus an optional decimal point.*

You should be able to plug it into your breadboard, straddling the center channel. Put it all the way down at the bottom of the breadboard, as shown in Figure 4-31. Don't put any other components on the breadboard yet.

Now set your power supply to 9 volts, and apply the *negative* side of it to the row of holes running up the breadboard on the *righthand* side. Insert a 1K resistor between that negative supply and each of pins 18, 19, and 26 of the Kingbright display, which are the "common cathode," meaning the negative connection shared by each set of LED segments in the display. (The pin numbers of the chip are shown in Figure 4-33. If you're using another model of display, you'll have to consult a data sheet to find which pin(s) are designed to receive negative voltage.)

Switch on the power supply and touch the free end of the positive wire to each row of holes serving the display on its left and right sides. You should see each segment light up, as shown in Figure 4-31.

Each numeral from 0 to 9 is represented by a group of these segments. The segments are always identified with lowercase letters *a* through *g*, as shown in Figure 4-32. In addition, there is often a decimal point, and although we won't be using it, I've identified it with the letter *h*.

Check Figure 4-33 showing the Kingbright display, and you'll see I have annotated each pin with its function. You can step down the display with the positive wire from your power supply, making sure that each pin lights an appropriate segment.

Incidentally, this display has two pins, numbered 3 and 26, both labeled to receive negative voltage for the first of the digits. Why two pins instead of one? I don't know. You need to use only one, and as this is a passive chip, it doesn't matter if you leave the unused one unconnected. Just take care not to apply positive voltage to it, which would create a short circuit.

A numeric display has no power or intelligence of its own. It's just a bunch of light-emitting diodes. It's not much use, really, until we can figure out a way to illuminate the LEDs in appropriate groups—which will be the next step.

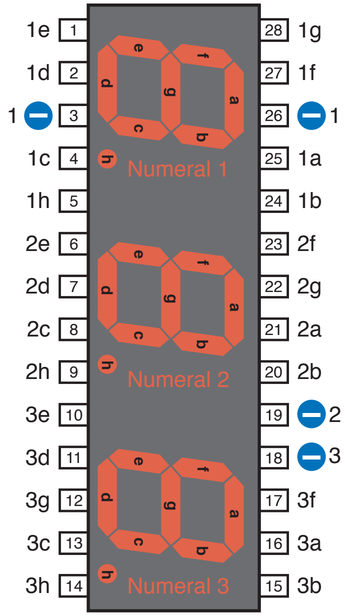

Figure 4-33. *This Kingbright unit incorporates three seven-segment numeric displays in one package, and can be driven by three chained 4026 decade counters. The pin numbers are shown close to the chip. Segments a through g of numeral 1 are identified as 1a through 1g. Segments a through g of numeral 2 are identified as 2a through 2g. Segments a through g of numeral 3 are identified as 3a through 3g.*

Step 2: Counting

Fortunately, we have a chip known as the 4026, which receives pulses, counts them, and creates an output designed to work with a seven-segment display so that it shows numbers 0–9. The only problem is that this is a rather old-fashioned CMOS chip (meaning, Complementary Metal Oxide Semiconductor) and is thus sensitive to static electricity. Check the caution on page 172 before continuing.

Switch off your power supply and connect its wires to the top of the breadboard, noting that for this experiment, we're going to need positive and negative power on both sides. See Figure 4-34 for details. If your breadboard does not already have the columns of holes color-coded, I suggest you use Sharpie markers to identify them, to avoid polarity errors that can fry your components.

The 4026 counter chip is barely powerful enough to drive the LEDs in our display when powered by 9 volts. Make sure you have the chip the right way up, and insert it into the breadboard immediately above your three-digit display, leaving just one row of holes between them empty.

The schematic in Figure 4-35 shows how the pins of the 4026 chip should be connected. The arrows tell you which pins on the display should be connected with pins on the counter.

Figure 4-36 shows the "pinouts" (i.e., the functions of each pin) of a 4026 counter chip. You should compare this with the schematic in Figure 4-35.

Include a tactile switch between the positive supply and pin 1 of the 4026 counter, with a 10K resistor to keep the input to the 4026 counter negative until the button is pressed. Make sure all your positives and negatives are correct, and turn on the power. You should find that when you tap the tactile switch lightly, the counter advances the numeric display from 0 through 9 and then begins all over again from 0. You may also find that the chip sometimes misinterprets your button-presses, and counts two or even three digits at a time. I'll deal with this problem a little further on.

The LED segments will not be glowing very brightly, because the 1K series resistors deprive of them of the power they would really like to receive. Those resistors are necessary to avoid overloading the outputs from the counter.

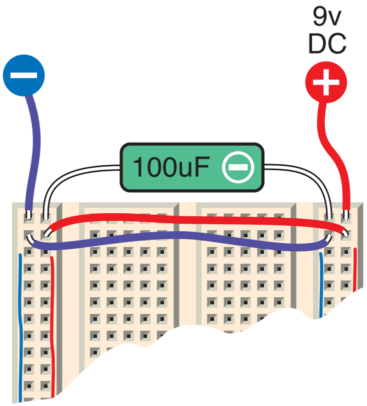

Figure 4-34. *When building circuits around chips, it's convenient to have a positive and negative power supply down each side of your breadboard. For the reaction timer circuit, a 9V supply with a 100 μF smoothing capacitor can be set up like this. If your breadboard doesn't color-code the columns of holes on the left and right sides, I suggest you do that yourself with a permanent marker.*

Grounding Yourself

To avoid the frustration that occurs when you power up a circuit and nothing happens, be sure to take these precautions when you use the older generation of CMOS chips (which often have part numbers from 4000 upward, such as 4002, 4020, and so on):

Chips are often shipped with their legs embedded in black foam. This is electrically conductive foam, and you should keep the chips embedded in it until you are ready to use them.

If the chips are supplied to you in plastic tubes, you can take them out and poke their legs into pieces of conductive foam or, if you don't have any, use aluminum foil. The idea is to avoid one pin on a chip acquiring an electric potential that is much higher than another pin.

While handling CMOS components, grounding yourself is important. I find that in dry weather, I accumulate a static charge merely by walking across a plastic floor-protecting mat in socks that contain some synthetic fibers. You can buy a wrist strap to keep yourself grounded, or simply touch a large metal object, such as a file cabinet, before you touch your circuit board. I am in the habit of working with my socked foot touching a file cabinet, which takes care of the problem.

Never solder a CMOS chip while there is power applied to it.

Grounding the tip of your soldering iron is a good idea.

Better still, don't solder CMOS chips at all. When you're ready to immortalize a project by moving it from a breadboard into perforated board, solder a socket into your perforated board, then push the chip into the socket. If there's a problem in the future, you can unplug the chip and plug in another.

Use a grounded, conductive surface on your workbench. The cheapest way to do this is to unroll some aluminum foil and ground it (with an alligator clip and a length of wire) to a radiator, a water pipe, or a large steel object. I like to use an area of conductive foam to cover my workbench—the same type of foam that is used for packaging chips. However, this foam is quite expensive.

Counter

Figure 4-36. *The 4026 decade counter is a CMOS chip that accepts clock pulses on pin 1, maintains a running total from 0 to 9, and outputs this total via pins designed to interface with a seven-segment LED numeric display.*

FUNDAMENTALS

Counters and seven-segment displays

Most counters accept a stream of pulses and distribute them to a series of pins in sequence. The 4026 decade counter is unusual in that it applies power to its output pins in a pattern that is just right to illuminate the segments of a 7-segment numeric display.

Some counters create positive outputs (they "source" current) while others create negative outputs (they "sink" current). Some seven-segment displays require positive input to light up the numbers. These are known as "common cathode" displays. Others require negative input and are known as "common anode" displays. The 4026 delivers positive outputs and requires a common cathode display.

Check the data sheet for any counter chip to find out how much power it requires, and how much it can deliver. CMOS chips are becoming dated, but they are very useful to hobbyists, because they will tolerate a wide range of supply voltage—from 5 to 15 volts in the case of the 4026. Other types of chips are much more limited.

Most counters can source or sink only a few milliamps of output power. When the 4026 is running on a 9-volt power supply, it can source about 4mA of power from each pin. This is barely enough to drive a seven-segment display.

You can insert a series resistor between each output pin of the counter and each input pin of the numeric display, but a simpler, quicker option is to use just one series resistor for each numeral, between the negative-power pin and ground. The experiment that I'm describing uses this shortcut. Its disadvantage is that digits that require only a couple of segments (such as numeral 1) will appear brighter than those that use many segments (such as numeral 8).

If you want your display to look bright and professional, you really need a transistor to drive each segment of each numeral. An alternative is to use a chip containing multiple "op amps" to amplify the current.

When a decade counter reaches 9 and rolls over to 0, it emits a pulse from its "carry" pin. This can drive another counter that will keep track of tens. The carry pin on that counter can be chained to a third counter that keeps track of hundreds, and so on. In addition to decade counters, there are hexadecimal counters (which count in 16s), octal counters (in 8s), and so on.

Why would you need to count in anything other than tens? Consider that the four numerals on a digital clock each count differently. The rightmost digit rolls over when it reaches 10. The next digit to the left counts in sixes. The first hours digit counts to 10, gives a carry signal, counts to 2, and gives another carry signal. The leftmost hours digit is either blank or 1, when displaying time in 12-hour format. Naturally there are counters specifically designed to do all this.

Counters have control pins such as "clock disable," which tells the counter to ignore its input pulses and freeze the display, "enable display," which enables the output from the chip, and "reset," which resets the count to zero.

The 4026 requires a positive input to activate each control pin. When the pins are grounded, their features are suppressed.

To make the 4026 count and display its running total you must ground the "clock disable" and "reset" pins (to suppress their function) and apply positive voltage to the "enable display" pin (to activate the output). See Figure 4-36 to see these pins identified.

Assuming that you succeed in getting your counter to drive the numeric display, you're ready to add two more counters, which will control the remaining two numerals. The first counter will count in ones, the second in tens, and the third in hundreds.

In Figure 4-37, I've continued to use arrows and numbers to tell you which pins of the counters should be connected to which pins of the numeric display. Otherwise, the schematic would be a confusing tangle of wires crossing each other.

At this point, you can give up in dismay at the number of connections—but really, using a breadboard, it shouldn't take you more than half an hour to complete this phase of the project. I suggest you give it a try, because there's

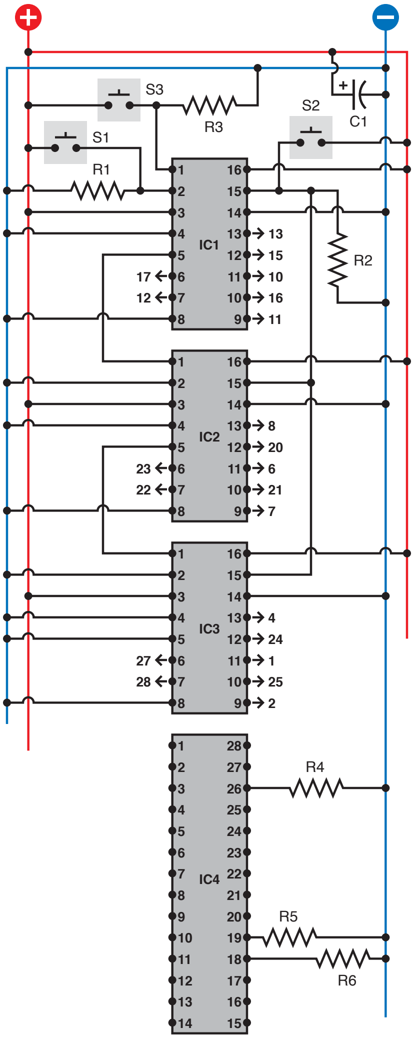

Figure 4-37. *This test circuit, laid out as you would be likely to place it on a breadboard, allows you to trigger a counter manually to verify that the display increments from 000 upward to 999.*

Component values:

All resistors are 1K.
S1, S2, S3: SPST tactile switches, normally open
IC1, IC2, IC3: 4026 decade counter chips
IC4: Kingbright 3-digit common-cathode display
C1: 100 µF (minimum) smoothing capacitor

Wire the output pins on IC1, IC2, and IC3 to the pins on IC4, according to the numbers preceded by arrows. The actual wires have been omitted for clarity. Check for the pinouts of IC4.

something magical about seeing a display count from 000 through 999 "all by itself," and I chose this project because it also has a lot of instructional value.

S1 is attached to the "clock disable" pin of IC1, so that when you hold down this button, it should stop that counter from counting. Because IC1 controls IC2, and IC2 controls IC3, if you freeze IC1, the other two will have to wait for it to resume. Therefore you won't need to make use of their "clock disable" features.

S2 is connected to the "reset" pins of all three counters, so that when you hold down this button, it should set them all to zero.

S3 sends positive pulses manually to the "clock input" pin of the first counter.

S1, S2, and S3 are all wired in parallel with 1K resistors connected to the negative side of the power supply. The idea is that when the buttons are not being pressed, the "pull-down" resistors keep the pins near ground (zero) voltage. When you press one of the buttons, it connects positive voltage directly to the chip, and easily overwhelms the negative voltage. This way, the pins remain either in a definitely positive or definitely negative state. If you disconnect one of these pull-down resistors you are likely to see the numeric display "flutter" erratically. (The numeric display chip has some unconnected pins, but this won't cause any problem, because it is a passive chip that is just a collection of LED segments.)

Always connect input pins of a CMOS chip so that they are either positive or negative. See the "No Floating Pins" warning on the next page.

I suggest that you connect all the wires shown in the schematic first. Then cut lengths of 22-gauge wire to join the remaining pins of the sockets from IC1, IC2, and IC3 to IC4.

Switch on the power and press S2. You'll see three zeros in your numeric display.

Each time you press S3, the count should advance by 1. If you press S2, the count should reset to three zeros. If you hold down S1 while you press S3 repeatedly, the counters should remain frozen, ignoring the pulses from S3.

FUNDAMENTALS

Switch bounce

When you hit S3, I think you'll find that the count sometimes increases by more than 1. This does not mean that there's something wrong with your circuit or your components; you are just observing a phenomenon known as "switch bounce."

On a microscopic level, the contacts inside a pushbutton switch do not close smoothly, firmly, and decisively. They vibrate for a few microseconds before settling; the counter chip detects this vibration as a series of pulses, not just one.

Various circuits are available to "debounce" a switch. The simplest option is to put a small capacitor in parallel with the switch, to absorb the fluctuations; but this is less than ideal. I'll come back to the topic of debouncing later in the book. Switch bounce is not a concern in this circuit, because we're about to get rid of S3 and substitute a 555 timer that generates nice clean bounceless pulses.

Pulse Generation

A 555 timer is ideal for driving a counter chip. You've already seen how to wire a 555 to create a stream of pulses that made noise through a loudspeaker. I'm reproducing the same circuit in Figure 4-38 in simplified form, using the positive and negative supply configuration in the current project. Also I'm showing the connection between pins 2 and 6 in the way that you're most likely to make it, via a wire that loops over the top of the chip.

For the current experiment, I'm suggesting initial component values that will generate only four pulses per second. Any faster than that, and you won't be able to verify that your counters are counting properly.

Install IC5 and its associated components on your breadboard immediately above IC1. Don't leave any gap between the chips. Disconnect S3 and R3 and connect a wire directly between pin 3 (output) of IC5 and pin 1 (clock) of IC1, the topmost counter. Power up again, and you should see the digits advancing rapidly in a smooth, regular fashion. Press S1, and while you hold it, the count should freeze. Release S1 and the count will resume. Press S2 and the counter should reset, even if you are pressing S1 at the same time.

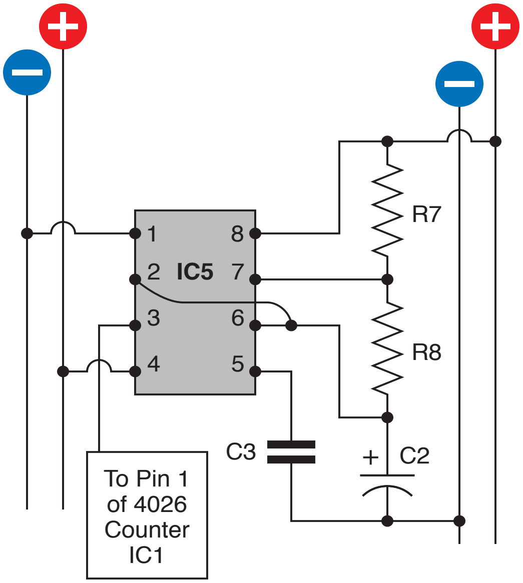

Figure 4-38. *A basic astable circuit to drive the decade counter in the previous schematic. Output is approximately 4 pulses per second.*

No Floating Pins!

A CMOS chip is hypersensitive. Any pin that is not wired either to the supply voltage or to ground is said to be "floating" and may act like an antenna, sensitive to the smallest fluctuations in the world around it.

The 4026 counter chip has a pin labeled "clock disable." The manufacturer's data sheet helpfully tells you that if you give this pin a positive voltage, the chip stops counting and freezes its display. As you don't want to do that, you may just ignore that pin and leave it unconnected, at least while you test the chip. This is a very bad idea!

What the data sheet doesn't bother to tell you (presumably because "everyone knows" such things) is that if you want the clock to run normally, the clock-disable feature itself has to be disabled, by wiring it to negative (ground) voltage. If you leave the pin floating (and I speak from experience), the chip will behave erratically and uselessly.

All input pins must be either positively or negatively wired, unless otherwise specified.

Refinements

Now it's time to remember that what we really want this circuit to do is test a person's reflexes. When the user starts it, we want an initial delay, followed by a signal—probably an LED that comes on. The user responds to the signal by pressing a button as quickly as possible. During the time it takes for the person to respond, the counter will count milliseconds. When the person presses the button, the counter will stop. The display then remains frozen indefinitely, displaying the number of pulses that were counted before the person was able to react.

How to arrange this? I think we need a flip-flop. When the flip-flop gets a signal, it starts the counter running—and keeps it running. When the flip-flop gets another signal (from the user pressing a button), it stops the counter running, and keeps it stopped.

How do we build this flip-flop? Believe it or not, we can use yet another 555 timer, in a new manner known as bistable mode.

FUNDAMENTALS

The bistable 555 timer

Figure 4-39 shows the internal layout of a 555 timer, as before, but the external components on the righthand side have been eliminated. Instead, I'm applying a constant negative voltage to pin 6. Can you see the consequences? Suppose you apply a negative pulse to the trigger (pin 2). Normally when you do this and the 555 starts running, it generates a positive output while charging a capacitor attached to pin 6. When the capacitor reaches 2/3 of the full supply voltage, this tells the 555 to ends its positive output, and it flips back to negative.

Well, if there's no capacitor, there's nothing to stop the timer. Its positive output will just continue indefinitely. However, pin 4 (the reset) can still override everything, so if you apply negative voltage to pin 4, it flips the output to negative. After that, the output will stay negative indefinitely, as it usually does, until you trigger the timer by dropping the voltage to pin 2 again. This will flip the timer back to generating its positive output.

Here's a quick summary of the bistable configuration:

- A negative pulse to pin 2 turns the output positive.
- A negative pulse to pin 4 turns the output negative.
- The timer is stable in each of these states. Its run-time has become infinite.

It's OK to leave pins 5 and 7 of the timer unconnected, because we're pushing it into extreme states where any random signals from those pins will be ignored.

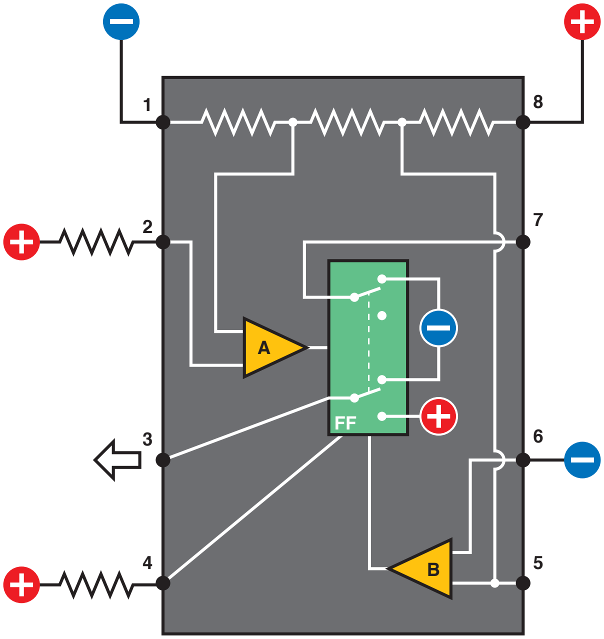

Figure 4-39. *In the bistable configuration, pin 6 of a 555 timer is perpetually negative, so the timer cycle never ends, unless you force it to do so by applying a negative pulse to pin 4 (the reset).*

In bistable mode, the 555 has turned into one big flip-flop. To avoid any uncertainty, we keep pins 2 and 4 normally positive via pull-up resistors, but negative pulses on those pins can overwhelm them when we want to flip the 555 into its opposite state. The schematic for running a 555 timer in bistable mode, controlled by two pushbuttons, is shown in Figure 4-40. You can add this above your existing circuit. Because you're going to attach the output from IC6 to pin 2 of IC1, the topmost counter, you can disconnect S1 and R1 from that pin. See Figure 4-41.

Now, power up the circuit again. You should find that it counts in the same way as before, but when you press S4, it freezes. This is because your bistable 555 timer is sending its positive output to the "clock disable" pin on the counter. The counter is still receiving a stream of pulses from the astable 555 timer, but as long as pin 2 is positive on the counter, the counter simply ignores the pulses.

Now press S5, which flips your bistable 555 back to delivering a negative output, at which point the count resumes.

We're getting close to a final working circuit here. We can reset the count to zero (with S3), start the count (with S5), and wait for the user to stop the count (with S4). The only thing missing is a way to start the count unexpectedly.

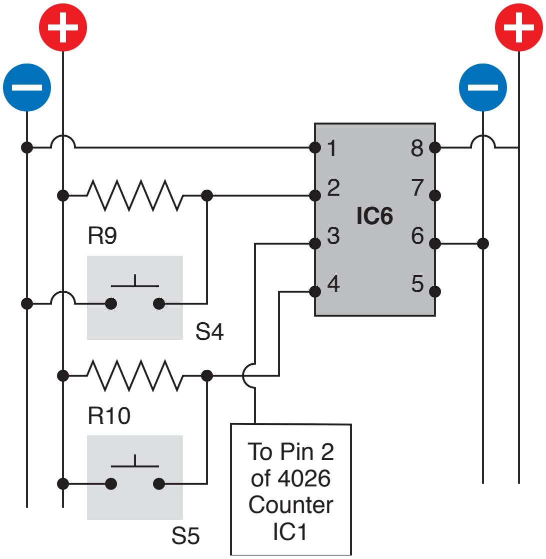

Figure 4-40. *Adding a bistable 555 timer to the reflex tester will stop the counter with a touch of a button, and keep it stopped.*

The Delay

Suppose we set up yet another 555 in monostable mode. Trigger its pin 2 with a negative pulse, and the timer delivers a positive output that lasts for, say, 4 seconds. At the end of that time, its output goes back to being negative. Maybe we can hook that positive-to-negative transition to pin 4 of IC6. We can use this instead of switch S5, which you were pressing previously to start the count.

Check the new schematic in Figure 4-41 which adds another 555 timer, IC7 above IC6. When the output from IC7 goes from positive to negative, it will trigger the reset of IC6, flipping its output negative, which allows the count to begin. So IC7 has taken the place of the start switch, S4. You can get rid of S4, but keep the pull-up resistor, R9, so that the reset of IC6 remains positive the rest of the time.

This arrangement works because I have used a capacitor, C4, to connect the output of IC7 to the reset of IC6. The capacitor communicates the sudden change from positive to negative, but the rest of the time it blocks the steady voltage from IC7 so that it won't interfere with IC6.

The final schematic in Figure 4-41 shows the three 555 timers all linked together, as you should insert them above the topmost counter, IC1. I also added an LED to signal the user. Figure 4-42 is a photograph of my working model of the circuit.

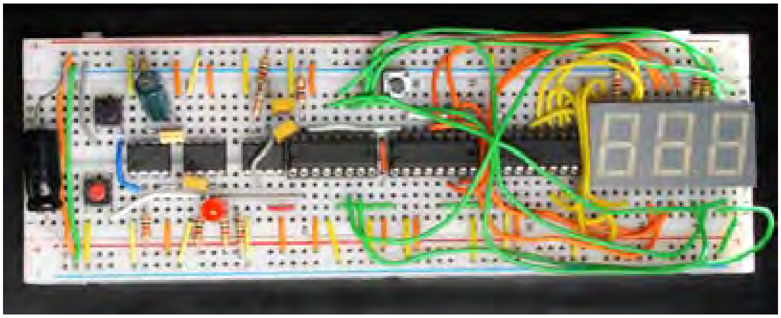

Figure 4-42. *The complete reaction-timer circuit barely fits on a 63-row breadboard.*

Because this circuit is complicated, I'll summarize the sequence of events when it's working. Refer to Figure 4-41 while following these steps:

1. User presses Start Delay button S4, which triggers IC7.
2. IC7 output goes high for a few seconds while C5 charges.
3. IC7 output drops back low.
4. IC7 communicates a pulse of low voltage through C4 to IC6, pin 4.
5. IC 6 output flips to low and flops there.
6. Low output from IC6 sinks current through LED and lights it.
7. Low output from IC6 also goes to pin 2 of IC1.

8. Low voltage on pin 2 of IC1 allows IC1 to start counting.
9. User presses S3, the "stop" button.
10. S3 connects pin 2 of IC6 to ground.
11. IC6 output flips to high and flops there.
12. High output from IC6 turns off the LED.
13. High output from IC6 also goes to pin 2 of IC1.
14. High voltage on pin 2 of IC1 stops it from counting.
15. After assessing the result, user presses S2.
16. S2 applies positive voltage to pin 15 of IC1, IC2, IC3.
17. Positive voltage resets counters to zero.
18. The user can now try again.
19. Meanwhile, IC5 is running continuously throughout.

In case you find a block diagram easier to understand, I've included that, too, in Figure 4-43.

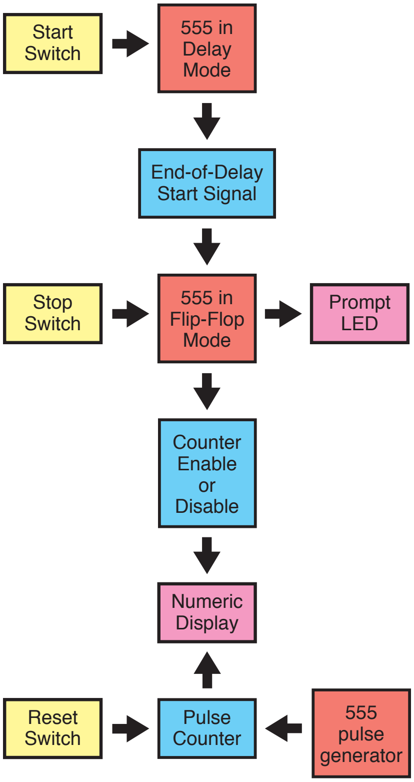

Figure 4-43. *The functions of the reflex tester, summarized as a block diagram.*

Using the Reflex Tester

At this point, you should be able to test the circuit fully. When you first switch it on, it will start counting, which is slightly annoying, but easily fixed. Press S3 to stop the count. Press S2 to reset to zero.

Now press S4. Nothing seems to happen—but that's the whole idea. The delay cycle has begun in stealth mode. After a few seconds, the delay cycle ends, and the LED lights up. Simultaneously, the count begins. As quickly as possible, the user presses S3 to stop the count. The numerals freeze, showing how much time elapsed.

There's only one problem—the system has not yet been calibrated. It is still running in slow-motion mode. You need to change the resistor and capacitor attached to IC5 to make it generate 1,000 pulses per second instead of just three or four.

Substitute a 10K trimmer potentiometer for R8 and a 1 μF capacitor for C2. This combination will generate about 690 pulses per second when the trimmer is presenting maximum resistance. When you turn the trimmer down to decrease its resistance, somewhere around its halfway mark the timer will be running at 1,000 pulses per second.

How will you know exactly where this point is? Ideally, you would attach an oscilloscope probe to the output from IC5. But, most likely, you don't have an oscilloscope, so here are a couple other suggestions.

First remove the 1 μF capacitor at C2 and substitute a 10 μF capacitor. Because you are multiplying the capacitance by 10, you will reduce the speed by 10. The leftmost digit in your display should now count in seconds, reaching 9 and rolling over to 0 every 10 seconds. You can adjust your trimmer potentiometer while timing the display with a stopwatch. When you have it right, remove the 10 μF capacitor and replace the 1 μF capacitor at C2.

The only problem is, the values of capacitors may be off by as much as 10%. If you want to fine-tune your reflex timer, you can proceed as follows.

Disconnect the wire from pin 5 of IC3, and substitute an LED with a 1K series resistor between pin 5 and ground. Pin 5 is the "carry" pin, which will emit a positive pulse whenever IC3 counts up to 9 and rolls over to start at 0 again. Because IC3 is counting tenths of a second, you want its carry output to occur once per second.

Now run the circuit for a full minute, using your stopwatch to see if the flashing LED drifts gradually faster or slower than once per second. If you have a camcorder that has a time display in its viewfinder, you can use that to observe the LED.

If the LED flashes too briefly to be easily visible, you can run a wire from pin 5 to another 555 timer that is set up in monostable mode to create an output lasting for around 1/10 of a second. The output from that timer can drive an LED.

Enhancements

It goes without saying that anytime you finish a project, you see some opportunities to improve it. Here are some suggestions:

1. No counting at power-up. It would be nice if the circuit begins in its "ready" state, rather than already counting. To achieve this you need to send a negative pulse to pin 2 of IC6, and maybe a positive pulse to pin 15 of IC1. Maybe an extra 555 timer could do this. I'm going to leave you to experiment with it.
2. Audible feedback when pressing the Start button. Currently, there's no confirmation that the Start button has done anything. All you need to do is buy a piezoelectric beeper and wire it between the righthand side of the Start button and the positive side of the power supply.
3. A random delay interval before the count begins. Making electronic components behave randomly is very difficult, but one way to do it would be to require the user to hold his finger on a couple of metal contacts. The skin resistance of the finger would substitute for R11. Because the finger pressure would not be exactly the same each time, the delay would vary. You'd have to adjust the value of C5.

Summing Up

This project demonstrated how a counter chip can be controlled, how counter chips can be chained together, and three different functions for 555 timers. It also showed you how chips can communicate with each other, and introduced you to the business of calibrating a circuit after you've finished building it.

Naturally, if you want to get some practical use from the circuit, you should build it into an enclosure with heavier-duty pushbuttons—especially the button that stops the count. You'll find that when people's reflexes are being tested, they are liable to hit the stop button quite hard.

Because this was a major project, I'll follow it up here with some quicker, easier ones as we move into the fascinating world of another kind of integrated circuit: logic chips.

Experiment 19: Learning Logic

You will need:

- Assorted resistors and capacitors.
- 74HC00 quad 2-input NAND chip, 74HC08 quad 2-input AND chip, and LM7805 voltage regulator. Quantity: 1 of each.
- Signal diode, 1N4148 or similar. Quantity: 1.
- Low-current LED. Quantity: 1.
- SPST tactile switches. Quantity: 2.

You're going to be entering the realm of pure digital electronics, using "logic gates" that are fundamental in every electronic computing device. When you deal with them individually, they're extremely easy to understand. When you start chaining them together, they can seem intimidatingly complex. So let's start with them one at a time.

Logic gates are much fussier than the 555 timer or the 4026 counter that you used previously. They demand an absolutely precise 5 volts DC, with no fluctuations or "spikes" in the flow of current. Fortunately, this is easy to achieve: just set up your breadboard with an LM7805 voltage regulator, as shown in the schematic in Figure 4-44 and the photograph in Figure 4-45. The regulator receives 9 volts from your usual voltage supply, and reduces it to 5 volts, with the help of a couple of capacitors. You apply the 9 volts to the regulator, and distribute the 5 volts down the sides of your breadboard instead of the unregulated voltage that you used previously. Use your meter to verify the voltage, and make sure you have the polarity clearly marked.

After installing your regulator, take a couple of tactile switches, two 10K resistors, a low-current LED, and a 1K resistor, and set them around a 74HC00 logic chip as shown in Figure 4-46. You may notice that many of the pins of the chip are shorted together and connected to the negative side of the power supply. I'll explain that in a moment.

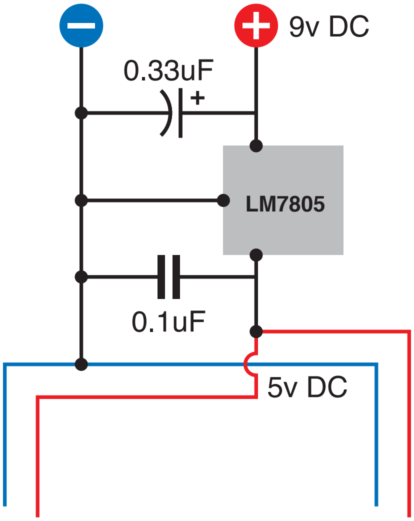

Figure 4-44. *This simple circuit is essential to provide a regulated 5V DC supply for logic chips.*

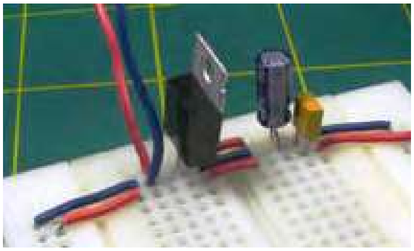

Figure 4-45. *The voltage regulator and its two capacitors can fit snugly at the top of a breadboard. Remember to apply the 9V input voltage at the left pin of the regulator, and distribute the 5V output down the sides of the breadboard.*

FUNDAMENTALS

Voltage regulators

The simplest versions of these little semiconductors accept a higher DC voltage on one pin and deliver a lower DC voltage on another pin, with a third pin (usually in the middle) serving as a common negative, or ground. You should also attach a couple of capacitors to smooth the current, as shown in Figure 4-46.

Typically you can put a 7.5-volt or 9-volt supply on the "input" side of a 5-volt regular, and draw a precise 5 volts from the "output" side. If you're wondering where the extra voltage goes, the answer is, the regulator turns the electricity into heat. For this reason, small regulators (such as the one in Figure 4-8) often have a metal back with a hole in the top. Its purpose is to radiate heat, which it will do more effectively if you bolt it to a piece of aluminum, since aluminum conducts heat very effectively. The aluminum is known as a heat sink, and you can buy fancy ones that have multiple cooling fins.

For our purposes, we won't be drawing enough current to require a heat sink.

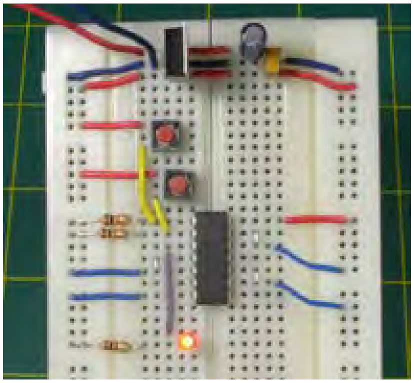

Figure 4-47. *This breadboard layout is exactly equivalent to the schematic in Figure 4-46.*

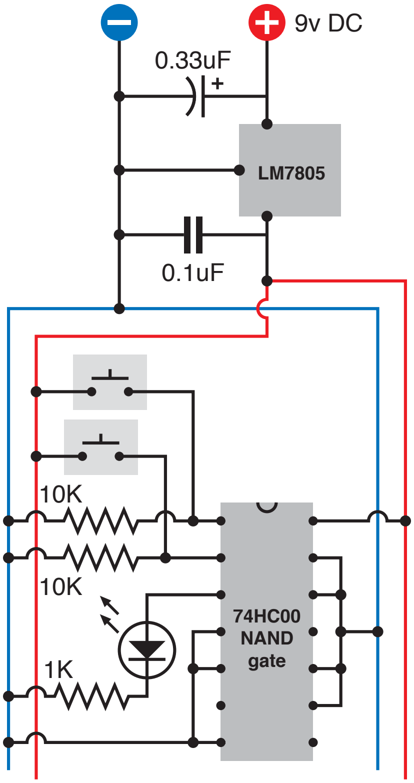

Figure 4-46. *By observing the LED when you press either, both, or neither of the buttons, you can easily figure out the logical function of the NAND gate.*

When you connect power, the LED should light up. Press one of the tactile switches, and the LED remains illuminated. Press the other tactile switch, and again the LED stays on. Now press both switches, and the light should go out.

Pins 1 and 2 are logic inputs for the 74HC00 chip. Initially they were held at negative voltage, being connected to the negative side of the power supply through 10K resistors. But each pushbutton overrides its pull-down resistor and forces the input pin to go positive.

The logic output from the chip, as you saw, is normally positive—but *not* if the first input *and* the second input are positive. Because the chip does a "Not AND" operation, it's known as a NAND logic gate. You can see the breadboard layout in Figure 4-47. Figure 4-48 is a simplified version of the circuit. The U-shaped thing with a circle at the bottom is the logic symbol for a NAND gate. No power supply is shown for it, but in fact all logic chips require a power supply, which enables them to put out more current than they take in. Anytime you see a symbol for a logic chip, try to remember that it has to have power to function.

The 74HC00 actually contains four NAND gates, each with two logical inputs and one output. They are arrayed as shown in Figure 4-49. Because only one gate was needed for the simple test, the input pins of the unused gates were shorted to the negative side of the power supply.

Pin 14 supplies positive power for the chip; pin 7 is its ground pin. Almost all the 7400 family of logic chips use the same pins for positive and negative power, so you can swap them easily.

In fact, let's do that right now. First, disconnect the power. Carefully pull out the 74HC00 and put it away with its legs embedded in conductive foam. Substitute a 74HC08 chip, which is an AND chip. Make sure you have it the right way up, with its notch at the top. Reconnect the power and use the pushbuttons as you did before. This time, you should find that the LED comes on if the first input AND the second input are both positive, but it remains dark otherwise. Thus, the AND chip functions exactly opposite to the NAND chip. Its pinouts are shown in Figure 4-50.

You may be wondering why these things are useful. Soon you'll see that we can put logic gates together to do things such as create an electronic combination lock, or a pair of electronic dice, or a computerized version of a TV quiz show where users compete to answer a question. And if you were really insanely ambitious, you could build an entire computer out of logic gates.

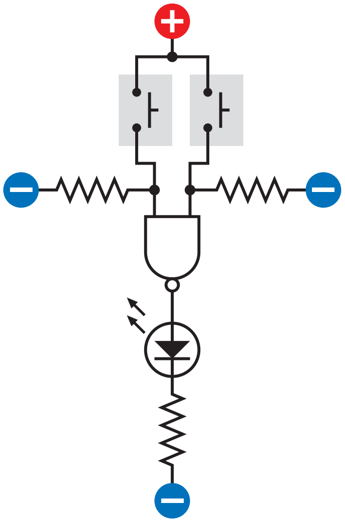

Figure 4-48. *The structure and function of the NAND gate is easier to visualize with this simplified schematic that omits the power supply for the chip and doesn't attempt to place the wires to fit a breadboard layout.*

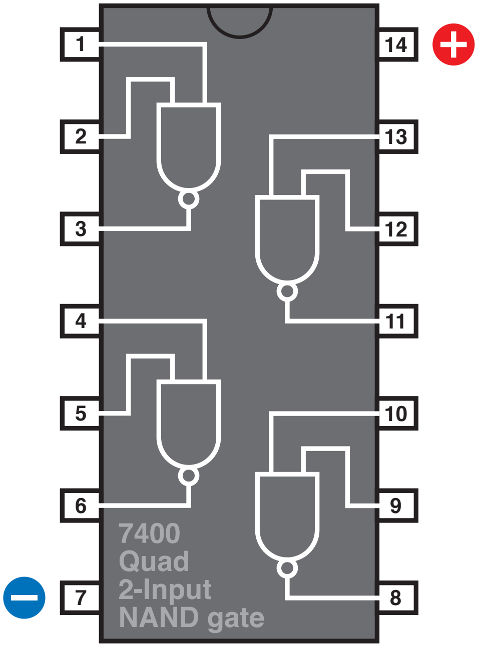

Figure 4-49. *The pinouts of the logic gates in a 74HC00chip.*

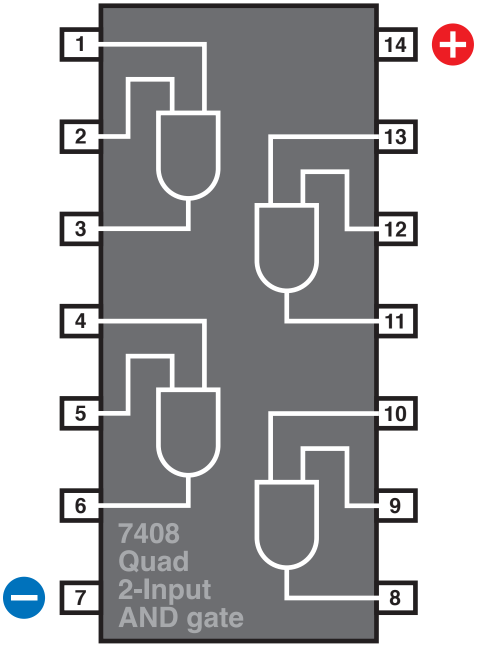

Figure 4-50. *The pinouts of the logic gates in a 74HC08chip.*

BACKGROUND

From Boole to Shannon

George Boole was a British mathematician, born in 1815, who did something that few people are ever lucky enough or smart enough to do: he invented an entirely new branch of mathematics.

Interestingly, it was not based on numbers. Boole had a relentlessly logical mind, and he wanted to reduce the world to a series of true-or-false statements which could overlap in interesting ways. For instance, suppose there is a couple named Ann and Bob who have so little money, they only own one hat. Clearly, if you happen to run into Ann and Bob walking down the street, there are four possibilities: neither of them may be wearing a hat, Ann may be wearing it, or Bob may be wearing it, but they cannot both be wearing it.

The diagram in Figure 4-51 illustrates this. All the states are possible except the one where the circles overlap. (This is known as a Venn diagram. I leave it to you to search for this term if it interests you and you'd like to learn more.) Boole took this concept much further, and showed how to create and simplify extremely complex arrays of logic.

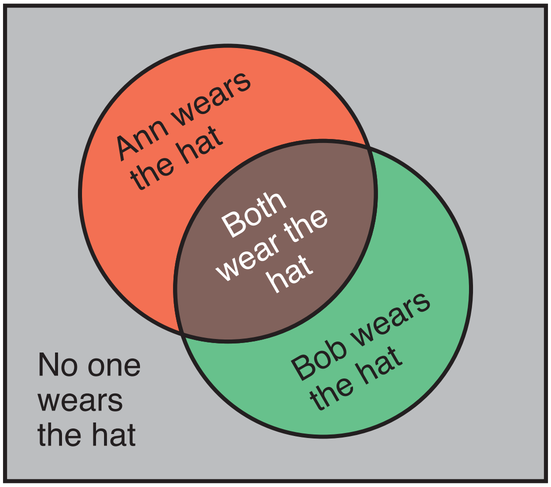

Figure 4-51. *This slightly frivolous Venn diagram illustrates the various possibilities for two people, Ann and Bob, who own only one hat.*

Another way to summarize the hat-wearing situation is to make the "truth table" shown in Figure 4-52. The rightmost column shows whether each combination of propositions can be true. Now check the table in Figure 4-53. It's the same table but uses different labels, which describe the pattern you have seen while using the NAND gate.

Boole published his treatise on logic in 1854, long before it could be applied to electrical or electronic devices. In fact, during his lifetime, his work seemed to have no practical applications at all. But a man named Claude Shannon encountered Boolean logic while studying at MIT in the 1930s, and in 1938 he published a paper describing how Boolean analysis could be applied to circuits using relays. This had immediate practical applications, as telephone networks were growing rapidly, creating complicated switching problems.

BACKGROUND

From Boole to Shannon (continued)

Ann is wearing the hat	Bob is wearing the hat	This combination can be
NO	NO	TRUE
NO	YES	TRUE
YES	NO	TRUE
YES	YES	FALSE

Figure 4-52. *The hat-wearing possibilities can be expressed in a "truth table."*

Input A	Input B	Output
OFF	OFF	ON
OFF	ON	ON
ON	OFF	ON
ON	ON	OFF

Figure 4-53. *The truth-table from can be relabeled to describe the inputs and outputs of a NAND gate.*

A very simple telephone problem could be expressed like this. Suppose two customers in a rural area share one telephone line. If one of them wants to use the line, or the other wants to use it, or neither of them wants to use it, there's no problem. But they cannot both use it at once. You may notice that this is exactly the same as the hat-wearing situation for Ann and Bob.

We can easily draw a circuit using two normally closed relays that creates the desired outcome (see Figure 4-54), but if you imagine a telephone exchange serving many thousands of customers, the situation becomes very complicated indeed. In fact, in Shannon's time, no logical process existed to find the best solution and verify that it used fewer components than some other solution.

Shannon saw that Boolean analysis could be used for this purpose. Also, if you used an "on" condition to represent numeral 1 and an "off" condition to represent numeral 0, you could build a system of relays that could count. And if it could count, it could do arithmetic.

When vacuum tubes were substituted for relays, the first practical digital computers were built. Transistors took the place of vacuum tubes, and integrated circuit chips replaced transistors, leading to the desktop computers that we now take for granted today. But deep down, at the lowest levels of these incredibly complex devices, they still use the laws of logic discovered by George Boole. Today, when you use a search engine online, if you use the words AND and OR to refine your search, you're actually using Boolean operators.

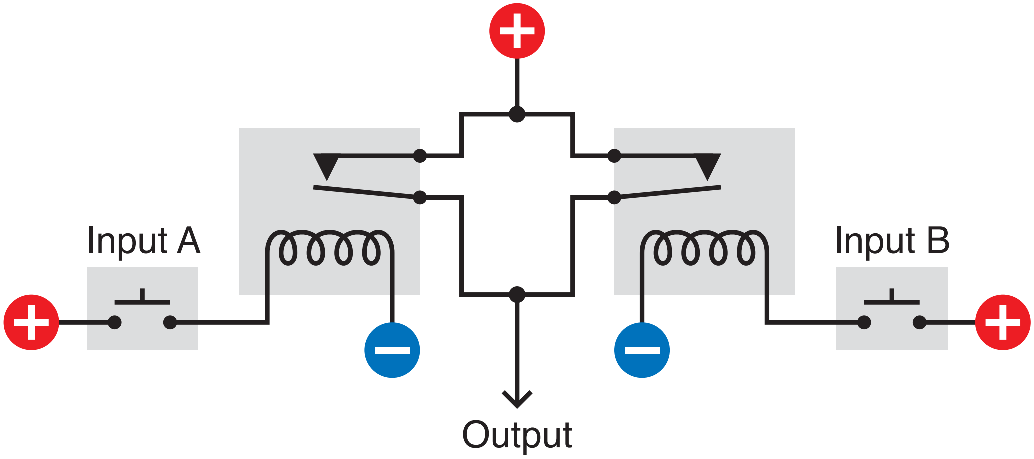

Figure 4-54. *This relay circuit could illustrate the desired logic for two telephone customers wanting to share one line, and its behavior is almost identical to that of the NAND schematic shown in Figure 4-48.*

Figure 4-55. *Ann and Bob attempt to overcome the limitations of Boolean logic.*

ESSENTIALS

Logic gate basics

The NAND gate is the most fundamental building block of digital computers, because (for reasons which I don't have space to explain here) it enables digital addition. If you want to explore more try searching online for topics such as "binary arithmetic" and "half-adder."

Generally, there are seven types of logic gates:

- AND
- NAND
- OR
- NOR
- XOR
- XNOR
- NOT

Of the six two-input gates, the XNOR is hardly ever used. The NOT gate has a single input, and simply gives a negative output when the input is positive or a positive output when the input is negative. The NOT is more often referred to as an "Inverter." The symbols for all seven gates are shown in Figure 4-56.

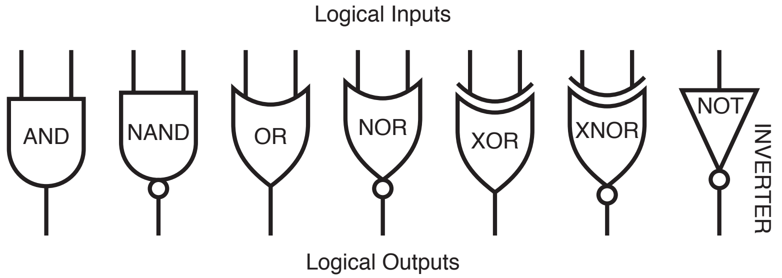

Figure 4-56. *American symbols for the six types of two-input logic gates, and the single-input inverter.*

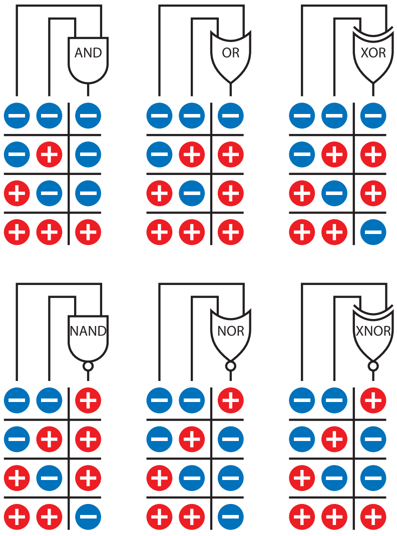
I've shown the American symbols. Other symbols have been adopted in Europe, but the traditional symbols shown here are the ones that you will usually find, even being used by Europeans. I also show the truth tables, in Figure 4-57, illustrating the logical output (high or low) for each pair of inputs of each type of gate.



AND		
−	−	−
−	+	−
+	−	−
+	+	+

OR

XNOR		
−	−	+
−	+	−
+	−	−
+	+	+

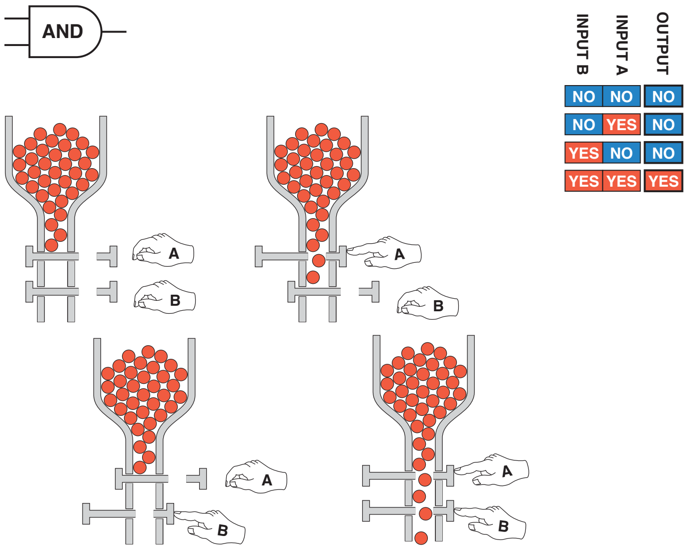
Figure 4-57. *Inputs and corresponding outputs for the six types of logic gates (note that the XNOR gate is seldom used). The minus signs indicate low voltage, close to ground potential. The plus signs indicate higher voltage, close to the positive potential of the power supply in the circuit. The exact voltages will vary depending on other components that may be actively connected.*

ESSENTIALS

Logic gate basics (continued)

If you have difficulty visualizing logic gates, a mechanical comparison may help. You can think of them as being like sliding plates with holes in them, in a bubblegum machine. Two people, A and B, can push the plates. These people are the two inputs, which are considered positive when they are doing something. (Negative logic systems also exist, but are uncommon, so I'm only going to talk about positive systems here.)

The flow of bubblegum represents a flow of positive current. The full set of possibilities is shown in Figures 4-58 through 4-63.



INPUT B	INPUT A	OUTPUT

BACKGROUND

The confusing world of TTL and CMOS

Back in the 1960s, the first logic gates were built with Transistor-Transistor Logic, abbreviated TTL, meaning that tiny bipolar transistors were etched into a single wafer of silicon. Soon, these were followed by Complementary Metal Oxide Semiconductors, abbreviated CMOS. Each of these chips was a collection of metal-oxide field-effect transistors (known as MOSFETs). The 4026 chip that you used earlier is an old CMOS.

You may remember that bipolar transistors amplify current. TTL circuits are similar: they are sensitive to current, rather than voltage. Thus they require a significant flow of electricity, to function. But CMOS chips are like the programmable unijunction transistor that I featured previously. They are voltage-sensitive, enabling them to draw hardly any current while they are waiting for a signal, or pausing after emitting a signal.

The two families named TTL and CMOS still exist today. The table in Figure 4-64 summarizes their basic advantages and disadvantages. The CMOS series, with part numbers from 4000 upward, were easily damaged by static electricity but were valuable because of their meager power consumption. The TTL series, with part numbers from 7400 upward, used much more power but were less sensitive and very fast. So, if you wanted to build a computer, you used the TTL family, but if you wanted to build a little gizmo that would run for weeks on a small battery, you used the CMOS family.

From this point on everything became extremely confusing, because CMOS manufacturers wanted to grab market share by emulating the advantages of TTL chips. Newer generations of CMOS chips even changed their part numbers to begin with "74" to emphasize their compatibility, and the functions of pins on CMOS chips were swapped around to match the functions of pins on TTL chips. Consequently, the pinouts of CMOS and TTL chips are usually now identical, but the meaning of "high" and "low" states changed in each new generation, and the maximum supply voltages for CMOS chips were revised downward. Note I have included question marks beside two categories in the CMOS column, as modern CMOS chips have overcome those disadvantages—at least to some extent.

Here's a quick summary, which will be useful to you if you look at a circuit that you find online, and you wonder about the chips that have been specified.

Where you see a letter "x," it means that various numbers may appear in that location. Thus "74xx" includes the 7400 NAND gate, the 7402 NOR gate, the 74150 16-bit data selector, and so on. A combination of letters preceding the "74" identifies the chip manufacturer, while letters following the part number may identify the style of package, may indicate whether it contains heavy metals that are environmentally toxic, and other details.

	TTL	CMOS
Part number series	7400	4000 (Later adopted 7400 numbering)
Vulnerable to static electricity	Less	More?
Speed	Faster	Slower?
Power Consumption	Higher	Very Low
Power Supply Range	Narrow 5v	Wider 3v-6v
Input Impedance	Low	Very High

Figure 4-64. *The basic differences between the two families of logic chips. In successive generations, these differences have gradually diminished.*

TTL family:

74xx
The old original generation, now obsolete.

74Sxx
Higher speed "Schottky" series, now obsolete.

74LSxx
Lower power Schottky series, still used occasionally.

74ALSxx
Advanced low-power Schottky.

74Fxx
Faster than the ALS series.

BACKGROUND

The confusing world of TTL and CMOS (continued)

CMOS family:

40xx

The old original generation, now obsolete.

40xxB

The 4000B series was improved but still susceptible to damage from static electricity. Many hobby circuits still use these chips because they will run from relatively high voltages and can power LEDs and even small relays directly.

74HCxx

Higher-speed CMOS, with part numbers matching the TTL family, and pinouts matching the TTL family, but input and output voltages not quite the same as the TTL family. I've used this generation extensively in this book, because it's widely available, and the circuits here have no need for greater speed or power.

74HCTxx

Like the HC series but matching the TTL voltages.

74ACxx

Advanced version of HC series. Faster, with higher output capacity.

74ACTxx

Like the AC series but with the same pin functions and voltages as TTL.

74AHCxx

Advanced higher-speed CMOS.

74AHCTxx

Like the AHC series but with the same pin functions and voltages as TTL.

74LVxx

Lower voltage (3.3v) versions, including LV, LVC, LVT, and ALVC series.

As you can see, these days you have to interpret part numbers very carefully. But which family and generation of chips should you use? Well, that depends! Following are some guidelines.

What you don't need:

1. Speed differences are irrelevant from our point of view, as we're not going to be building circuits running at millions of cycles per second.
2. Price differences are so small as to be inconsequential.
3. Lower-voltage (LV) CMOS chips are not very interesting for our small experimental circuits.
4. Try to avoid mixing different families, and different generations of the same family, in the same circuit. They may not be compatible.
5. Some modern chip varieties may be only available in the surface-mount package format. Because they're so much more difficult to deal with, and their only major advantage is miniaturization, I don't recommend them.
6. In the TTL family, the LS and ALS series cannot handle as much output current as the S series and the F series. You don't need them.

What you should use:

1. The old 74LSxx series of TTL chips was so popular, you'll still find schematics that specify these chips. You should still be able to buy them from sources online, but if not, you can substitute the 74HCTxx chips, which are designed to function identically.
2. The old 4000B series of CMOS chips are still used by hobbyists because their willingness to tolerate high voltages is convenient. While TTL or TTL-compatible chips require a carefully regulated 5 volts, the 4000B chips would handle 15 volts—and also delivered enough power to energize LEDs or even very small relays. Some hobbyists also have a nostalgic affection for the 74Cxx series of chips, which had the same pin connections as the TTL chips but could still tolerate higher voltages and higher output current. The trouble is, some of the 74Cxx chips are almost extinct, and while the 4000B chips are still available, they are considered almost obsolete.

BACKGROUND

The confusing world of TTL and CMOS (continued)

Bottom line: I suggest you use the 4000B chips only if you want to replicate an old circuit, or if a modern equivalent is unavailable (which is why I specified the 4026B chip for the reaction timer—I could not find a modern equivalent that will drive seven-segment numeric displays directly, and I didn't want you to have to deal with more parts than necessary).

If you check online suppliers such as *Mouser.com* you'll find that the HC family is by far the most popular right now. They are all available in through-hole format (to fit your breadboard and perforated board). They have the high input impedance of CMOS (which is useful) and they have the same pin identities as the old 74LSxx series.

Abbreviations

When looking at data sheets, you are likely to encounter some or all of these abbreviations:

- VOH min: Minimum output voltage in high state
- VOL max: Maximum output voltage in low state
- VIH min: Minimum input voltage to be recognized as high
- VIL max: Maximum input voltage recognized as low

BACKGROUND

Logic gate origins

The 7400 family of integrated circuits was introduced by Texas Instruments, beginning with the 7400 NAND gate in 1962. Other companies had sold logic chips previously, but the 7400 series came to dominate the market. The Apollo lunar missions used a computer built with 7400 chips, and they were a mainstay of minicomputers during the 1970s.

RCA introduced its 4000 series of logic chips in 1968, built around CMOS transistors; Texas Instruments had chosen TTL. The CMOS chips used less power, thus generating much less heat and enabling flexible circuit design, as each chip could power many others. CMOS was also tolerant of wide voltage ranges (from 3 to 15 volts) but prohibited switching speeds faster than around 1MHz. TTL was 10 times faster.

Design tweaks gradually eradicated the speed penalty for CMOS, and TTL chips have become relatively rare. Still, some people retain a special nostalgic loyalty to "the logic gates that went to the moon." A hardcore enthusiast named Bill Buzbee has built an entire web server from TTL-type 7400 chips, currently online at *http://magic-1.org*. Figure 4-65 shows just one of the handmade circuit boards that Bill assembled to run his computer.

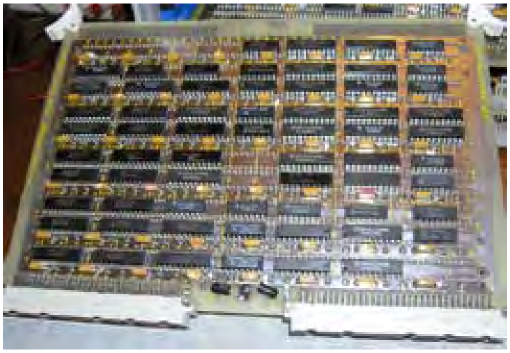

Figure 4-65. *Hobbyist Bill Buzbee built himself a web server entirely from 7400 series logic chips, the oldest of which was fabricated back in 1969. The web server can be found online at http://magic-1.org, displaying pictures of itself and details of its construction. The picture here that Bill took shows just one of the circuit boards of this remarkable project.*

FUNDAMENTALS

Common part numbers

Each 14-pin chip can contain four 2-input gates, three 3-input gates, two 4-input gates, one 8-input gate, or six single-input inverters, as shown in the following table.

	2 input	3 input	4 input	8 input
AND	7408	7411	7421	
NAND	7400	7410	7420	7430
OR	7432			744078*
NOR	7402	7427		744078*
XOR	7486			
XNOR	747266			
Inverter	(1 input) 7404			

*The 744078 has an OR output and a NOR output on the same chip.

Figures 4-66 through 4-74 show the internal connections of the logic chips that you are most likely to use. Note that the 7402 NOR gate has its logical inputs and outputs arranged differently from all the other chips.

Figure 4-66. *Figures 4-66 through 4-74 show pinouts for some of the most widely used logic chips. Note that the inputs of the 7402 are reversed compared with the other chips.*

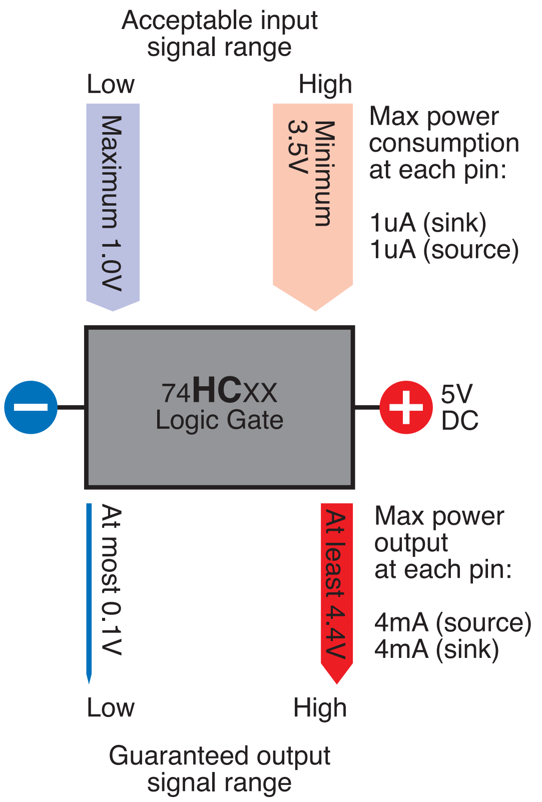
FUNDAMENTALS

Rules for connecting logic gates

Permitted:

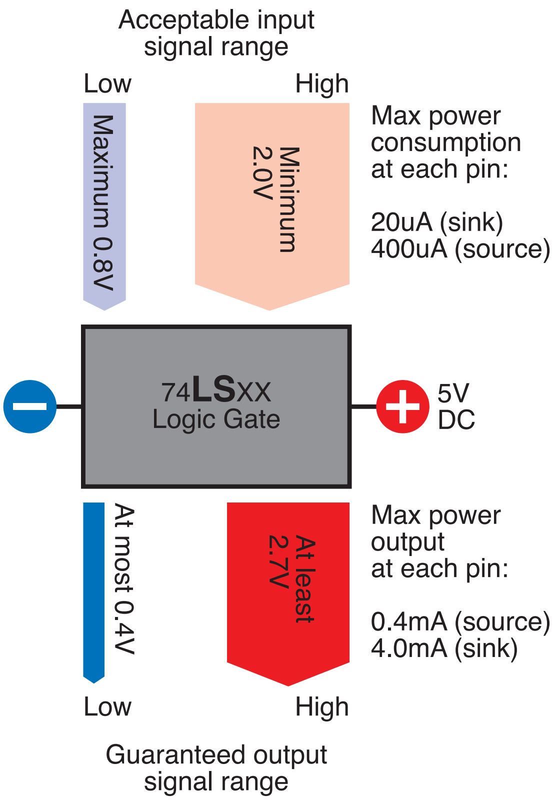
- You can connect the input of a gate directly to your regulated power supply, either positive side or negative side.
- You can connect the output from one gate directly to the input of another gate.
- The output from one gate can power the inputs of many other gates (this is known as "fanout"). The exact ratio depends on the chip, but you can always power at least ten inputs with one logic output. The output from a logic chip can drive the trigger (pin 3) of a 555 timer. The output from the timer can then deliver 100mA, easily enough for half-a-dozen LEDs or a small relay.
- Low input doesn't have to be zero. A 74HCxx logic gate will recognize any voltage up to 1 volt as "low."
- High input doesn't have to be 5 volts. A 74HCxx logic gate will recognize any voltage above 3.5 volts as "high."

See Figures 4-75 and 4-76 for a comparison of permitted voltages on the input and output side of 74HCxx and 74LSxx chips.



Acceptable input signal range
Low
High
Maximum 1.0V
Minimum 3.5V
Max power consumption at each pin:
1uA (sink)
1uA (source)
74HCxx Logic Gate
5V DC
At most 0.1V
At least 4.4V
Max power output at each pin:
4mA (source)
4mA (sink)
Low
High
Guaranteed output signal range

Figure 4-75. *Each family of logic chips, and each generation in each family, has different standards for input and output minimum and maximum voltages. This diagram shows the standards used by the HC generation of the CMOS family, which was chosen for most of the projects in this book. Note that the current required for input is minimal compared with the current available for output. The power supply to the chip makes up the difference.*



Acceptable input signal range
Low
High
Maximum 0.8V
Minimum 2.0V
Max power consumption at each pin:
20uA (sink)
400uA (source)
74LSxx Logic Gate
5V DC
At most 0.4V
At least 2.7V
Max power output at each pin:
0.4mA (source)
4.0mA (sink)
Low
High
Guaranteed output signal range

Figure 4-76. *Because the LS generation of the TTL family has such different tolerances for input voltages and different standards for output voltages, the LS generation of TTL chips should not be mixed in the same circuit as the HC generation of CMOS chips, unless pull-up resistors are used to bring the LS chips into conformance with standards expected by the HC chips. See Experiment 21 for a case study in using LS chips.*

FUNDAMENTALS

Rules for connecting logic gates (continued)

Not permitted:

- No floating-input pins! On CMOS chips such as the HC family, you must always connect all input pins with a known voltage, even if they supply a gate on the chip that you're not using. When you use a SPST switch to control an input, remember that in its "off" position, it leaves the input unconnected. Use a pull-up or pull-down resistor to prevent this situation. See Figure 4-77.
- Don't use an unregulated power supply, or more than 5 volts, to power 74HCxx or 74LSxx logic gates.
- Be careful when using the output from a logic gate to power even a low-current LED. Check how many milliamps are being drawn. Also be careful when "sharing" the output from a logic gate with the input of another gate, at the same time that it is driving an LED. The LED may pull down the output voltage, to a point where the other gate won't recognize it. Always check currents and voltages when modifying a circuit or designing a new one.
- Never apply a significant voltage or current to the output pin of a logic gate. In other words, don't force an input into an output.
- Never link the outputs from two or more logic gates. If they must share a common output wire, use diodes to protect them from each other. See Figure 4-78.

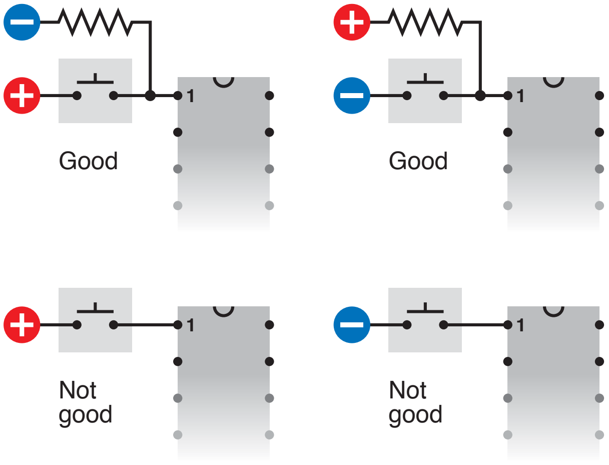


Figure 4-77. *Because a CMOS chip is so sensitive to input fluctuations, a logical input should never be left "floating," or unattached to a defined voltage source. This means that any single-throw switch or pushbutton should be used with a pull-up or pull-down resistor, so that when the contacts are open, the input is still defined.*

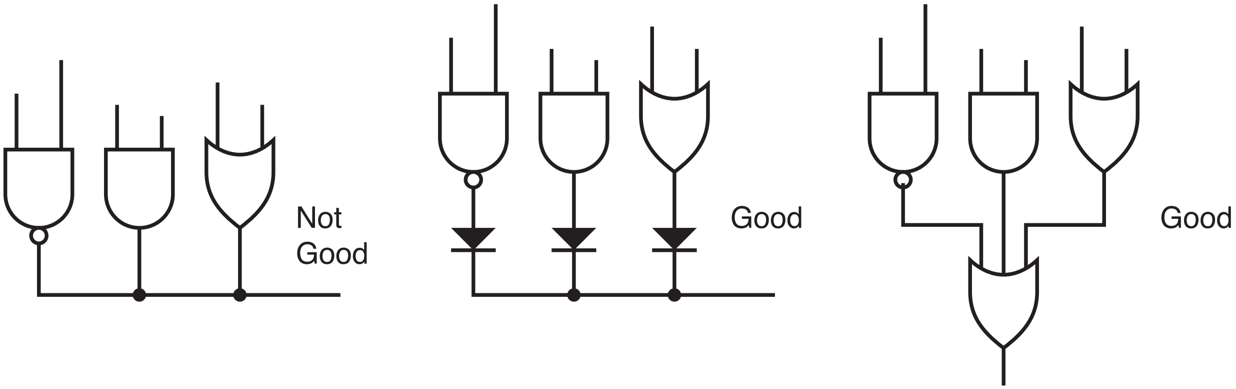

Figure 4-78. *The output from one logic gate must not be allowed to feed back into the output from another logic gate. Diodes can be used to isolate them, or they can be linked via another gate.*

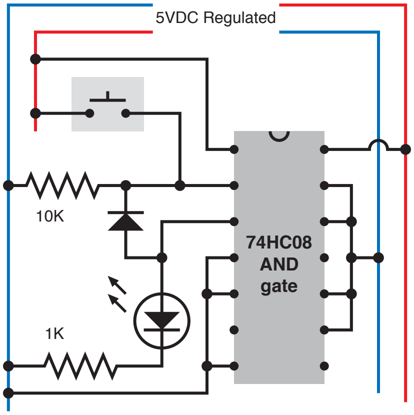

Figure 4-79. *Using a diode, the logical output from a gate can be allowed to feed back to one of its inputs, so that the gate latches after receiving a brief logical input pulse.*

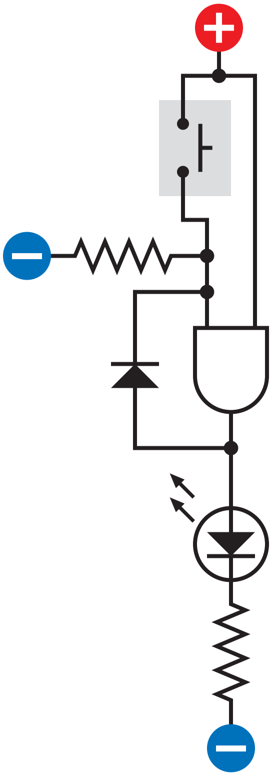

Figure 4-80. *The breadboard-format schematic in is simplified here to show more clearly the way in which a gate can latch itself after receiving an input pulse.*

In the 74HCxx logic family, each input of a logic gate consumes just a microamp, while the output can source 4 milliamps. This seems paradoxical: how can the chip give out more than it takes in? The answer is that it also consumes power from the power supply attached to pins 7 and 14. That's where the additional electricity comes from.

Because the logical output from a chip can be greater than the logical input, we can put the chip in a state where it keeps itself "switched on" in a way which is similar to the way the relay in the alarm project was wired to lock itself on. The simplest way to do this in a logic chip is by feeding some of the output back to one of the inputs.

Figure 4-79 shows an AND gate with one of its inputs wired to positive and its other input held low by a pull-down resistor, with a pushbutton that can make the input high. A signal diode connects the output of the chip back to the pushbutton-controlled input. Remember that the diode has a mark on it indicating the end which should be connected to the *negative* side of the power supply, which in this case will be the end of the 10K resistor.

The schematic in Figure 4-79 shows how the circuit should look in breadboard format. Figure 4-80 shows it in a simpler format.

> *From this point on, I won't bother to show the power regulator and the capacitors associated with it. Just remember to include them every time you see the power supply labeled as "5V DC Regulated."*

When you switch on the power, the LED is dark, as before. The AND gate needs a positive voltage on both of its logical inputs, to create a positive output, but it now has positive voltage only on one of its inputs, while the other input is pulled down by the 10K resistor. Now touch the pushbutton, and the LED comes on. Let go of the pushbutton, and the LED stays on, because the positive output from the AND gate circulates back through the diode and is high enough to overcome the negative voltage coming through the pull-down resistor.

The output from the AND gate is powering its own input, so the LED will stay on until we disconnect it. This arrangement is a simple kind of "latch," and can be very useful when we want an output that continues after the user presses and releases a button.

You can't just connect the output from the gate to one of its inputs using an ordinary piece of wire, because this would allow positive voltage from the tactile switch to flow around and interfere with the output signal. Remember, you must never apply voltage to the output pin of a logic gate. The diode prevents this from happening.

If you've grasped the basics of logic gates, you're ready now to continue to our first real project, which will use all the information that I've set out so far.

Experiment 20: A Powerful Combination

Suppose you want to prevent other people from using your computer. I can think of two ways to do this: using software, or using hardware. The software would be some kind of startup program that intercepts the normal boot sequence and requests a password. You could certainly do it that way, but I think it would be more fun (and more relevant to this book) to do it with hardware. What I'm imagining is a numeric keypad requiring the user to enter a secret combination before the computer can be switched on.

You will need:

- Numeric keypad. As specified in the shopping list at the beginning of this chapter, it must have a "common terminal" or "common output." The schematic in Figure 4-82 shows what I mean. Inside the keypad, one conductor (which I have colored red to distinguish it from the others) connects with one side of every pushbutton. This conductor is "common" to all of them. It emerges from the keypad on an edge connector or set of pins at the bottom, which I've colored yellow.

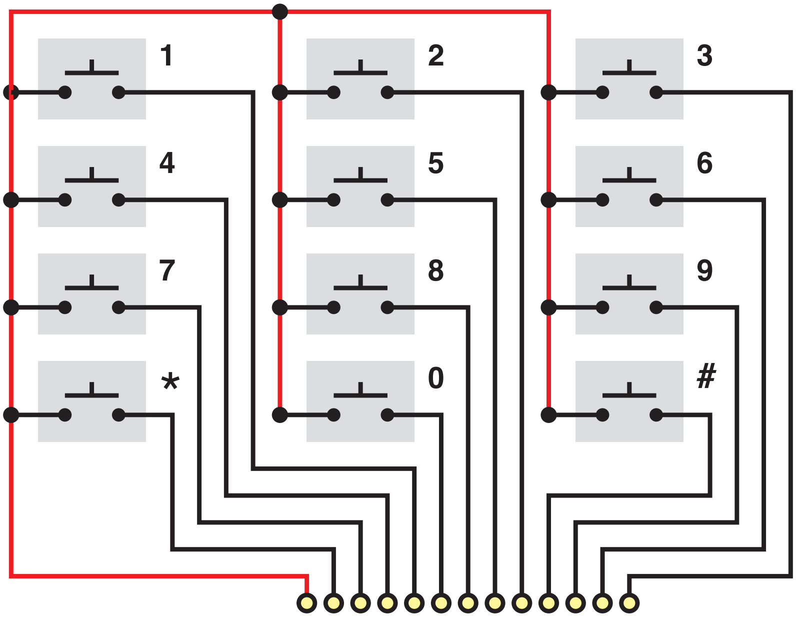

Figure 4-82. *A keypad of the type required for Experiment 20 incorporates a common terminal connected to one side of each of the 12 pushbuttons. The wire from the common terminal is shown red, here, to make it more easily identifiable.*

- Keypads that use "matrix encoding" won't work with the circuit that I'm going to describe. If the Velleman keypad, which I recommend, is unavailable, and you can't find another like it, you can use 12 separate SPST pushbuttons. Of course, that will cost a little more.
- 74HC08 logic chip containing four AND gates. Quantity: 1.
- 74HC04 logic chip containing six inverters. Quantity: 1.
- 555 timer chip. Quantity: 1.

The Warranty Issue

If you follow this project all the way to its conclusion, you'll open your desktop computer, cut a wire, and saw a hole in the cabinet. Without a doubt, this will void your warranty. If this makes you nervous, here are three options:

1. Breadboard the circuit for fun, and leave it at that.

2. Use the numeric keypad on some other device.

3. Use it on an old computer.

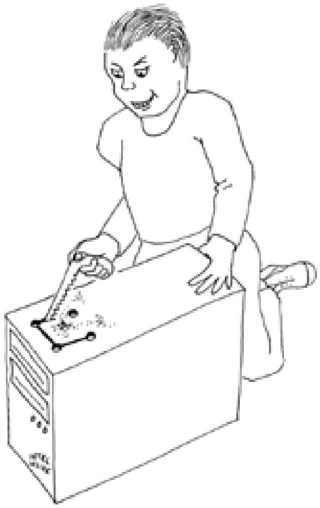

Figure 4-81. *Caution: This just might void your warranty.*

- Latching relay, 5 volt, DPST or DPDT, "2 form C" package, Panasonic DS2E-SL2-DC5V or similar. Must have two separate coils (one to latch, one to unlatch) with separate inputs. Quantity: 1.
- LEDs, 5mm generic, your choice of colors. Quantity: 3.
- Ribbon cable, with six conductors minimum, if you want to do a really neat job. You can use a cable of the type sold for hard drives, and split off the six conductors that you need, or shop around on eBay.
- Tools to open your computer, drill four holes, and make saw cuts between the holes, to create a rectangular opening for the keypad (if you want to take this project to its conclusion). Also, four small bolts to attach the keypad to the computer cabinet after you create the opening for it.

The Schematic

This time I'd like you to study the schematic before building anything. Let's start with the simplified version, shown in Figure 4-83.

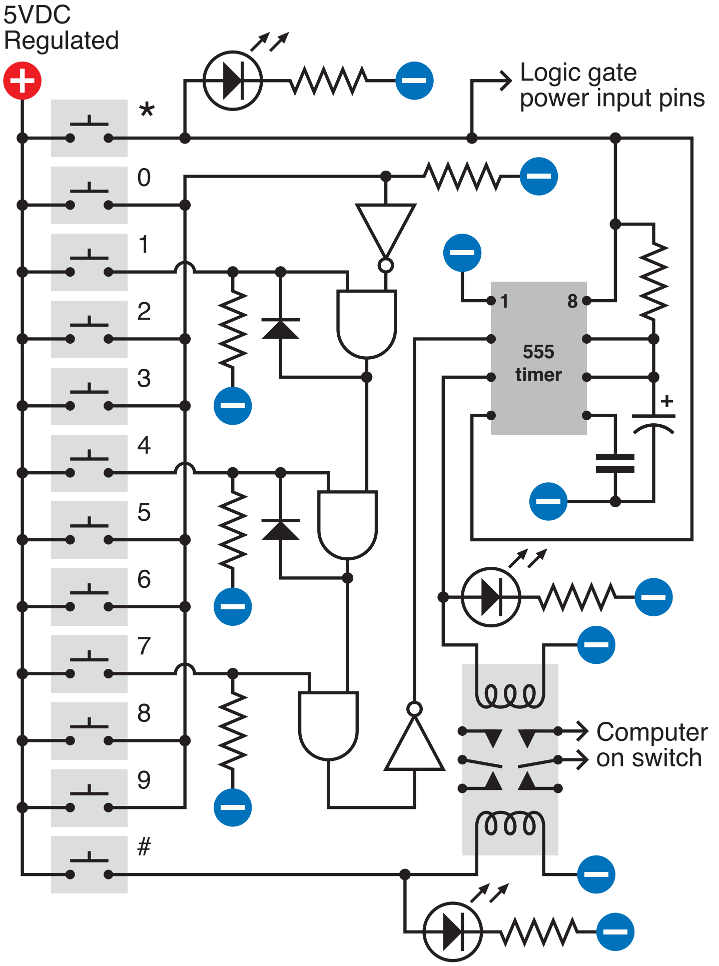

Figure 4-83. *A simplified schematic showing the basic structure of the combination lock circuit.*

I want this to be a battery-powered circuit, so that you don't have to run a separate power supply to it or (worse) try to tap into your computer's 5-volt bus. Battery power means that the circuit has to be "off" most of the time, to prevent the battery from running down. Because the keypad has two spare buttons (the asterisk and the pound sign), I'm going to use the asterisk as the "power on" button. When you press it, the LED at the top of the schematic lights up to confirm that everything's working, and the button sends power to the two logic chips and the 555 timer. You have to hold down the asterisk button while you punch in a three-digit code to unlock the computer.

Arbitrarily, I've chosen 1-4-7 as the three-digit code. Let's track what happens when you enter this sequence. (Naturally, if you build the circuit, you can wire it to choose any three digits you prefer.)

Pressing the 1 button sends positive power to one logical input of the first AND gate. The other logical input of this gate is also positive, because an inverter is supplying it, and the input of the inverter is being held negative by a pull-down resistor. When an inverter has a negative input, it gives a positive output, so pressing the 1 button activates the AND gate, and makes its output positive. The AND gate locks itself on, as its output cycles back to its switched input via a diode. So the gate output remains high even after you let go of the 1 button.

The output from the first AND gate also supplies one logical input of the second AND gate. When you press the 4 button, you send positive voltage to the other logical input of this AND gate, so its output goes high, and it locks itself on, just as the first gate did.

The second AND gate feeds the third AND gate, so when you press the 7 button, the third AND gate changes its output from low to high. This passes through an inverter, so the output from the inverter goes from high to low. This in turn goes to the trigger of a 555 timer wired in monostable mode.

When the trigger of a 555 timer goes from high to low, the timer emits a positive pulse through its output, pin 3. This runs down to the upper coil of the latching relay, and also flashes an LED to confirm that the code has been accepted and the relay has been activated.

Two of the contacts in the relay are wired into the power-up button of your computer. A little later in this description I'll explain why this should be safe with any modern computer.

Because we're using a latching relay, it flips into its "on" state and remains there, even when the power pulse from the timer ends. So now you can let go of the asterisk button to disconnect the battery power to your combination lock, and press the power-up button that switches on your computer.

At the end of your work session, you shut down your computer as usual, then press the pound button on your keypad, which flips the relay into its other position, reactivating the combination lock.

Incorrect Inputs

What happens if you enter the wrong code? If you press any button other than 1, 4, or 7, it sends positive voltage to the inverter near the top of the schematic. The positive voltage overwhelms the negative voltage being applied to the inverter through a pull-down resistor, and causes the inverter to output a negative voltage, which it applies to one of the logical inputs of the first AND gate. If the AND gate was locked on, the negative input will switch it off. If it was supplying the second AND gate, it'll switch that one off too.

Thus, any error when entering the first, second, or third digit of the secret code will reset the AND gates, forcing you to begin the sequence all over again.

What if you enter 1, 4, and 7 out of their correct sequence? The circuit won't respond. The third AND gate needs a high input supplied by the second AND gate, and the second AND gate needs a high input supplied by the first AND gate. So you have to activate the AND gates in the correct sequence.

Questions

Why did I use a 555 timer to deliver the pulse to the relay? Because the logical output from an AND gate cannot deliver sufficient power. I could have passed it through a transistor, but I liked the idea of a pulse of a fixed length to flip the relay and illuminate an LED for about 1 second, regardless of how briefly the user presses the 7 button.

Why do I need three LEDs? Because when you're punching buttons to unlock your computer, you need to know what's going on. The Power On LED reassures you that your battery isn't dead. The Relay Active LED tells you that the system is now unlocked, in case you are unable to hear the relay click. The System Relocked LED reassures you that you have secured your computer.

Because all the LEDs are driven either directly from the 5-volt supply or from the output of the 555 timer, they don't have to be low-current LEDs and can be used with 330Ω series resistors, so they'll be nice and bright.

How do you connect the keypad with the circuit? That's where your ribbon cable comes in. You carefully strip insulation from each of the conductors, and solder them to the contact strip or edge connector on your keypad. Push the conductors on the other end of the cable into your breadboard (when you're test-building the circuit) or solder them into perforated board (when you're building it permanently). Find a convenient spot inside your computer case where you can attach the perforated board, with double-sided adhesive or small bolts or whatever is convenient. Include a 9-volt battery carrier, and don't forget your power regulator to step the voltage down to 5 volts.

Breadboarding

No doubt you have realized by now that breadboards are very convenient as a quick way to push in some components and create connections, but the layout of their conductors forces you to put components in unintuitive configurations. Still, if you carefully compare the breadboard schematic in Figure 4-83 with the simplified schematic in Figure 4-84, you'll find that the connections are the same.

To help it make sense, I've shown the logic gates that exist inside the chips. I've also colored the power supply wires, as before, to reduce the risk of confusion. The positive side of the supply goes only to the common terminal on your keypad, and you have to press the asterisk key to send the power back down the ribbon cable, to supply the chips.

If you build the circuit and you can't understand why everything's dead, it's most likely because you forgot to hold down the asterisk button.

Note that the "wrong" numbers on the keypad are all shorted together. This will create some inconvenience if you want to change the combination in the future. I'll suggest a different option in the "enhancements" section that follows. For now, ideally, you should run a wire from every contact on your keypad, down to your circuit on its breadboard, and short the "wrong" keypad numbers together with jumper wires on the breadboard.

Also note that if you use a meter to test the inputs to the AND gates, and you touch your finger against the meter probe while doing so, this can be sufficient to trigger the sensitive CMOS inputs and give a false positive.

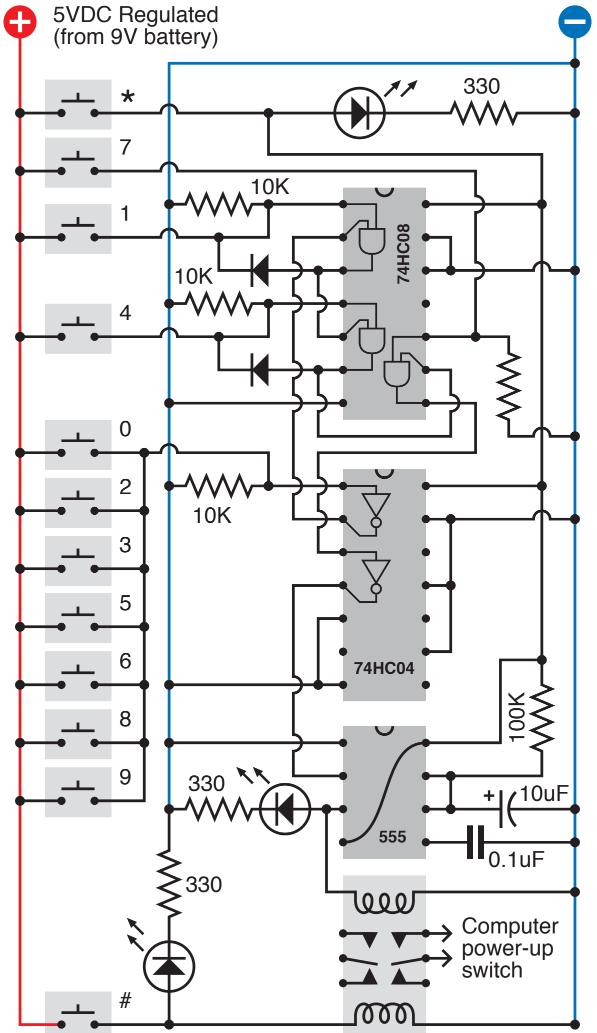

Figure 4-84. *The combination lock schematic redrawn to show how the components can be laid out on a breadboard.*

One Little Detail: The Computer Interface

Old computers used to have a big switch at the back, attached to the heavy metal box inside the computer, that transformed house current to regulated voltages that the computer needs. Most modern computers are not designed this way; you leave the computer plugged in, and you touch a little button on the box (if it's a Windows machine) or the keyboard (if it's a Mac), which sends a low-voltage pulse to the motherboard.

This is ideal from our point of view, because we don't have to mess with high voltages. Don't even think of opening that metal box with the fan mounted in it, containing the computer power supply. Just look for the wire (usually containing two conductors, on a Windows machine) that runs from the "power up" button to the motherboard.

To check that you found the right one, *make sure that your computer is unplugged*, ground yourself (because computers contain CMOS chips that are sensitive to static electricity) and very carefully snip just one of the two conductors in the wire. Now plug in your computer and try to use the "power up" button. If nothing happens, you've probably cut the right wire. Even if you cut the wrong wire, it still prevented your computer from booting, which is what you want, so you can use it anyway. Remember, we are not going to introduce any voltage to this wire. We're just going to use the relay as a switch to reconnect the conductor that you cut. You should have no problem if you maintain a cool and calm demeanor, and look for that single wire that starts everything. Check online for the maintenance manual for your computer if you're really concerned about making an error.

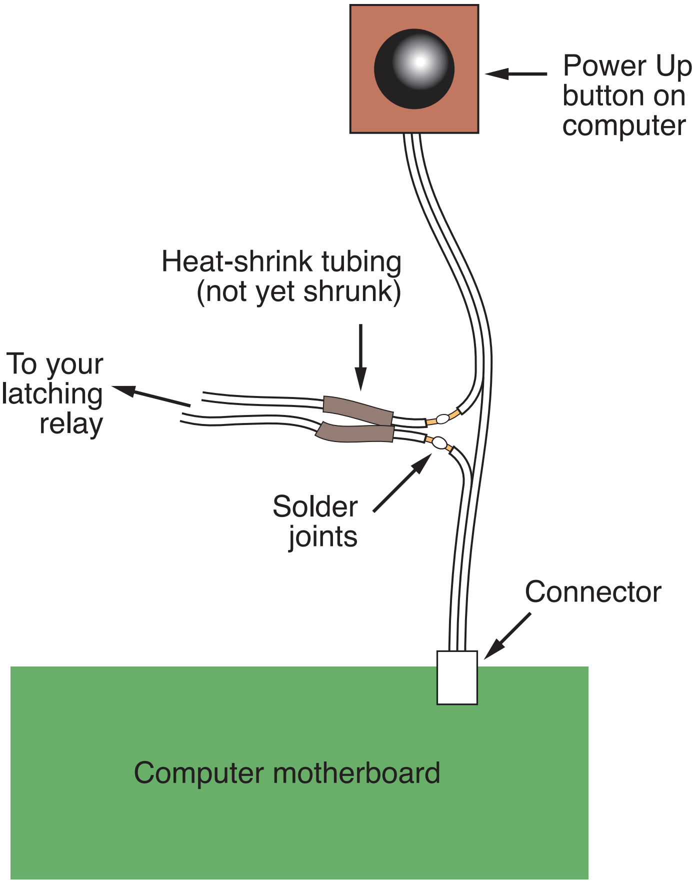
After you find the wire and cut just one of its conductors, unplug your computer again, and keep it unplugged during the next steps.

Find where the wire attaches to the motherboard. Usually there's a small unpluggable connector. First, mark it so that you know how to plug it back in the right way around, and then disconnect it while you follow the next couple of steps.

Strip insulation from the two ends of the wire that you cut, and solder an additional piece of two-conductor wire, as shown in Figure 4-85, with heat-shrink tube to protect the solder joints. (This is very important!)

Run your new piece of wire to the latching relay, making sure you attach it to the pair of contacts which close, inside the relay, when it is energized by the unlocking operation. You don't want to make the mistake of unlocking your computer when you think you're locking it, and vice versa.

Reconnect the connector that you disconnected from your motherboard, plug in your computer, and try to power it up. If nothing happens, this is probably good! Now enter the secret combination on your keypad (while holding down the asterisk button to provide battery power) and listen for the click as the relay latches. Now try the "power up" button again, and everything should work.



Power Up
button on
computer
Heat-shrink tubing
(not yet shrunk)
To your
latching
relay
Solder
joints
Connector
Computer motherboard

Figure 4-85. *The combination lock project can be interfaced with a typical desktop computer by cutting one conductor in the wire from the "power up" pushbutton, soldering an extension, and covering the joints with heat-shrink tube.*

Enhancements

At the end of any project, there's always more you can do.

To make this setup more secure, you could remove the usual screws that secure the case of the computer, and replace them with tamper-proof screws. Check any online source for "tamper-proof screws," such as *http://www.mcmaster.com*. Naturally, you will also need the special tool that fits the screws, so that you can install them (or remove them, if your security system malfunctions for any reason).

Another enhancement could be an additional 555 timer that is activated by the asterisk button, and delivers power to the other chips for, say, a limited period of 30 seconds, allowing you that much time to unlock the system. This would eliminate the need to hold down the asterisk button while you enter the unlocking code. A 555 timer can supply power to all the other chips, because they don't use very much. I omitted this feature for the sake of simplicity.

Yet another enhancement, if you are security-crazed, is to go for a four-button code. After all, the 74HC08 chip still has one unused AND gate. You could insert that into the chain of the existing AND gates and wire it to another keypad button of your choice.

Still another enhancement would be a way to change the code without unsoldering and resoldering wires. You can use the miniature sockets that I suggested in the heartbeat flasher project. These should enable you to swap around the ends of your wires from the keypad.

And for those who are absolutely, positively, totally paranoid, you could fix things so that entering a wrong code flips a second high-amperage relay which supplies a massive power overload, melting your CPU and sending a big pulse through a magnetic coil clamped to your hard drive, instantly turning the data to garbage (Figure 4-86). Really, if you want to protect information, messing up the hardware has major advantages compared with trying to erase data using software. It's faster, difficult to stop, and tends to be permanent. So, when the Record Industry Association of America comes to your home and asks to switch on your computer so that they can search for illegal file sharing, just accidentally give them an incorrect unlocking code, sit back, and wait for the pungent smell of melting insulation.

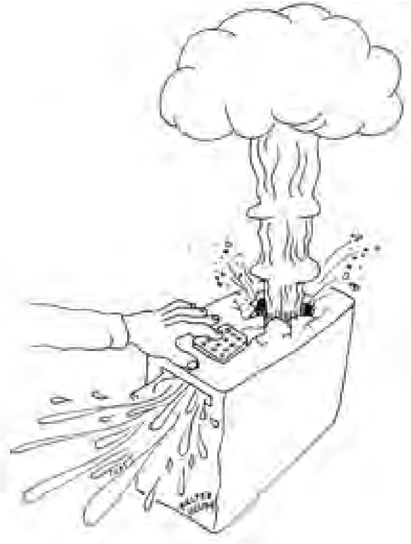


Figure 4-86. *For those who are absolutely, positively, totally paranoid: a meltdown/self-destruct system controlled by a secret key combination provides enhanced protection against data theft or intrusions by RIAA investigators asking annoying questions about file sharing.*

If you pursue this option, I *definitely* take no responsibility for the consequences.

On a more realistic level, no system is totally secure. The value of a hardware locking device is that if someone does defeat it (for instance, by figuring out how to unscrew your tamper-proof screws, or simply ripping your keypad out of the computer case with metal shears), at least you'll know that something happened—especially if you put little dabs of paint over the screws to reveal whether they've been messed with. By comparison, if you use password-protection software and someone defeats it, you may never know that your system has been compromised.

Experiment 21: Race to Place

The next project is going to get us deeper into the concept of feedback, where the output is piped back to affect the input—in this case, blocking it. It's a small project, but quite subtle, and the concepts will be useful to you in the future.

You will need:

- 74HC32 chip containing four OR gates. Quantity: 1.
- 555 timers. Quantity: 2.
- SPDT switch. Quantity: 1.
- SPST tactile switches. Quantity: 2.
- Various resistors.
- 5V supply using power regulator as before.

The Goal

On quiz shows such as *Jeopardy*, contestants race to answer each question. The first person who hits his answer button automatically locks out the other contestants, so that their buttons become inactive. How can we make a circuit that will do the same thing?

If you search online, you'll find several hobby sites where other people have suggested circuits to work this way, but they lack some features that I think are necessary. The approach I'm going to use here is both simpler and more elaborate. It's simpler because it has a very low chip count, but it's more elaborate in that it incorporates "quizmaster control" to make a more realistic game.

I'll suggest some initial ideas for a two-player version. After I develop that idea, I'll show how it could be expanded to four or even more players.

A Conceptual Experiment

I want to show how this kind of project grows from an idea to the finished version. By going through the steps of developing a circuit, I'm hoping I may inspire you to develop ideas of your own in the future, which is much more valuable than just replicating someone else's work. So join me in a conceptual experiment, thinking our way from a problem to a solution.

First consider the basic concept: two people have two buttons, and whoever goes first locks out the other person. I always find it helps me to visualize this kind of thing if I draw a sketch, so that's where I'll begin. In Figure 4-87, the signal from each button passes through a component that I'll call a "button blocker," activated by the other person's button. I'm not exactly sure what the button blocker will be or how it will work, yet.

Now that I'm looking at it, I see a problem here. If I want to expand this to three players, it will get complicated, because each player must activate the "button blockers" of *two* opponents. Figure 4-88 shows this. And if I have four players, it's going to get even more complicated.

Anytime I see this kind of complexity, I think there has to be a better way.

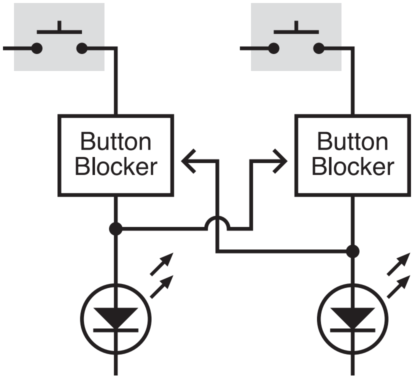

Figure 4-87. *The basic concept of the quiz project is that the output from one button should feed back to intercept the output of another button. At this point, the way in which the "button blocker" circuit works has not been figured out.*

Also, there's another problem. After a player lets his finger off the button, the other players' buttons will be unblocked again. I need a latch to hold the signal from the first player's button and continue to block the other players.

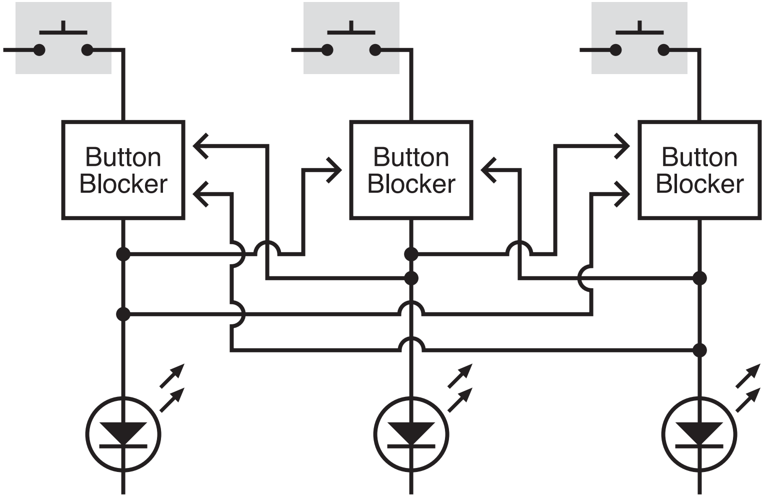

Figure 4-88. *The quiz concept becomes more complicated when an additional pushbutton is added. Now each button must block two other buttons. If a fourth button is added, the circuit will become unmanageably complex. There has to be a better way.*

This now sounds even more complicated. But wait a minute, if I have a latch which allows the winning player to take his finger off his button, I don't care if any of the buttons are being pressed anymore—including the button of the winning player. As soon as his signal is latched, *all* the buttons can be blocked. This makes things much simpler. I can summarize it as a sequence of events:

1. First player presses his button.
2. The signal is latched.
3. The latched signal feeds back and blocks all the buttons.

The new sketch in Figure 4-89 shows this. Now the configuration is modular, and can be expanded to almost any number of players, just by adding more modules.

There's something important missing, though: a reset switch, to put the system back to its starting mode after the players have had time to press their buttons and see who won. Also, I need a way to prevent players from pressing their buttons too soon, before the quizmaster has finished asking the question. Maybe I can combine this function in just one switch, which will be under the quizmaster's control. In its Reset position, the switch can reset the system and remove power to the buttons. In its Play position, the switch stops holding the system in reset mode, and provides power to the buttons. Figure 4-90 shows this. I've gone back to showing just two players, to minimize the clutter of lines and boxes, but the concept is still easily expandable.

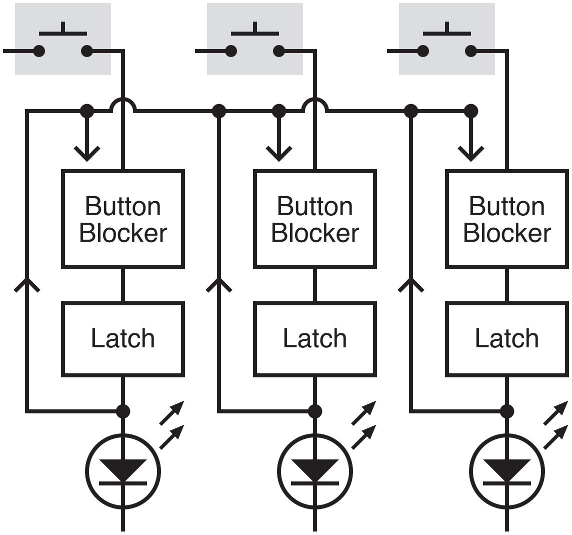

Figure 4-89. *If a latch is added below each button, it can retain one input and then block all inputs from all buttons. This simplifies the concept.*

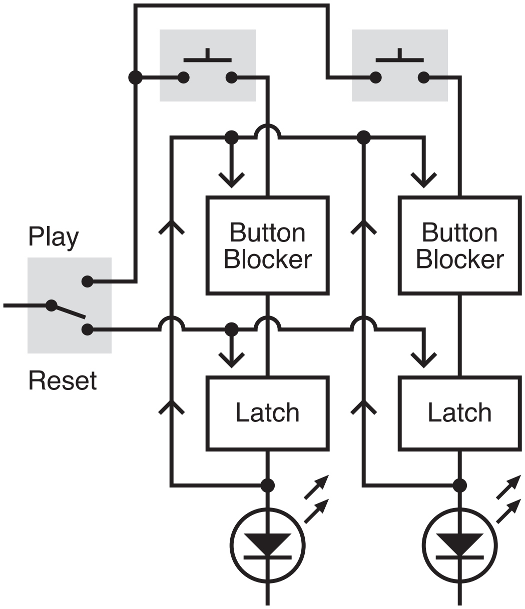

Figure 4-90. *A quizmaster switch will be needed to activate the buttons initially and then reset the circuit after a winning input has been recorded.*

Now I have to deal with a logic problem in the diagram. The way I've drawn it, after the output from the lefthand latch goes up to the "button blockers," it can also run down the wire to the other half of the circuit (against the direction to the arrows), because everything is joined together. In other words, if the lefthand LED lights up, the righthand LED will light up, too. How can I stop this from happening?

Well, I could put diodes in the "up" wires to block current from running down them. But I have a more elegant idea: I'll add an OR gate, because the inputs to an OR gate are separated from each other electrically. Figure 4-91 shows this.

Usually an OR gate has only two logical inputs. Will this prevent me from adding more players? No, because you can actually buy an OR that has eight inputs. If any one of them is high, the output is high. For fewer than eight players, I can short the unused inputs to ground, and ignore them.

Looking again at Figure 4-91, I'm getting a clearer idea of what the thing I've called a "button blocker" should actually be. I think it should be another logic gate. It should say, "If there's only one input, from a button, I'll let it through. But if there is a second input from the OR gate, I won't let it through."

That sounds like a NAND gate, but before I start choosing chips, I have to decide what the latch will be. I can buy an off-the-shelf flip-flop, which flips "on" if it gets one signal and "off" if it gets another, but the trouble is, chips containing flip-flops tend to have more features than I need for a simple circuit like this. Therefore I'm going to use 555 timers again, in flip-flop mode. They require very few connections, work very simply, and can deliver a good amount of current. The only problem with them is that they require a negative input at the trigger pin to create a positive output. But I think I can work with that.

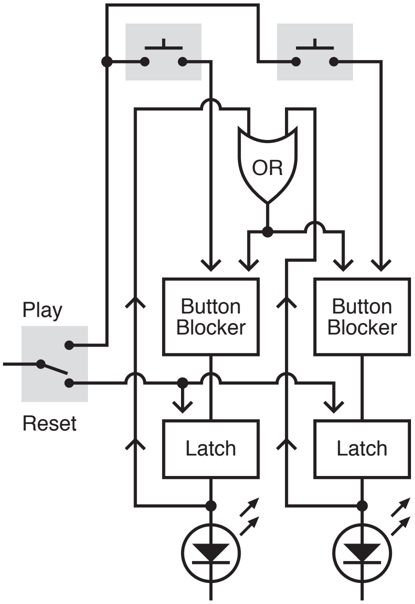

Figure 4-91. *To prevent the output from one latch feeding back around the circuit to the output from another latch, the outputs can be combined in an OR gate.*

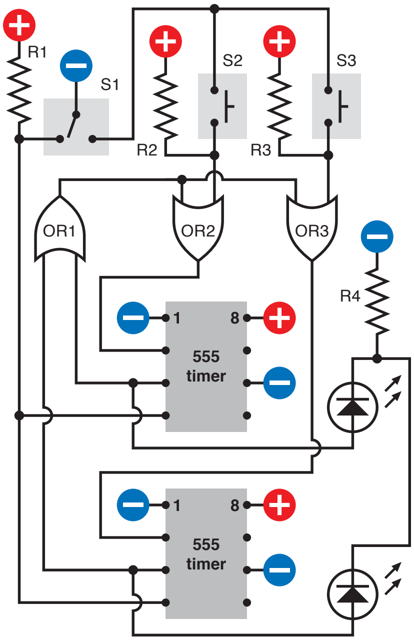

Figure 4-92. *Now that the basic concept of the quiz circuit has been roughed out, specific components can be inserted, with compatible inputs and outputs.*

So now, finally, here's a simplified schematic, in Figure 4-92. I like to show the pins of the 555 timers in their correct positions, so I had to move the components around a little to minimize wire crossovers, but you can see that logically, it's the same basic idea.

Before you try to build it, just run through the theory of it, because that's the final step, to make sure there are no mistakes. The important thing to bear in mind is that because the 555 needs a negative input on its trigger pin to create its output, when any of the players presses a button, the button has to create a negative "flow" through the circuit. This is a bit counterintuitive, so I'm including a three-step visualization in Figure 4-93, showing how it will work.

In Step 1, the quizmaster has asked a question and flipped his switch to the right, to supply (negative) power to the players' buttons. So long as no one presses a button, the pull-up resistors supply positive voltage to OR2 and OR3. An OR gate has a positive output if it has any positive input, so OR2 and OR3 keep the trigger inputs of the 555 timers positive. Their outputs remain low, and nothing is happening yet.

In Step 2, the lefthand player has pressed his button. Now OR2 has two negative inputs, so its output has gone low. But IC1 hasn't reacted yet.

In Step 3, just a microsecond later, IC1 has sensed the low voltage on its trigger, so its output from pin 3 has gone high, lighting the LED. Remember, this 555 timer is in flip-flop mode, so it locks itself into this state immediately. Meanwhile its high output also feeds back to OR1. Because OR1 is an OR gate, just one high input is enough to make a high output, so it feeds this back to OR2 and OR3. And now that they have high inputs, their outputs also go high, and will stay high, regardless of any future button-presses.

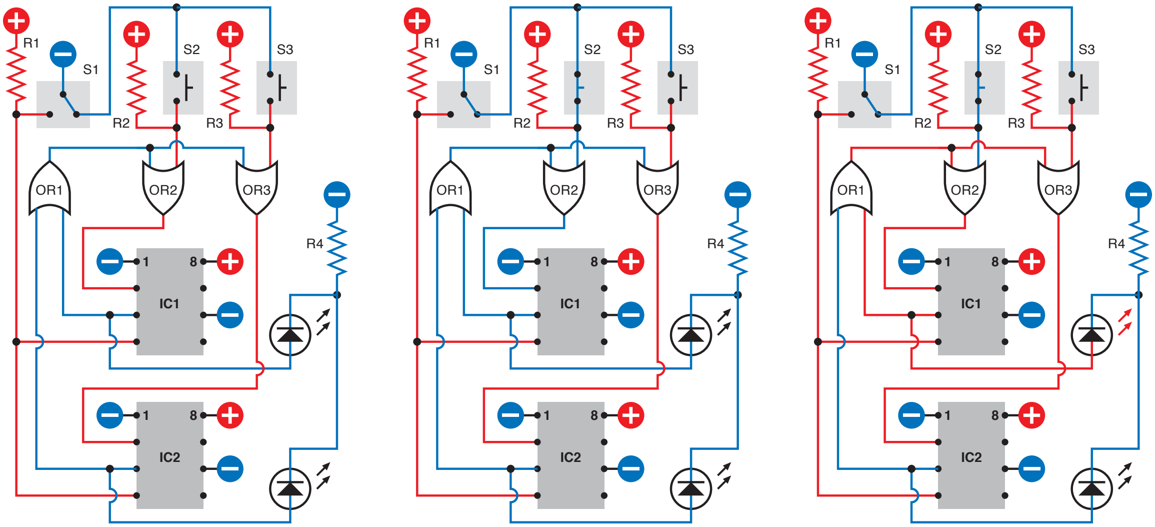

Figure 4-93. *These three schematics show the prevalence of higher and lower voltages (red and blue lines) through the quiz circuit when a pushbutton is pressed.*

Because OR2 and OR3 now have high inputs and outputs, IC1 and IC2 cannot be triggered. But IC1 is still locked into its "on" state, keeping the LED illuminated.

The only way to change IC1 is if the quizmaster flips his switch back to the left. That applies negative power to the reset pins of both the timers. Consequently their outputs go low, the LED goes out, and the circuit goes back into the same state as where it started. Having reset it, the quizmaster can ask another question, but the players' buttons are not activated until the quizmaster flips the switch back to the right again.

There's only one situation that I haven't addressed: what if both players press their buttons absolutely simultaneously? In the world of digital electronics, this is highly unlikely. Even a difference of a microsecond should be enough time for the circuit to react and block the second button. But if somehow both buttons are pressed at the same instant, both of the timers should react, and both of the LEDs will light up, showing that there has been a tie.

In case you feel a little uncertain about the way in which a two-player circuit can be upgraded to handle extra players, I've included a simplified three-player schematic in Figure 4-94.

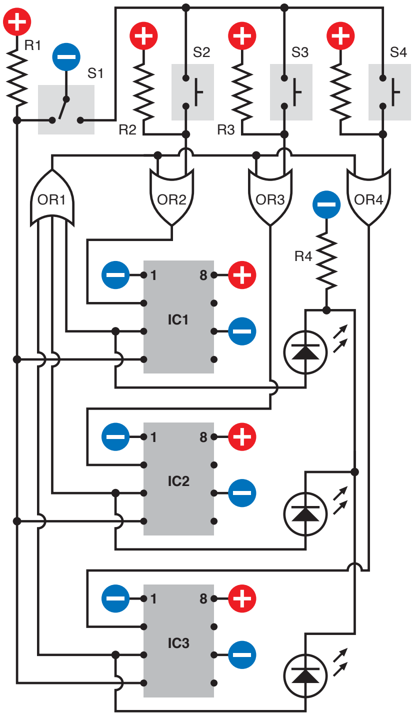

Figure 4-94. *The two-player schematic in can be easily upgraded to a three-player version, as shown here, provided the first OR gate can handle three inputs.*

Breadboarding It

Now it's time to create a schematic that's as close to the breadboard layout as possible, so that you can build this thing easily. The schematic is shown in Figure 4-95 and the actual components on a breadboard are in Figure 4-96. Because the only logic gates that I've used are OR gates, and there are only three of them, I just need one logic chip: the 74HC32, which contains four 2-input OR gates. (I've grounded the inputs to the fourth). The two OR gates on the left side of the chip have the same functions as OR2 and OR3 in my simplified schematic, and the OR gate at the bottom-right side of the chip works as OR1, receiving input from pin 3 of each 555 timer. If you have all the components, you should be able to put this together and test it quite quickly.

You may notice that I've made one modification of the previous schematic. A 0.01 µF capacitor has been added between pin 2 of each 555 timer (the Input) and negative ground. Why? Because when I tested the circuit without the capacitors, sometimes I found that one or both of the 555 timers would be triggered simply by flipping S1, the quizmaster switch, without anyone pressing a button.

At first this puzzled me. How were the timers getting triggered, without anyone doing anything? Maybe they were responding to "bounce" in the quizmaster switch. Sure enough, the small capacitors solved the problem. They may also slow the response of the 555 timers fractionally, but not enough to interfere with slow human reflexes.

As for the buttons, it doesn't matter if they "bounce," because each timer locks itself on at the very first impulse and ignores any hesitations that follow.

You can experiment building the circuit, disconnecting the 0.01 µF capacitors, and flipping S1 to and fro a dozen times. If you have a high-quality switch, you may not experience any problem. If you have a lower-quality switch, you may see a number of "false positives." I'm going to explain more about "bounce," and how to get rid of it, in the next experiment.

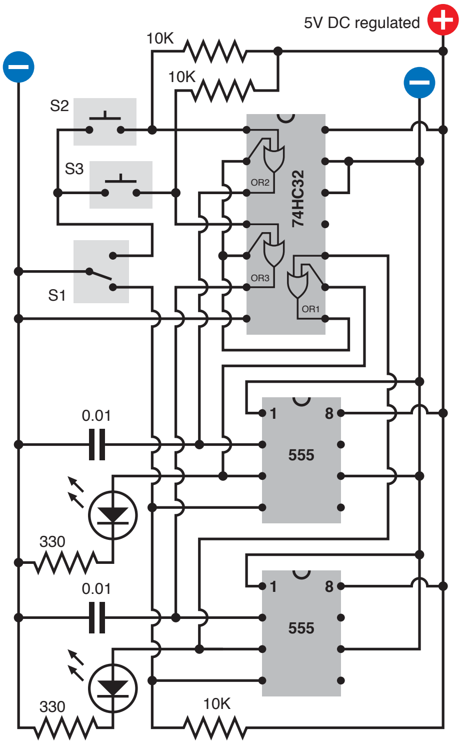

Figure 4-95. *Applying the simplified schematic to a breadboard inevitably entails a wiring layout that is less intuitively obvious and appears more complex. The connections are the same, though.*

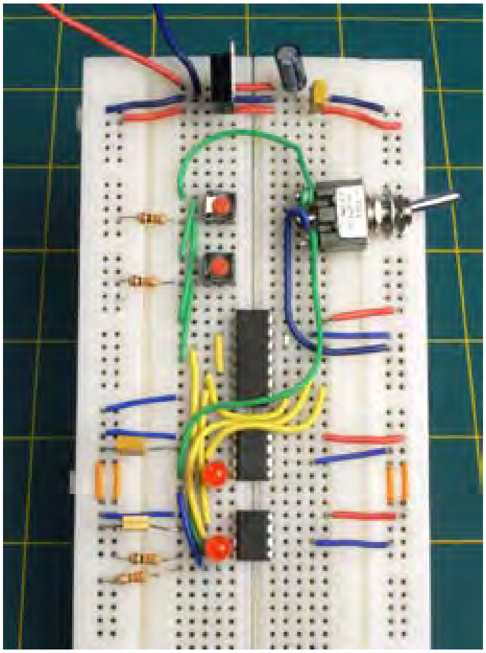

Figure 4-96. *The quiz schematic applied to a breadboard, to test the concept prior to full-scale implementation.*

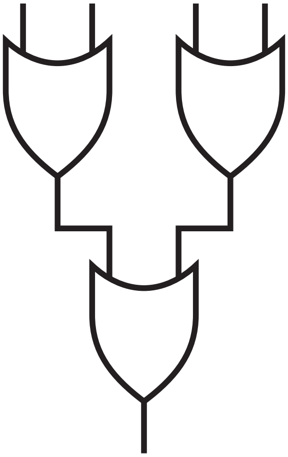

Figure 4-97. *Although a four-input OR gate is not manufactured, its functionality can be achieved easily by linking three 2-input OR gates together.*

Enhancements

After you breadboard the circuit, if you proceed to build a permanent version, I suggest that you expand it so that at least four players can participate. This will require an OR gate capable of receiving four inputs. The 74HC4078 is the obvious choice, as it allows up to eight. Just connect any unused inputs to negative ground.

Alternatively, if you already have a couple of 74HC32 chips and you don't want to bother ordering a 74HC4078, you can gang together three of the gates inside a single 74HC32 so that they function like a four-input OR. Look at the simple logic diagram in Figure 4-97 showing three ORs, and remember that the output from each OR will go high if at least one input is high.

And while you're thinking about this, see if you can figure out the inputs and output of three ANDs in the same configuration.

For a four-player game, you'll also need two additional 555 timers, of course, and two more LEDs, and two more pushbuttons.

As for creating a schematic for the four-player game—I'm going to leave that to you. Begin by sketching a simplified version, just showing the logic symbols. Then convert that to a breadboard layout. And here's a suggestion: pencil, paper, and an eraser can still be quicker, initially, than circuit-design software or graphic-design software, in my opinion.

Experiment 22: Flipping and Bouncing

I mentioned in the previous experiment that "bounce" from the buttons in the circuit wouldn't be a problem, because the buttons were activating 555 timers that were wired in bistable, flip-flop mode. As soon as the timer receives the very first pulse, it flips into its new state and flops there, ignoring any additional noise in the circuit. So can we debounce a switch or a button using a flip-flop? And as some 74HCxx chips are available containing flip-flops, can we use them?

The answers are yes, and yes, although it's not quite as simple as it sounds.

You will need:

- 74HC02 logic chip containing 4 NOR gates. 74HC00 logic chip containing 4 NAND gates. Quantity: 1 of each.
- SPDT switch. Quantity: 1.
- LEDs, low-current. Quantity: 2.
- 10K resistors and 1K resistors. Quantity: 2 of each.

Assemble the components on your breadboard, following the schematic shown in Figure 4-98. When you apply power (through your regulated 5-volt supply), one of the LEDs should be lit.

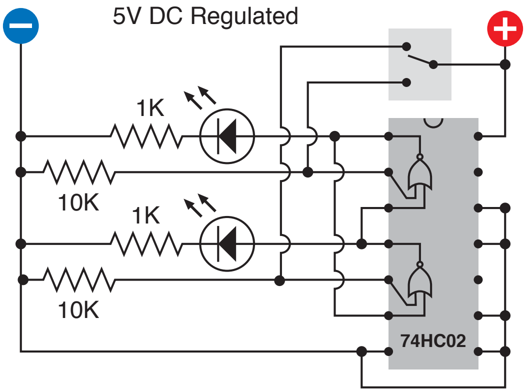

Figure 4-98. *A simple circuit to test the behavior of two NOR gates wired as a simple flip-flop that retains its state after an input pulse ceases.*

Now I want you to do something odd. Please disconnect the SPDT switch by taking hold of the wire that connects the positive power supply to the pole of the switch, and pulling the end of the wire out of the breadboard. When you do this, you may be surprised to find that the LED remains lit.

Push the wire back into the breadboard, flip the switch, and the first LED should go out, while the other LED should become lit. Once again, pull out the wire, and once again, the LED should remain lit.

Here's the take-home message:

- A flip-flop requires only an initial pulse.
- After that, it ignores its input.

How It Works

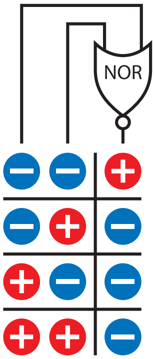
Two NOR gates or two NAND gates can function as a flip-flop:

- Use NOR gates when you have a positive input from a double-throw switch.
- Use NAND gates when you have a negative input from a double-throw switch.

Either way, you have to use a double-throw switch.

I've mentioned the double-throw switch three times (actually, four times if you count this sentence!) because for some strange reason, most introductory books fail to emphasize this point. When I first started learning electronics, I went crazy trying to understand how two NORs or two NANDs could debounce a simple SPST pushbutton—until finally I realized that they can't. The reason is that when you power up the circuit, the NOR gates (or NAND gates) need to be told in which state they should begin. They need an initial orientation, which comes from the switch being in one state or the other. So it has to be a double-throw switch. (Now I've mentioned it five times.)

I'm using another simplified multiple-step schematic, Figure 4-99, to show the changes that occur as the switch flips to and fro with two NOR gates. To refresh your memory, I've also included a truth table showing the logical outputs from NOR gates for each combination of inputs.



−	−	+
−	+	−
+	−	−
+	+	−

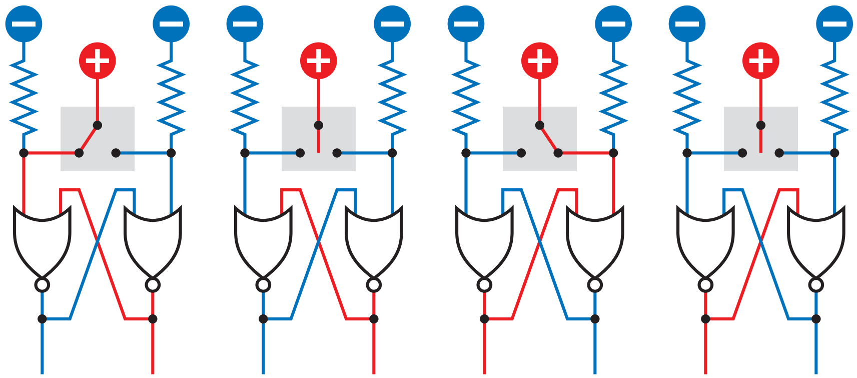


Figure 4-99. *Using two NOR gates in conjunction with a positive input through a SPDT switch, this sequence of four diagrams shows how a flip-flop circuit responds.*

Suppose that the switch is turned to the left. It sends positive current to the lefthand side of the circuit, overwhelming the negative supply from the pull-down resistor, so we can be sure that the NOR gate on the left has one positive logical input. Because any positive logical input will make the NOR give a negative output (as shown in the truth table), the negative output crosses over to the righthand NOR, so that it now has two negative inputs, which make it give a positive output. This crosses back to the lefthand NOR gate. So, in this configuration everything is stable.

Now comes the clever part. Suppose that you move the switch so that it doesn't touch either of its contacts. (Or suppose that the switch contacts are bouncing, and failing to make a good contact. Or suppose you disconnect the switch entirely.) Without a positive supply from the switch, the lefthand input of the left NOR gate goes from positive to negative, as a result of the pull-down resistor. But the righthand input of this gate is still positive, and one positive is all it takes to make the NOR maintain its negative output, so nothing changes. In other words, the circuit has "flopped" in this state.

Now if the switch turns fully to the right and supplies positive power to the righthand pin of the right NOR gate, quick as a flash, that NOR recognizes that it now has a positive logical input, so it changes its logical output to negative. That goes across to the other NOR gate, which now has two negative inputs, so its output goes positive, and runs back to the right NOR.

In this way, the output states of the two NOR gates change places. They flip, and then flop there, even if the switch breaks contact or is disconnected again. The second set of drawings in Figure 4-100 shows exactly the same logic, using a negatively powered switch and two NAND gates. You can use your 74HC00 chip, specified in the parts list for this experiment, to test this yourself.

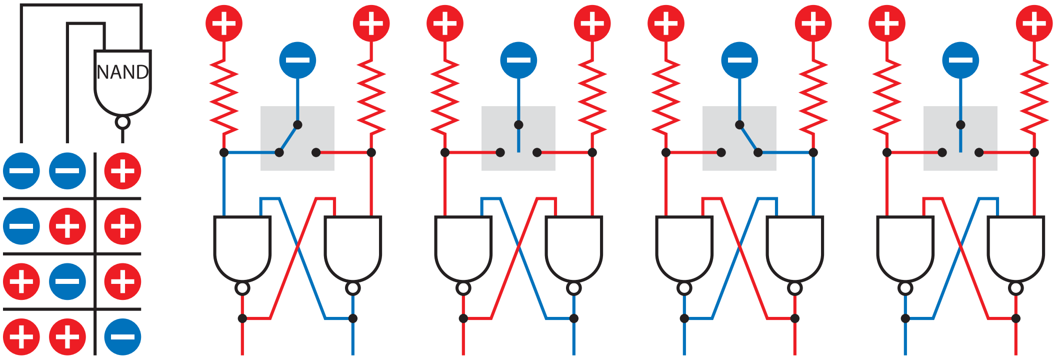

Figure 4-100. *The schematic from Figure 4-99 can be rewired with NAND gates and a negative switched input.*

Both of these configurations are examples of a jam-type flip-flop, so called because the switch forces it to respond immediately, and jams it into that state. You can use this circuit anytime you need to debounce a switch (as long as it's a double-throw switch).

A more sophisticated version is a clocked flip-flop, which requires you to set the state of each input first and then supply a clock pulse to make the flip-flop respond. The pulse has to be clean and precise, which means that if you supply it from a switch, the switch must be debounced—probably by using another jam-type flip-flop! Considerations of this type have made me reluctant to use clocked flip-flops in this book. They add a layer of complexity, which I prefer to avoid in an introductory text.

What if you want to debounce a single-throw button or switch? Well, you have a problem! One solution is to buy a special-purpose chip such as the 4490 "bounce eliminator," which contains digital delay circuitry. A specific part number is the MC14490PG from On Semiconductor. This contains six circuits for six separate inputs, each with an internal pull-up resistor. It's relatively expensive, however—more than 10 times the price of a 74HC02 containing NOR gates. Really, it may be simpler to use double-throw switches that are easily debounced as described previously.

Experiment 23: Nice Dice

This is the one experiment where I want you to use the 74LSxx generation of the TTL logic family, instead of the 74HCxx family of CMOS. Two reasons: first, I need to use the 7492 counter, which is unavailable in the HC family. And second, you should know the basic facts about the LS series of TTL chips, as they still crop up in circuits that you'll find in electronics books and online.

In addition, you'll learn about "open collector" TTL chips such as the 74LS06 inverter, which can be a convenient substitute for transistors when you want to deliver as much as 40mA of current.

The idea of this circuit is simple enough: run a 555 timer sending very fast pulses to a counter that counts in sixes, driving LEDs that are placed to imitate the spots on a die. (Note that the word "die" is the singular of "dice.") The counter runs so fast, the die-spots become a blur. When the user presses a button, the counter stops arbitrarily, displaying an unpredictable spot pattern.

Dice simulations have been around for many, many years, and you can even buy kits online. But this one will do something more: it will also demonstrate the principles of binary code.

So, if you're ready for the triple threat of TTL chips, open collectors, and binary, let's begin.

You will need:

- 74LS92 counter such as SN74LS92N by Texas Instruments. Quantity: 1 if you want to create one die, 2 to make two dice.
- 74LS27 three-input NOR gate such as SN74LS27N by Texas Instruments. Quantity: 1.
- 555 timers. Quantity: 1 if you want to make one die, 2 to make two dice.
- Signal diodes, 1N4148 or similar. Quantity: 4, or 8 to make two dice.

Seeing Binary

The counter that we dealt with before was unusual, in that its outputs were designed to drive seven-segment numerals. A more common type has outputs that count in binary code.

The 74LS92 pinouts are shown in Figure 4-101. Plug the chip into your breadboard and make connections as shown in Figure 4-102. Initially, the 555 timer will drive the counter in slow-motion, at around 1 step per second. Figure 4-103 shows the actual components on a breadboard.

Note that the counter has unusual power inputs, on pins 5 and 10 instead of at the corners. Also four of its pins are completely unused, and do not connect with anything inside the chip. Therefore, you don't need to attach any wire to them on the outside.

Figure 4-103. *The breadboard version of the schematic in Figure 4-102 to display the outputs from a 74LS92 counter.*

Now we come to the first new and difficult fact about the 74LSxx generation of TTL chips that makes them less desirable, for our purposes, than the 74HCxx generation of CMOS chips that I have recommended in previous projects. The modern and civilized HC chips will source 4mA or sink 4mA at each logical output, but the older LS generation is fussier. It will sink around 8mA into each output pin from a positive source, but when its output is high, it hardly gives you anything at all. This is a very basic principle:

- Outputs from TTL logic chips are designed to sink current.
- They are not designed to source significant current.

In fact, the 74LS92 is rated to deliver less than half a milliamp. This is quite acceptable when you're just connecting it with another logic chip, but if you want to drive an external device, it doesn't provide much to work with.

The proper solution is to say to the chip, "All right, we'll do it your way," and set things up with a positive source that flows through a load resistor to the LED that you want to use, and from there into the output from the chip. This is the "better" option shown in Figure 4-104.

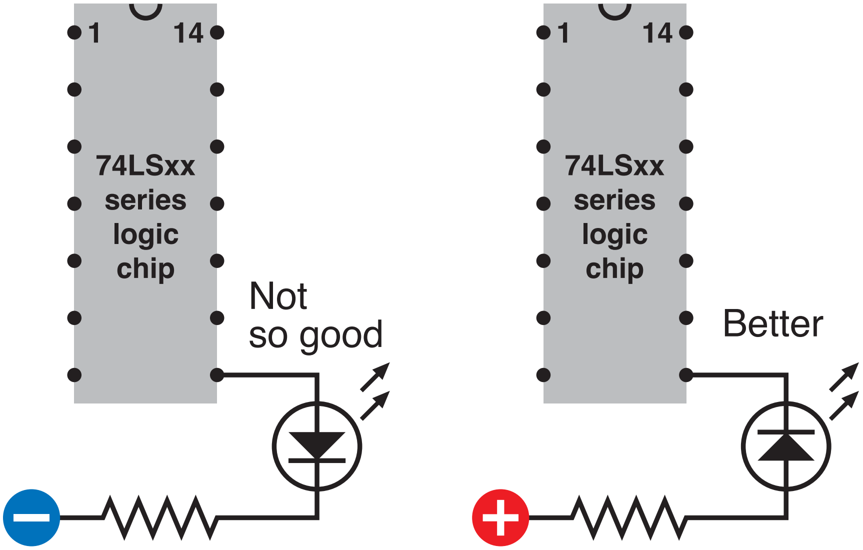

Figure 4-104. *Most TTL chips, including those in the LS generation, are unable to source much current from their logical output pins (left) and should usually be wired to sink current from a positive source (right).*

The only problem is that now the LED lights up when the counter's output is low. But the counter is designed to display its output in high pulses. So your LED is now off when it should be on, and on when it should be off.

You can fix this by passing the signal through an inverter, but already I'm getting impatient with this inconvenience. My way around the problem, at least for demo purposes, is to use the "Not so good" option in Figure 4-104 and make it work by connecting a very-low-current LED with a large 4K7 load resistor. This will enable us to "see" the output from the counter without asking it to give more than its rated limit, and if you want to create a more visibly powerful display for a finished version of the dice circuit, I'll deal with that later. According to my meter, the 4K7 resistor holds the current between 0.3mA and 0.4mA, which is the counter's rated maximum.

Set up your initial version of the circuit as shown in Figures 4-102 and 4-103. Be careful when you wire the positive and negative power supply to the counter chip, with its nonstandard pin assignments.

The 555 will run in astable mode, at about 1 pulse per second. This becomes the clock signal for the counter. The first three binary outputs from the counter then drive the three LEDs.

The counter advances when the input signal goes from *high* to *low*. So when the LED beside the 555 timer goes out, that's when the counter advances.

If you stare at the pattern generated by the outputs for long enough, you may be able to see the logic to it, bearing in mind that its zero state is when they are all off, and it counts up through five more steps before it repeats. The diagram in Figure 4-105 shows this sequence. If you want to know why the pattern works this way, check the following section, "Theory: Binary arithmetic."

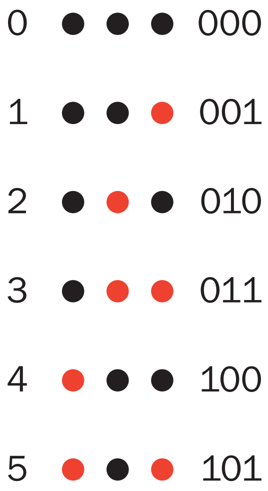

Figure 4-105. *The three output pins of the 74LS92 counter have high states shown by the red circles as the counter steps from 000 to 101 in binary notation.*

THEORY

Binary arithmetic

The rule for binary counting is just a variation of the rule that we normally use for everyday counting, probably without thinking much about it. In a 10-based system, we count from 0 to 9, then carry 1 over to the next position on the left, and go from 0 to 9 again in the right-most position. We repeat this procedure until we get to 99, then carry a 1 over to a new position to make 100, and continue counting.

In binary we do the same thing, except that we restrict ourselves to digits 0 and 1 only. So begin with 0 in the rightmost position, and count up to 1. As 1 is our limit, to continue counting we carry 1 over to the next place on the left, and start again from 0 in the right-most position. Count up to 1, then add 1 to the next place on the left—but, it already has a 1 in it, so it can't count any higher. So, carry 1 from there one space further, to the next place beside that—and so on.

If a glowing LED represents a 1, and a dark LED represents a 0, the diagram in Figure 4-105 shows how the 74LS92 counts up from 0 to (decimal) 6 or (binary) 101 in its inimitable fashion. I've also included a diagram in Figure 4-106 showing how a counter with four binary outputs would display decimal numbers from 0 through 15, again using the LEDs to represent 1s and 0s.

Here's a question for you: how many LEDs would you need to represent the decimal number 1024 in binary? And how many for 1023?

Obviously binary code is ideally suited to a machine full of logic components that either have a high or a low state. So it is that all digital computers use binary arithmetic (which they convert to decimal, just to please us).

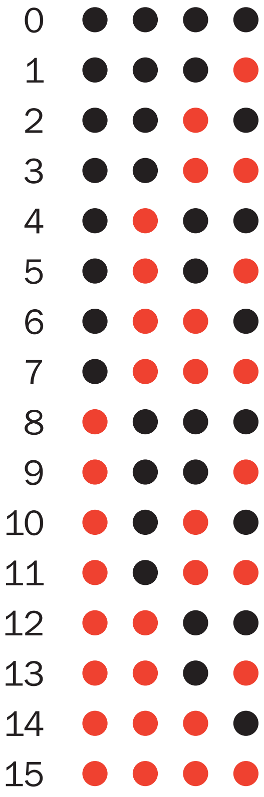

Figure 4-106. *A hexadecimal (16-based) binary counter would generate this succession of high states from its four output pins as it counts from 0 through 15 in decimal notation.*

Getting back to our project: I want to take the three binary outputs and make them create patterns like the spots on a die. How can I do this? Quite easily, as it turns out.

I'm assuming that I'll use seven LEDs to simulate the patterns of spots on a die. These patterns can be broken down into groups, which I have assigned to the three outputs from the counter in Figure 4-108. The first output (farthest to the right) can drive an LED representing the dot at the center of the die face. The second (middle) output can drive two more diagonal LEDs. The third output must switch on all four corner LEDs.

This will work for patterns 1 through 5, but won't display the die pattern for a 6. Suppose I tap into all three outputs from the counter with a three-input NOR gate. It has an output that goes high only when all three of its inputs are low, so it will only give a high output when the counter is beginning with all-low outputs. I can take advantage of this to make a 6 pattern.

Note that it's bad practice to mix the LS generation of TTL chips with the HC generation of CMOS chips, as their input and output ranges are different; so, the NOR chip has to be a 74LS27, not a 74HC27.

We're ready now for a simple schematic. In Figure 4-107 I've colored some of the wires just to make it easier for you to distinguish them. The colors have no other significance.

Figure 4-108. *Binary outputs from the 74LS92 counter can be used to power LEDs arrayed in groups to simulate the pattern of spots on a die.*

Each of the LEDs is grounded through a separate 4K7 load resistor. Unfortunately, this means that when they are displaying the pattern for a 6, all of them are running in parallel from the output of the NOR gate, which overloads it. As long as you don't leave the display in this mode for very long periods, it shouldn't cause a problem. You could compensate by increasing the load resistors, or by running pairs of the LEDs through one resistor, but this will make them so dim that they'll be difficult to see, as they're so close to their lower limit for current already.

Notice how I have added four signal diodes, D1 through D4. When Output C goes high, it has to illuminate all four corner LEDs, and so its power goes into the brown wire as well as the gray wire. But we must never allow one output to feed back into another, so D4 is needed to protect Output B when Output C is high.

Because there is now a connection between B and C, we need D2 to protect Output C when Output B is high. And because Output B must only feed two of the corner LEDs, we also need D3 to stop it from illuminating the other two. And, we have to protect the output from the NOR gate when either Output C or Output B is high. This requires D1.

Figure 4-109 shows everything that I've described so far assembled in breadboard format, while Figure 4-110 shows the test version that I built. Note that the unused logical inputs on the 74LS27 chip are shorted together and connected to the *positive* side of the power supply. Here's the rule:

- When using CMOS chips (such as the HC series), connect unused logical inputs to the negative side of the power supply.
- When using TTL chips (such as the LS series), connect unused logical inputs to the positive side of the power supply.

I assume that you have had enough fun watching the LEDs count slowly, so I've changed the capacitor and resistor values for the 555 to increase its speed from approximately 1 pulse per second to about 50,000 pulses per second. The counter could run much faster than this, but I just want it to cycle fast enough so that when the user presses and releases a button, the count will stop at an unforeseeable number.

The button starts and stops the 555 timer by applying and releasing power to the timing circuit only. This is the equivalent of shaking and then throwing the die.

While the counter is running fast, the LEDs are flashing so fast that all of them will seem to be on at once. At the same time, the circuit charges a new 68 µF capacitor, which I have added between the pushbutton and ground. When you release the button, this capacitor discharges itself through the 1K timing resistor. As the charge dissipates, the timing capacitor will take longer and longer to charge, and discharge, and the frequency of the 555 will gradually diminish. Consequently the LED display will also flash slower, like the reel on a Las Vegas slot machine gradually coming to a stop. This increases the tension as players can see the die display counting to the number that they're hoping for—and maybe going one step beyond it.

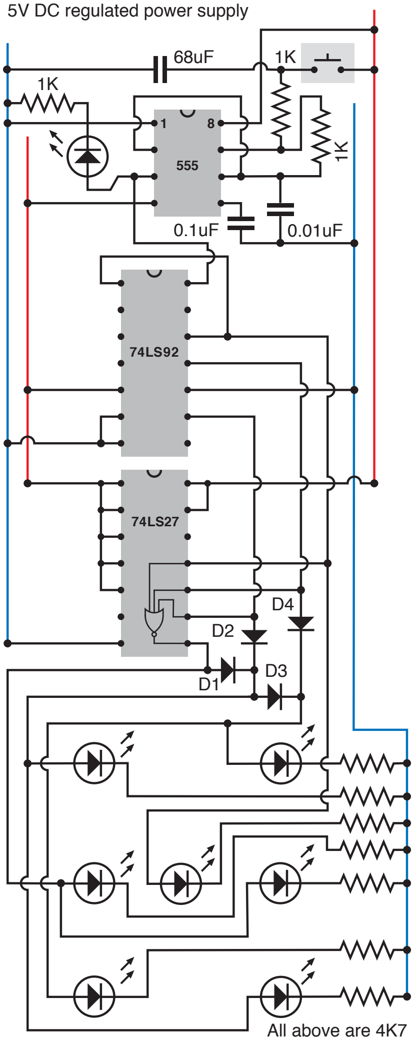

Figure 4-109. *With some extra components, the schematics from Figures 4-102 and 4-107 can be combined to make the working dice simulation.*

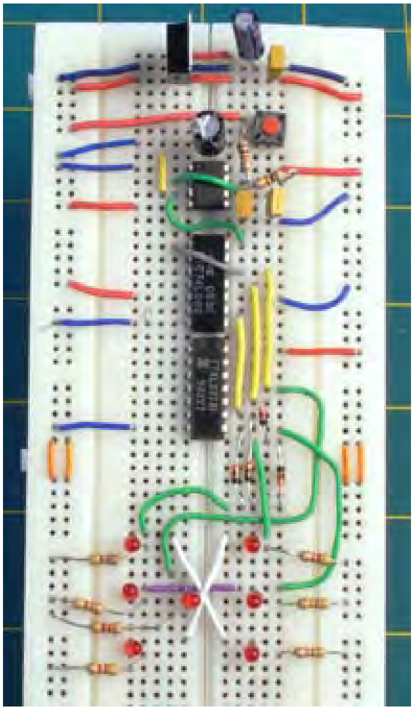

Figure 4-110. *The electronic dice schematic applied to a breadboard, with a pushbutton at the top to start and stop the counter, and 7 LEDs at the bottom to display the output.*

Note that to maximize this effect, the button has to be held down for a full second or more, so that the 68 µF capacitor becomes fully charged before the button is released.

So, this circuit now fulfills the original goal. But can it be better? Of course it can.

Enhancements

The main thing I want to improve is the brightness of the LEDs. I could add a transistor to amplify the current to each one, but there's a simpler alternative: a TTL "open collector" inverter.

I want to use an inverter because in the world of TTL, as I mentioned earlier, we can sink much more power into the output pin of a chip than we can source from it. So, I'm going to turn each LED the other way around and connect their load resistors to the positive side of the power supply. This way, they'll sink their power into the outputs of the inverter.

And the great advantage of an "open collector" version of the inverter chip is that it is designed to sink much more current than a normal TTL logic chip. It is rated for 40mA per pin. The only disadvantage is that it cannot source any current at all; instead of its output going high, it just behaves like an open switch. But that's OK for this circuit.

So the next and final schematic, in Figure 4-111, includes the 74LS06 inverter, which has also been added to the breadboarded version shown in Figure 4-112. I suggest that you put aside the little low-current LEDs and substitute some normal-size ones. Using Kingbright "standard" WP15031D 5mm LEDs, I find that each draws almost exactly 20mA with a voltage drop of about 2V with a 120 ohm series resistor. Because each output pin from the 74LS06 inverter powers no more than two LEDs at a time, this is exactly within its specification. I suggest that if you build this circuit, you check the consumption of your particular choice of LEDs and adjust the resistors if necessary.

Remember: to measure the voltage drop across an LED, simply touch the probes of your meter across it while it is illuminated. To measure the current, disconnect one side of the LED and insert the meter, in milliamp mode, between the leg of the LED and the contact that it normally makes in the circuit.

For a really dramatic display, you can get some 1 cm diameter LEDs (Figure 4-113). Check the specification, and you should find that many of these don't use more power than the usual 5 mm type. But whatever kind you use, don't forget to turn them around so that their negative sides face toward the inverter, and their positive sides face the resistors, which are connected to the positive side of the power supply.

One last detail: I had to add two 10K resistors to this version of the circuit. Can you see why? Diodes D1 through D4 are designed to transmit positive voltage through to the inverter when appropriate, but they prevent the inputs of the inverter from "seeing" the negative side of the power supply when the counter outputs are low. These inverter inputs require pull-down resistors to prevent them from "floating" and producing erroneous results.

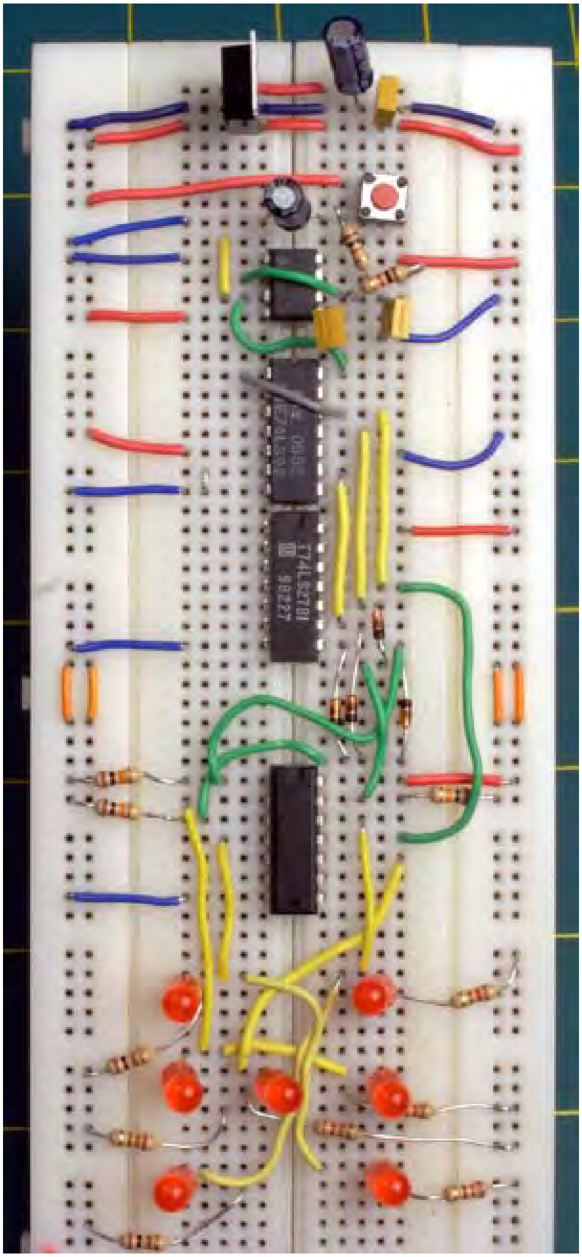

Figure 4-112. *The completed circuit using an open-collector inverter to drive full-size LEDs.*

The final enhancements are up to you. Most obviously, you can add a second die, as many games require two dice. The 74LS27 chip still has a couple of spare NOR gates in it, one of which you can make use of, but you will need an additional 555 timer, running at a significantly different speed to ensure randomness, and it will have to drive a second counter.

After you get your dice up and running, you may want to test them for randomness. Because the pulses from a 555 timer are of equal length, every number has an equal chance of coming up; but the longer you hold down the Start button, the better your odds are of interrupting the counting process at a truly random moment. Anyone using your electronic dice should be told that "shaking" them for a full second is mandatory.

Of course, I could have simulated dice more easily by writing a few lines of software to generate random numbers on a screen, but even a fancy screen image cannot have the same appeal as a well-made piece of hardware. Figure 4-113 shows white 1 cm LEDs mounted in a sanded polycarbonate enclosure for dramatic effect.

Most of all, I derived satisfaction from using simple, dedicated chips that demonstrate the binary arithmetic that is fundamental in every computer.

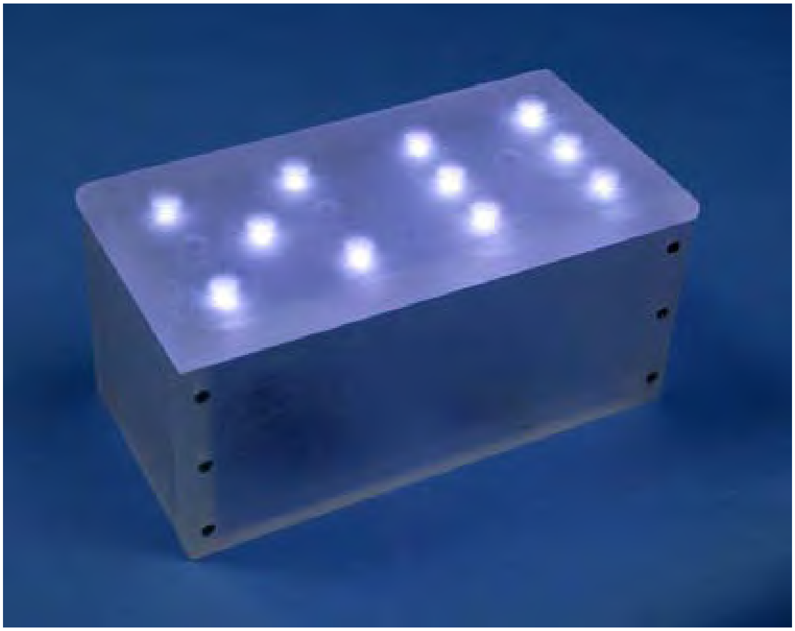

Figure 4-113. *The open-collector inverter chip in the dice circuit is sufficiently powerful to drive 1-cm white LEDs that draw about 20mA each, using a potential of 2V. In this finished version, the LEDs were embedded in cavities drilled from the underside of half-inch polycarbonate, which has been treated with an orbital sander to create a translucent finish.*

Experiment 24: Intrusion Alarm Completed

Now let me suggest how you can apply the knowledge from this chapter of the book to upgrade the burglar alarm project that was last modified in Experiment 15. You'll probably need to check Chapters 2 and 3 to refamiliarize yourself with some features of the alarm.

Upgrade 1: Delayed Activation

The biggest flaw in the alarm was that as soon as it was activated, it would immediately respond to any signal from the door and window sensors. It needed a feature to delay activation to give you a chance to exit from the building before the alarm armed itself. A 555 timer can provide this functionality, probably in conjunction with a relay. The power to the alarm should pass through the contacts of the relay, which are normally closed. When you press a button on the timer, it sends a positive pulse to the relay lasting for around 30 seconds, holding the relay open for that period. You could mount the timer in its own little box with a button on it, which you press when you're ready to leave the building. The 12-volt power supply to the burglar alarm passes through the box containing the delay circuit. For 30 seconds, the 555 interrupts power to the alarm, and then restores it, ready for action.

Upgrade 2: Keypad Deactivation

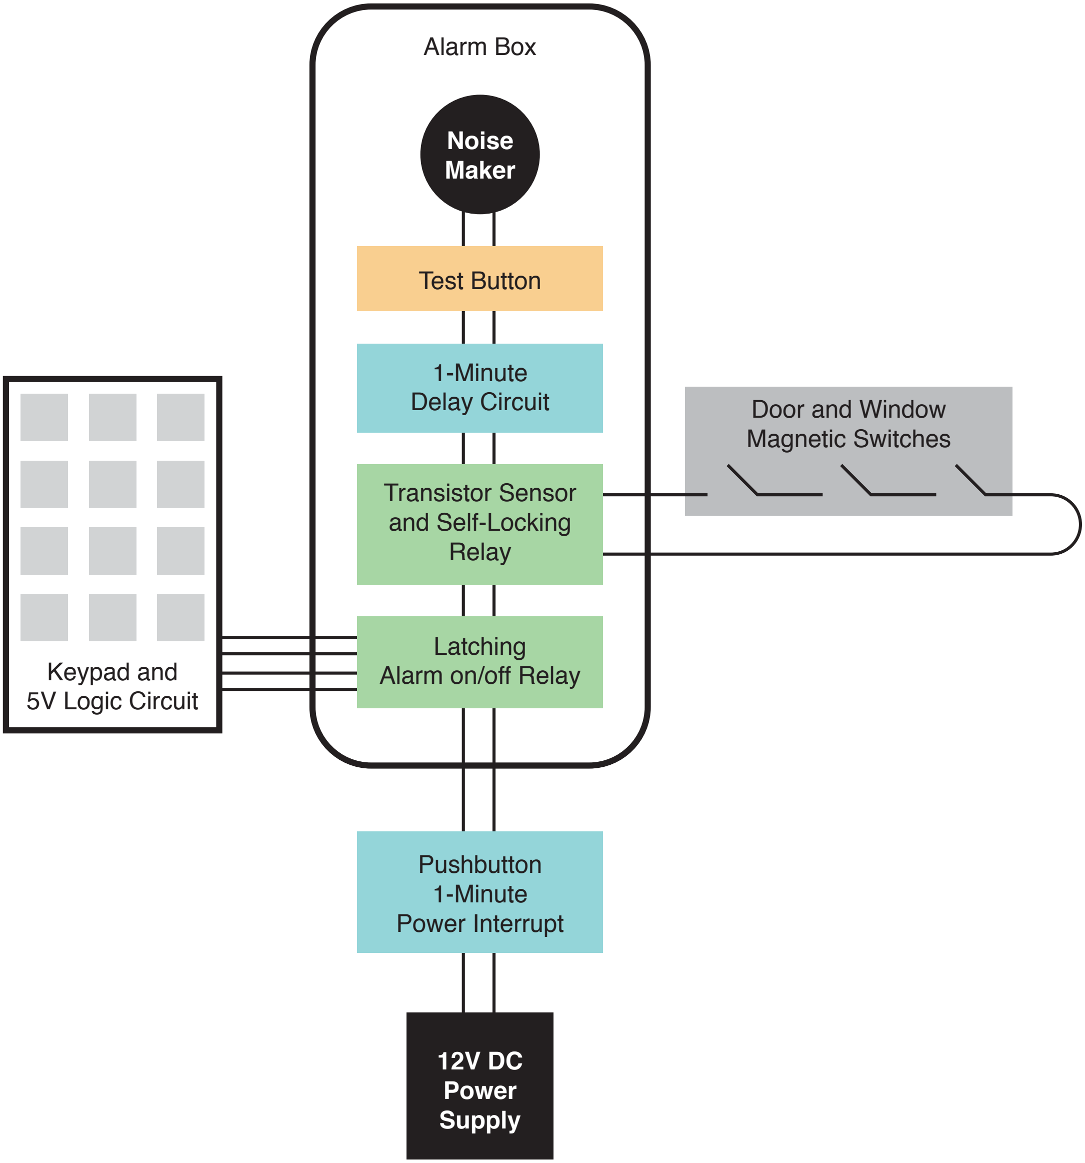
This is now really simple. You can substitute a latching relay instead of the switch, S1, on the alarm box (shown in Figure 3-110), and use a keypad to set and reset the relay in exactly the same way as in the combination lock in Experiment 20. You'll have to run an additional three wires from the relay, out of the alarm box, to the keypad (one supplying power to the "on" relay coil, another supplying power to the "off" coil, the third being a common ground). You can either use a 9-volt battery to power the electronics in association with the keypad, or run an additional fourth wire from the alarm box, to carry positive power to the logic chips, bearing in mind that you have to insert a voltage regulator at some point, to drop the 12 volts that the alarm uses to the 5 volts that the logic gates require. As the gates consume so little power, the 12-to-5 drop should be OK for the voltage regulator; it won't have to dissipate too much heat.

With this additional feature, you can use the alarm like this:

- Press the pound key on the keypad to flip the latching relay into its "on" mode, so that it passes power to the alarm box, which is now armed.
- If you want to leave the house, push the button on the delay unit to give you 30 seconds in which to do so.
- If the alarm is triggered, enter your secret code on the keypad to deactivate it by flipping the latching relay to its "off" position and cutting power to the alarm box.

These modifications are so simple that I think the block diagram in Figure 4-114 should be all you need. I don't think I need to give you any schematics. The only change you have to make to the existing alarm is to substitute the latching relay for the on/off switch.

But, there is still one obvious necessary enhancement needed: how can you get back into the house without instantly triggering the alarm?



Alarm Box
Noise Maker
Test Button
1-Minute Delay Circuit
Transistor Sensor and Self-Locking Relay
Latching Alarm on/off Relay
Door and Window Magnetic Switches
Keypad and 5V Logic Circuit
Pushbutton 1-Minute Power Interrupt
12V DC Power Supply

Figure 4-114. *This block diagram shows the relative placement of the old and new components. The pushbutton power interrupt (which allows you to leave the house before the alarm switches itself back on) goes between the power supply and everything else. The latching relay substitutes for the DPDT switch on the previous version of the alarm. The transistor and self-locking relay, connected with the door and window magnetic switches, remain unchanged. The new delay circuit is inserted between the self-locking relay and the noisemaker. The test button is wired with the latching relay in the same way that it was wired previously with the DPDT switch.*

Upgrade 3: Delay Before Deactivation

Typically, alarms include another delay feature. When you open a door on your way into the building and it triggers the alarm, you have 30 seconds to deactivate it, before it starts making a noise.

How can we implement this delay feature? If I try to use another 555 timer to generate a pulse to inhibit the noise, that won't work, because the output from either the transistor or the relay can continue indefinitely. The relay locks itself on, and the transistor can continue passing voltage for as long as someone leaves a door open. If either of these signals activates a timer in monostable mode, the pulse from the timer will never end, and it will suppress the alarm indefinitely.

I think what I have to do is use a resistor and a capacitor to create a delay. I'll power them through the existing relay, so that I can be sure that they'll receive the full voltage of the power supply, after beginning from zero. Gradually the capacitor will acquire voltage—but I can't connect this directly to the noisemaker, because the noisemaker will gradually get louder as the voltage increases.

I have to insert a device that will be triggered to give full voltage when the input rises past a certain point. To do this, I'll use a 555 timer that's wired in bistable mode. This kind of modification is generally known as a "kludge," because it's not elegant, uses too many components, and does not use them appropriately. What I really need is a comparator, but I don't have space to get into that topic. So, using the knowledge that you have so far, the schematic in Figure 4-115 shows how a delay can be added to the alarm—not elegantly, but reliably.

The only problem is that if you power up a 555 timer in bistable mode, there's a 50-50 chance that the timer starts itself with its output high or low. So I need to pull the voltage low on the reset pin (to start the timer with its output inhibited) and gradually let it become positive (to permit the output). At the same time, I want to start with the voltage high on the trigger pin and gradually lower it, until it falls below 1/3 of the power supply and triggers the output.

So there are two timing circuits. The one for the reset pin works faster than the one on the trigger pin, so that at the point when the timer is triggered, the reset won't stop it.

The schematic shows component values that will do this. The 10 µF capacitor starts low but is charged through the 10K resistor in a couple of seconds. The timer is now ready to be triggered. But the 68 µF capacitor starts high (being connected with the positive side of the power supply) and takes a full minute to be pulled down to 1/3 of supply voltage through the 1M resistor. At that point, its voltage is low enough to trigger the 555. The timer output goes high and supplies the noisemaker.

You should be able to insert this little delay module in your alarm box, between the output from the relay and the input to the noisemaker without too much trouble. And if you want to adjust the delay, just use a higher or lower value resistor than 1M.

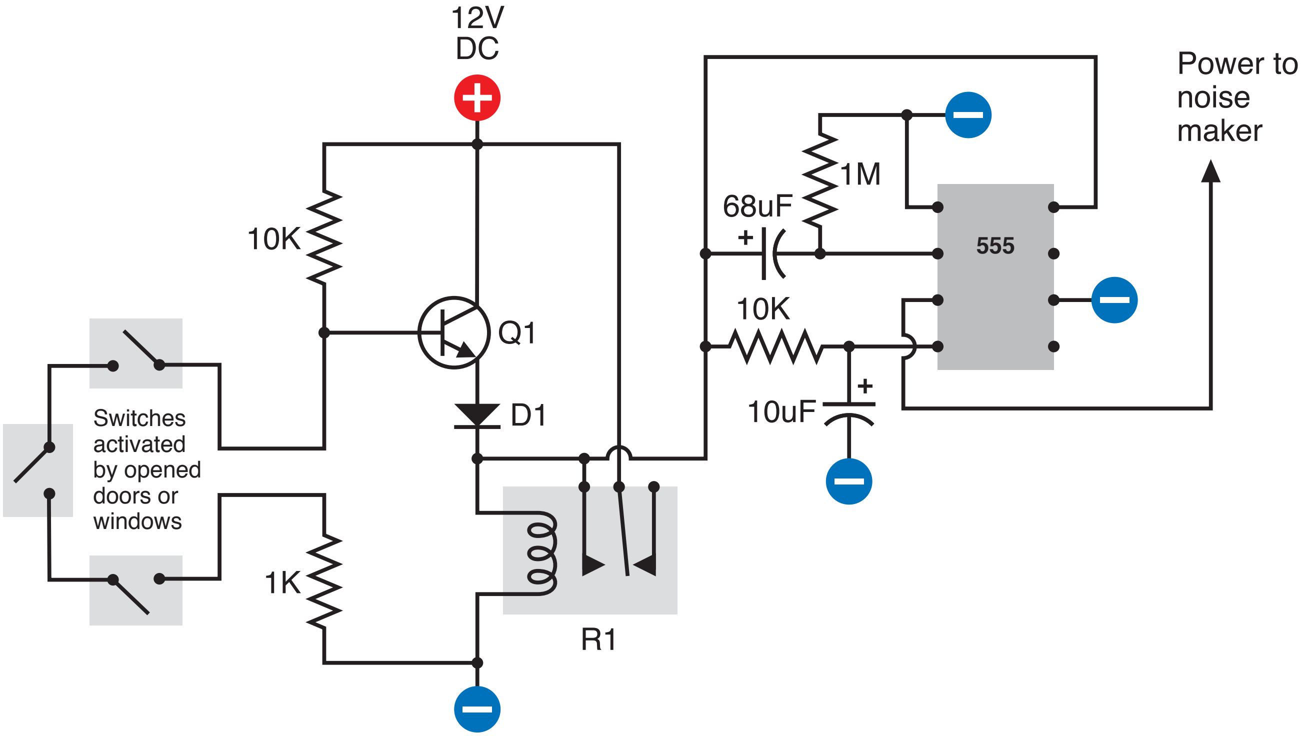


Figure 4-115. *This addition to the original alarm circuit imposes a one-minute delay before the alarm sounds. The 555 timer (wired in bistable mode) receives power through relay R1. The lower timing circuit initially applies negative voltage to the reset, ensuring that the 555 powers up with its output suppressed. This voltage quickly rises. Meanwhile the upper timing circuit applies a voltage to the trigger that gradually diminishes as the 68 µF capacitor equalizes its charge through the 1M resistor. When the voltage diminishes to 1/3 of the supply, the timer's output goes high and starts the noisemaker. If the power to the circuit is interrupted at any time before this, the relay relaxes, the capacitors gradually discharge, and the alarm does not sound.*

The Wrap-Up

If you add these three enhancements, your alarm will have all the features on my original wish list. Of course, if I were designing it from scratch, with all the information that has been added in this chapter of the book, it could be more elegant. But the modifications have not entailed making destructive changes to our original project, and all the design goals have been met.

Experiment 34: Hardware Meets Software
Experiment 35: Checking the Real World
Experiment 36: The Lock, Revisited
In Closing

At this point, we can branch out in numerous directions. Here are some possibilities:

Audio electronics

This is a field in itself, including hobby projects, such as simple amplifiers and "stomp boxes," to modify guitar sound.

Radio-frequency devices

Anything that receives or transmits radio waves, from an ultra-simple AM radio to remote controllers.

Motors

The field of robotics has encouraged the growth of many online sites selling stepper motors, gear motors, synchronous motors, servo motors, and more.

Programmable microcontrollers

These are tiny computers on a single chip. You write a little program on your desktop computer, which will tell the chip to follow a series of procedures, such as receiving input from a sensor, waiting for a fixed period, and sending output to a motor. Then you download your program onto the chip, which stores it in nonvolatile memory. Popular controllers include the PICAXE, BASIC Stamp, Arduino, and many more. The cheapest ones retail for a mere $5 each.

Obviously, I don't have space to develop all of these topics fully, so what I'm going to do is introduce you to them by describing just one or two projects in each category. You can decide which interests you the most, and then proceed beyond this book by reading other guides that specialize in that interest.

I'm also going to make some suggestions about setting up a productive work area, reading relevant books, catalogs, and other printed sources, and generally proceeding further into hobby electronics.

Shopping List: Experiments 25 Through 36

Tools

You won't need any new tools for this section of the book.

Supplies and Components

As we have progressed to the point where you may want to pick and choose which projects you attempt, I will list the supplies and components at the beginning of each experiment.

Customizing Your Work Area

At this point, if you're getting hooked on the fun of creating hardware but haven't allocated a permanent corner to your new hobby, I have some suggestions. Having tried many different options over the years, my main piece of advice is this: don't build a workbench!

Many hobby electronics books want you to go shopping for 2×4s and plywood, as if a workbench has to be custom-fabricated to satisfy strict criteria about size and shape. I find this puzzling. To me, the exact size and shape of a bench is not very important. I think the most important issue is storage.

I want tools and parts to be easily accessible, whether they're tiny transistors or big spools of wire. I certainly don't want to go digging around on shelves that require me to get up and walk across the room.

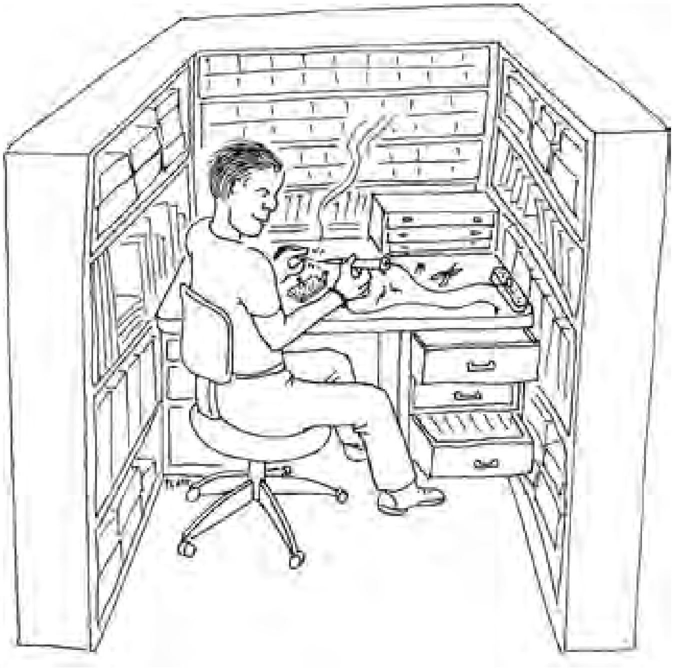

Figure 5-1. *The ideal work area: surrounded by storage. Never again will you need to get out of your chair!*

This leads me to two conclusions:

1. You need storage above the workbench.
2. You need storage below the workbench.

Many DIY workbench projects allow little or no storage underneath. Or, they suggest open shelves, which will be vulnerable to dust. My minimum configuration would be a pair of two-drawer file cabinets with a slab of 3/4-inch plywood or a Formica-clad kitchen countertop placed across them. File cabinets are ideal for storing all kinds of objects, not just files.

Of all the workbenches I've used, the one I liked best was an old-fashioned steel office desk—the kind of monster that dates back to the 1950s. They're difficult to move (because of their weight) and don't look beautiful, but you can buy them cheaply from used office furniture dealers, they're generous in size, they withstand abuse, and they last forever. The drawers are deep and usually slide in and out smoothly, like good file-cabinet drawers. Best of all, the desk has so much steel in it that you can use it to ground yourself before touching components that are sensitive to static electricity. If you use an antistatic wrist strap, you can simply attach it to a sheet-metal screw that you drive into one corner of the desk.

What will you put in the deep drawers of your desk or file cabinets? Some paperwork may be useful, perhaps including the following documents:

- Product data sheets
- Parts catalogs
- Sketches and plans that you draw yourself

The remaining capacity of each drawer can be filled with plastic storage boxes. The boxes can contain tools that you don't use so often (such as a heat gun or a high-capacity soldering iron), and larger-sized components (such as loudspeakers, AC adapters, project boxes, and circuit boards). You should look for storage boxes that measure around 11 inches long, 8 inches wide, and 5 inches deep, with straight sides. Boxes that you can buy at Wal-Mart will be cheaper, but they often have tapering sides (which are not space-efficient).

The boxes that I like best are Akro-Grids, made by Akro-Mils (see Figures 5-2 and 5-3). These are very rugged, straight-sided, with optional transparent snap-on lids. You can download the full Akro-Mills catalog from *http://www.akro-mils.com* and then search online for retail suppliers. You'll find that Akro-Mils also sells an incredible variety of parts bins, but I don't like open bins because their contents are vulnerable to dust and dirt.

For medium-size components, such as potentiometers, power connectors, control knobs, and toggle switches, I like storage containers measuring about 11 inches long, 8 inches wide, and 2 inches deep , divided into four to six sections. You can buy these from Michaels (the craft store), but I prefer to shop online for the Plano brand, as they seem more durably constructed. The Plano products that are most suitable for medium-size electronic parts are classified as fishing-tackle boxes, and you'll see them at *http://www.planomolding.com/tackle/products.asp*.

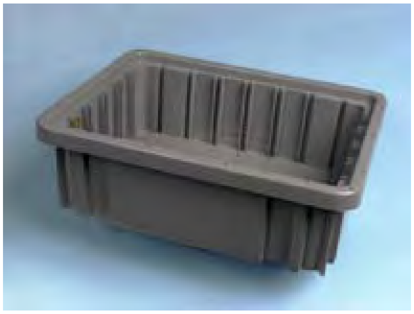

Figure 5-2. *Akro-Grid boxes contain grooves allowing them to be partitioned into numerous compartments for convenient parts storage.*

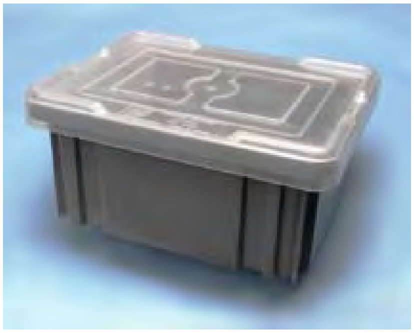

Figure 5-3. *Lids are sold separately for Akro-Grid boxes to keep the contents dust-free. The height of the box in Figure 5-2 allows three to be stacked in a typical file-cabinet drawer. The box shown here allows two to be stacked.*

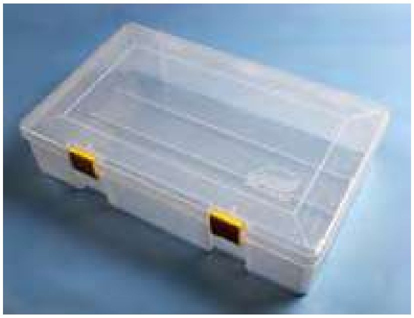

Figure 5-4. *This Plano brand box is undivided, making it useful for storing spools of wire or medium-size tools. When stacked upright on its long edge, three will fit precisely in a file-cabinet drawer.*

For undivided, flat-format storage boxes, the Prolatch 23600-00 is ideally sized to fit a file-cabinet drawer, and the latches are sufficiently secure that you could stack a series of them on their long edges. See Figure 5-4.

Plano also sells some really nicely designed toolboxes, one of which you can place on your desktop. It will have small drawers for easy access to screwdrivers, pliers, and other basics. Because you need a work area that's only about three feet square for most electronics projects, surrendering some desk space to a toolbox is not a big sacrifice.

If you have a steel desk with relatively shallow drawers, one of them can be allocated for printed catalogs. Don't underrate the usefulness of hard copy, just because you can buy everything online. The Mouser catalog, for instance, has an index, which is better in some ways than their online search feature, and the catalog is divided into helpful categories. Many times I've found useful parts that I never knew existed, just by browsing, which is much quicker than flipping through PDF pages online, even with a broadband connection. Currently, Mouser is still quite generous about sending out their catalogs, which contain over 2,000 pages. McMaster-Carr will also send you a catalog, but only after you've ordered from them, and only once a year.

Now, the big question: how to store all those dinky little parts, such as resistors, capacitors, and chips? I've tried various solutions to this problem. The most obvious is to buy a case of small drawers, each of which is removable, so you can place it on your desk while you access its contents. But I don't like this system, for two reasons. First, for very small components, you need to subdivide the drawers, and the dividers are never secure. And second, the removability of the drawers creates the risk of accidentally emptying the contents on the floor. Maybe you're too careful to allow this to happen, but I'm not!

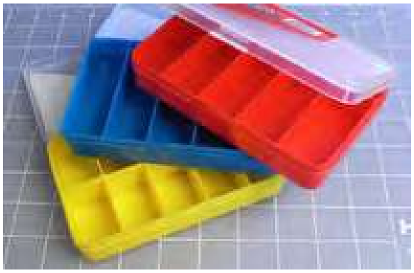

Figure 5-5. *Darice Mini-Storage boxes are ideal for components such as resistors, capacitors, and semiconductors. The boxes can be stacked stably or stored on shelves, with their ends labeled. The brand sticker is easily removed after being warmed with a heat gun.*

My personal preference is to use Darice Mini-Storage boxes, shown in Figure 5-5. You can find these at Michaels in small quantities, or buy them more economically in bulk online from suppliers such as *http://www.craftamerica.com*. The blue boxes are subdivided into five compartments that are exactly the right size and shape for resistors. The yellow boxes are subdivided into ten compartments, which are ideal for semiconductors. The purple boxes aren't divided at all, and the red boxes have a mix of divisions.

The dividers are molded into the boxes, so you don't have the annoyance associated with removable dividers that slip out of position, allowing components to mix together. The box lids fit tightly, so that even if you drop one of the boxes, it probably won't open. The lids have metal hinges, and a ridge around the edge that makes the boxes securely stackable.

I keep my little storage boxes on a set of shelves above the desk, with a gap of 3 inches between one shelf and the next, allowing two boxes to be stacked on each shelf. If I want to work with a particular subset of boxes, I shift them onto the desktop and stack them there.

Labeling

No matter which way you choose to store your parts, labeling them is essential. Any ink-jet printer will produce neat-looking labels, and if you use peelable (nonpermanent) labels, you'll be able to reorganize your parts in the future, as always seems to become necessary. I use color-coded labels for my collection of resistors, so that I can compare the stripes on a resistor with the code on the label, and see immediately if the resistor has been put in the wrong place. See Figure 5-6.

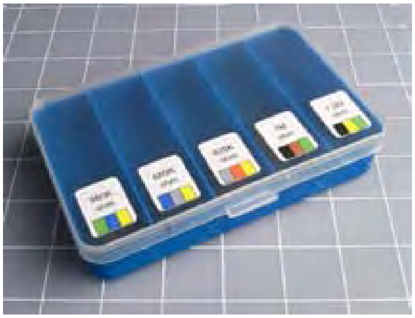

Figure 5-6. *To check that resistors are not placed in the wrong compartments, print the color code on each label.*

Even more important: you need to place a second (non-adhesive) label inside each compartment with the components. This label tells you the manufacturer's part number and the source, so that reordering is easy. I buy a lot of items from Mouser, and whenever I open their little plastic bags of parts, I snip out the section of the bag that has the identifying label on it, and slide it into the compartment of my parts box before I put the parts on top of it. This saves frustration later.

If I were *really* well organized, I would also keep a database on my computer listing everything that I buy, including the date, the source, the type of component, and the quantity. But I'm not that well organized.

On the Bench

Some items are so essential that they should sit on the bench or desktop on a permanent basis. These include your soldering iron(s), helping hands with magnifier, desk lamp, breadboard, power strip, and power supply. For a desk lamp, I prefer the type that has a daylight-spectrum fluorescent bulb, because it spreads a uniform light and helps me to distinguish colors of adjacent stripes on resistors.

The power supply is a matter of personal preference. If you're serious about electronics, you can buy a unit that delivers properly smoothed current at a variety of properly regulated and calibrated voltages. Your little wall-plug unit from RadioShack cannot do any of these things, and its output may vary depending on how heavily you load it. Still, as you've seen, it is sufficient for basic experiments, and when you're working with logic chips, you need to mount a 5-volt regulator on your breadboard anyway. Overall, I consider a good power supply optional.

Another optional item is an oscilloscope. This will show you, graphically, the electrical fluctuations inside your wires and components, and by applying probes at different points, you can track down errors in your circuit. It's a neat gadget to own, but it will cost a few hundred dollars, and for our tasks so far, it has not been necessary. If you plan to get seriously into audio circuits, an oscilloscope becomes far more important, because you'll want to see the shapes of the waveforms that you generate.

You can try to economize on an oscilloscope by buying a unit that plugs into the USB port of your computer and uses your computer monitor to display the signal. I have tried one of these, and was not entirely happy with the results. It worked, but did not seem accurate or reliable for low-frequency signals. Maybe I was unlucky; I decided not to try any other brands.

The surface of your desk or workbench will undoubtedly become scarred by random scuffs, cut marks, and drops of molten solder. I use a piece of half-inch plywood, two feet square, to protect my primary work area, and I clamp a miniature vise to its edge. To reduce the risk of static electricity when working with sensitive components, I cover the plywood with a square of conductive foam. This is not cheap, but offers advantages in addition to protecting chips from being zapped. Instead of scattering stray components, I can stick them into the foam, like plants growing in a garden. And like a garden, I can divide it into sections, with resistors on one side, capacitors on the other, and chips straight ahead.

Inevitably, during your work you'll create a mess. Little pieces of bent wire, stray screws, fasteners, and fragments of stripped insulation tend to accumulate, and can be a liability. If metal parts or fragments get into a project that you're building, they can cause short circuits. So you need a trash container. But it has to be easy to use. I use a full-size garbage pail, because it's so big that I can't miss it when I throw something toward it, and I can never forget that it's there.

Last, but most essential: a computer. Now that all data sheets are available online, and all components can be ordered online, and many sample circuits are placed online by hobbyists and educators, I don't think anyone can work efficiently without quick Internet access. To avoid wasting space, I suggest you use a small, cheap laptop that has a minimal footprint. A possible workbench configuration, using a steel desk, is shown in Figure 5-7.

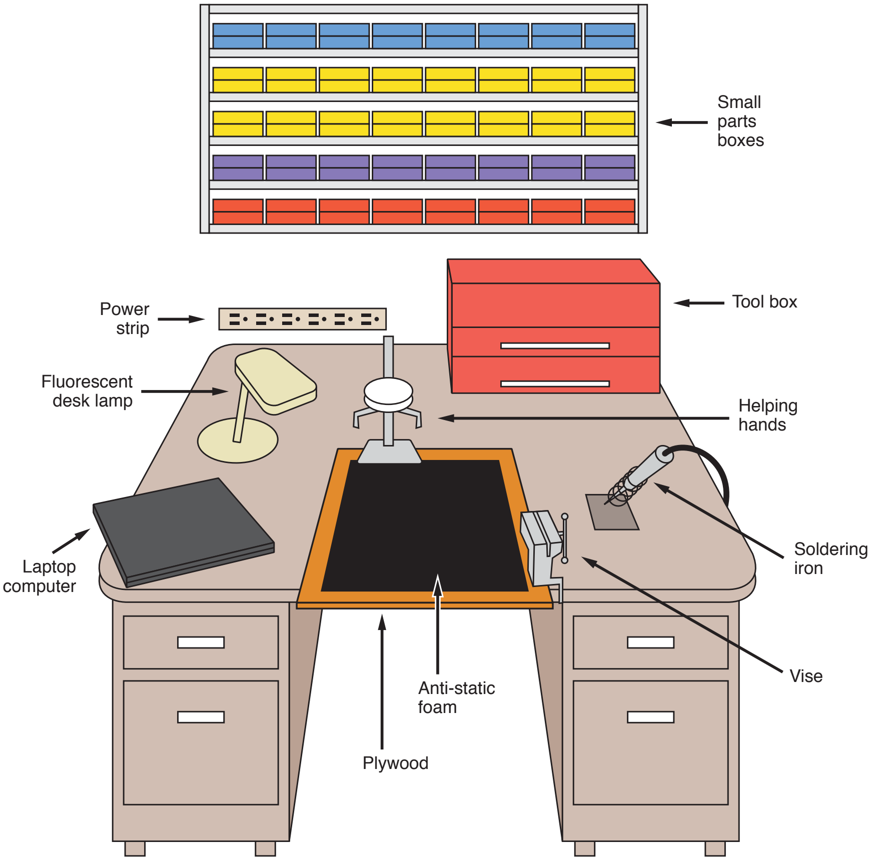

Figure 5-7. *An old steel office desk can be as good as, if not better than, a conventional workbench when building small electronics projects. It provides a large work area and ample storage, and has sufficient mass for you to ground yourself when dealing with components that are sensitive to static electricity.*

Reference Sources

Online

My favorite educational and reference site is Doctronics (*http://www.doctronics.co.uk)*. I like the way they draw their schematics, and I like the way they include many illustrations of circuits on breadboards (which most sites don't bother to do). They also sell kits, if you're willing to pay and wait for shipping from the UK. Part of a page from the doctronics website is reproduced in Figure 5-8.

Up to previous stage

Figure 5-8. *A sample page from http://www.doctronics.co.uk shows their detailed instructional approach. This is a valuable free online resource.*

My next favorite hobby site is also British-based: the Electronics Club (*http://www.kpsec.freeuk.com)*. It's not as comprehensive as Doctronics, but very friendly and easy to understand.

For a more theory-based approach, try *http://www.electronics-tutorials.ws*. This will go a little farther than the theory sections I've included here.

For an idiosyncratic selection of electronics topics, try Don Lancaster's Guru's Lair (*http://www.tinaja.com*). Lancaster wrote *The TTL Cookbook* more than 30 years ago, which opened up electronics to at least two generations of hobbyists and experimenters. He knows what he's talking about, and isn't afraid of getting into some fairly ambitious areas such as writing his own PostScript drivers and creating his own serial-port connections. You'll find a lot of ideas there.

Books

Yes, you do need books. As you're already reading this one, I won't recommend other beginners' guides. Instead, in keeping with the orientation of this chapter, I'll suggest some titles that will take you farther in various directions, and can be used for reference. I own all of these myself, and find them valuable:

Practical Electronics for Inventors, by Paul Scherz (McGraw-Hill, Second Edition, 2007)

> This is a massive, comprehensive book, well worth the $40 cover price. Despite its title, you won't need to invent anything to find it useful. It's my primary reference source, covering a wide range of concepts, from the basic properties of resistors and capacitors all the way to some fairly high-end math. If you buy only one book (in addition to this one, of course!), this would be my recommendation.

Getting Started with Arduino, by Massimo Banzi (Make: Books, 2009)

> If you enjoy the simplicity and convenience of the PICAXE programmable microcontroller that I describe later in this chapter, you'll find that the Arduino can do a lot more. *Getting Started* is the simplest introduction around, and will help to familiarize you with the Processing language used in Arduino (similar to the C language, not much like the version of BASIC used by the PICAXE).

Making Things Talk, by Tom Igoe (Make: Books, 2007)

> This ambitious and comprehensive volume shows how to make the most of the Arduino's ability to communicate with its environment, even getting it to access sites on the Internet.

TTL Cookbook, by Don Lancaster (Howard W. Sams & Co, 1974)

> The 1974 copyright date is not a misprint! You may be able to find some later editions, but whichever one you buy, it will be secondhand and possibly expensive, as this title now has collectible value. Lancaster wrote his guide before the 7400 series of chips was emulated on a pin-for-pin basis by CMOS versions, but it's still a good reference, because the concepts and part numbers haven't changed, and his writing is so accurate and concise.

CMOS Sourcebook, by Newton C. Braga (Sams Technical Publishing, 2001)

> This book is entirely devoted to the 4000 series of CMOS chips, not the 74HC00 series that I've dealt with primarily here. The 4000 series is older and must be handled more carefully, because it's more vulnerable to static electricity than the generations that came later. Still, the chips remain widely available, and their great advantage is their willingness to tolerate a wide voltage range, typically from 5 to 15 volts. This means you can set up a 12-volt circuit that drives a 555 timer, and use output from the timer to go straight into CMOS chips (for example). The book is well organized in three sections: CMOS basics, functional diagrams (showing pinouts for all the main chips), and simple circuits showing how to make the chips perform basic functions.

The Encyclopedia of Electronic Circuits, by Rudolf F. Graf (Tab Books, 1985)

A totally miscellaneous collection of schematics, with minimal explanations. This is a useful book to have around if you have an idea and want to see how someone else approached the problem. Examples are often more valuable than general explanations, and this book is a massive compendium of examples. Many additional volumes in the series have been published, but start with this one, and you may find it has everything you need.

The Circuit Designer's Companion, by Tim Williams (Newnes, Second Edition, 2005)

Much useful information about making things work in practical applications, but the style is dry and fairly technical. May be useful if you're interested in moving your electronics projects into the real world.

The Art of Electronics, by Paul Horowitz and Winfield Hill (Cambridge University Press, Second Edition, 1989)

The fact that this book has been through 20 printings tells you two things: (1) Many people regard it as a fundamental resource; (2) Secondhand copies should be widely available, which is an important consideration, as the list price is over $100. It's written by two academics, and has a more technical approach than *Practical Electronics for Inventors*, but I find it useful when I'm looking for backup information.

Getting Started in Electronics, by Forrest M. Mims III (Master Publishing, Fourth Edition, 2007)

Although the original dates back to 1983, this is still a fun book to have. I think I have covered many of its topics here, but you may benefit by reading explanations and advice from a completely different source, and it goes a little farther than I have into some electrical theory, on an easy-to-understand basis, with cute drawings. Be warned that it's a brief book with eclectic coverage. Don't expect it to have all the answers.

Experiment 25: Magnetism

This experiment should be a part of any school science class, but even if you remember doing it, I suggest that you do it again, because setting it up takes only a matter of moments, and it's going to be our entry point to a whole new topic: the relationship between electricity and magnetism. Quickly this will lead us into audio reproduction and radio, and I'll describe the fundamentals of self-inductance, which is the third and final basic property of passive components (resistance and capacitance being the other two). I left self-inductance until last because it's not very relevant to the experiments that you've done so far. But as soon as we start dealing with analog signals that fluctuate, it becomes essential.

You will need:

- Large screwdriver.
- 22-gauge wire (or thinner). Quantity: 6 feet.
- AA battery.

Procedure

This couldn't be simpler. Wind the wire around the shaft of the screwdriver, near its tip. The turns should be neat and tight and closely spaced, and you'll need to make 100 of them, within a distance of no more than 2 inches. To fit them into this space, you'll have to make turns on top of previous turns. If the final turn tends to unwind itself (which will happen if you're using stranded wire), secure it with a piece of tape. See Figure 5-11.

Now apply a battery, as shown in Figure 5-12. At first sight, this looks like a very bad idea, because you're going to short out your battery just as you did in Experiment 2. But by passing the current through a wire that's coiled instead of straight, we'll get some work out of it before the battery expires.

Put a small paper clip near the screwdriver blade, on a soft, smooth surface that will not present much friction. A tissue works well. Because many screwdrivers are already magnetic, you may find that the paper clip is naturally attracted to the tip of the blade. If this happens, move the clip just outside the range of attraction. Now apply the 1.5 volts to the circuit, and the clip should jump to the tip of the screwdriver. Congratulations: you just made an electromagnet.

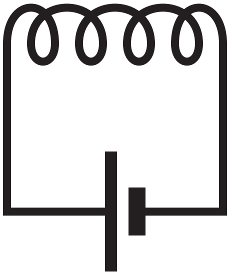

Figure 5-12. *A schematic can't get much simpler than this.*

FUNDAMENTALS

A two-way relationship

Every electric motor that was ever made uses some aspect of the relationship between electricity and magnetism. It's absolutely fundamental in the world around us. Remember that electricity can create magnetism:

When electricity flows through a wire, it creates a magnetic force around the wire.

The principle works in reverse: magnetism can create electricity.

When a wire moves through a magnetic field, it creates a flow of electricity in the wire.

This second principle is used in power generation. A diesel engine, or a water-powered turbine, or a windmill, or some other source of energy either turns coils of wire through a powerful magnetic field, or turns magnets amid some massive coils of wire. Electricity is induced in the coils. In the next experiment, you'll see a dramatic mini-demo of this effect.

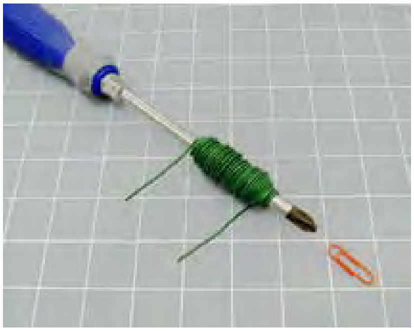

Figure 5-11. *Anyone who somehow missed this most basic childhood demo of electromagnetism should try it just for the fun of proving that a single AA battery can move a paper clip.*

THEORY

Inductance

When electricity flows through a wire, it creates a magnetic field around the wire. Because the electricity "induces" this effect, it is known as *inductance*. The effect is illustrated in Figure 5-13.

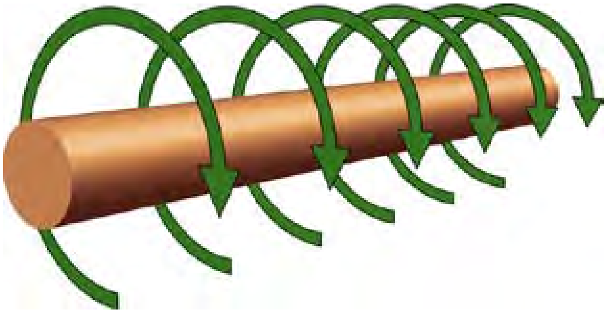

Figure 5-13. *When the flow of electricity is from left to right along this conductor, it induces a magnetic force shown by the green arrows.*

The field around a straight wire is very weak, but if we bend the wire into a circle, the magnetic force starts to accumulate, pointing through the center of the circle, as shown in Figure 5-14. If we add more circles, to form a coil, the force accumulates even more. And if we put a magnetic object (such as a screwdriver) in the center of the coil, the effectiveness increases further.

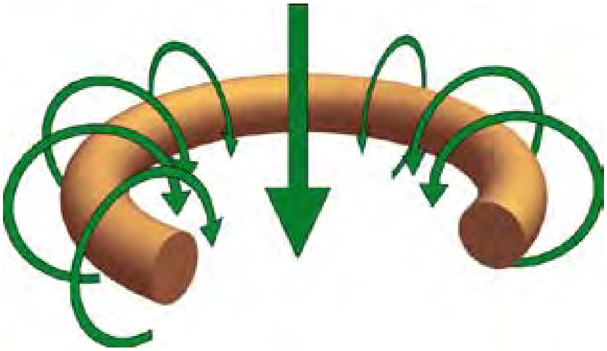

Figure 5-14. *When the conductor is bent to form a circle, the cumulative magnetic force acts through the center of the circle, as shown by the large arrow.*

Here's an approximated formula showing the relationship between the diameter of the coil, the width of the coil from end to end, the number of turns, and its inductance. The letter L is the symbol for inductance, even though the unit is the Henry, named after an American electrical pioneer named Joseph Henry:

> L (in microHenrys) =
> [(D × D) × (N x N)] / [(18 × D) + (40 × W)]
> (Approximately)

In this formula, D is the diameter of the coil, N is the number of turns, and W is the width of the coil from end to end. See Figure 5-15. Here are three simple conclusions from this formula:

- Inductance increases with the diameter of the coil.
- Inductance increases with the square of the number of turns. (In other words, three times as many turns create nine times the inductance.)
- If the number of turns remains the same, inductance is lower if you wind the coil so that it's slender and long, but is higher if you wind it so that it's fat and short.

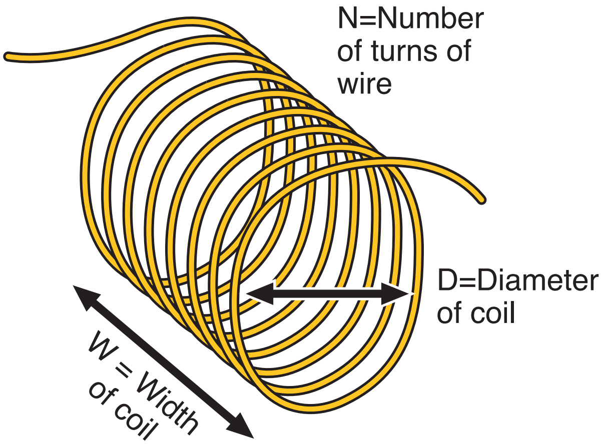

Figure 5-15. *The inductance of a coil increases with its diameter and with the square of its number of turns. If all other parameters remain the same, reducing the width (the distance from end to end) by packing the turns more tightly will increase the inductance.*

FUNDAMENTALS

Coil schematics and basics

Check the schematic symbols for coils in Figure 5-16. Note that if a coil has an iron core, this is shown with an extra couple of lines (sometimes only one line). If it has a ferrite core, the line is sometimes shown with dashes.

An iron core will add to the inductance of a coil, because it increases the magnetic effect.

A coil in isolation does not generally have any polarity. You can connect it either way around, but the magnetic force will be reversed accordingly (coils that interact with stuff—such as in transformers and solenoids—do have polarity).

Perhaps the most widespread application of coils is in transformers, where alternating current in one coil induces alternating current in another, often sharing the same iron core. If the primary (input) coil has half as many turns as the secondary (output) coil, the voltage will be doubled, at half the current—assuming hypothetically that the transformer is 100% efficient.

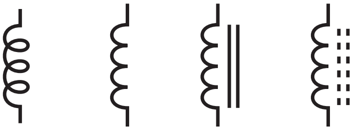

Figure 5-16. *Schematic diagrams represent coils. At far right is the older style. The third and fourth symbols indicate that the coil is wound around a solid or powdered magnetic core, respectively.*

BACKGROUND

Joseph Henry

Born in 1797, Joseph Henry was the first to develop and demonstrate powerful electromagnets. He also originated the concept of "self-inductance," meaning the "electrical inertia" that is a property of a coil of wire.

Henry started out as the son of a day laborer in Albany, New York. He worked in a general store before being apprenticed to a watchmaker, and was interested in becoming an actor. Friends persuaded him to enroll at the Albany Academy, where he turned out to have an aptitude for science. In 1826, he was appointed Professor of Mathematics and Natural Philosophy at the Academy, even though he was not a college graduate and described himself as being "principally self-educated." Michael Faraday was doing similar work in England, but Henry was unaware of it.

Henry was appointed to Princeton in 1832, where he received $1,000 per year and a free house. When Morse attempted to patent the telegraph, Henry testified that he was already aware of its concept, and indeed had rigged a system on similar principles to signal his wife, at home, when he was working in his laboratory at the Philosophical Hall.

Henry taught chemistry, astronomy, and architecture, in addition to physical science, and because science was not divided into strict specialties as it is now, he investigated phenomena such as phosphorescence, sound, capillary action, and ballistics. In 1846, he headed the newly founded Smithsonian Institution as its secretary.

Figure 5-17. *Joseph Henry was an American experimenter who pioneered the investigation of electromagnetism. This photograph is archived in Wikimedia Commons.*

Experiment 26: Tabletop Power Generation

If you have just three components, you can see magnetism generating electricity right in front of you, right now.

You will need:

- Cylindrical neodymium magnet, 3/4-inch diameter, axially magnetized. Quantity: 1. (Obtainable online at sites such as *http://www.kjmagnetics.com*.)
- Spool of hookup wire, 26-gauge, 100 feet. Quantity: 1.
- Spool of magnet wire, quarter-pound, 26-gauge, about 350 feet. Quantity: 1. (Search online for sources for "magnet wire.")
- Generic LED. Quantity: 1.
- 100 µF electrolytic capacitor. Quantity: 1.
- Signal diode, 2N4001 or similar. Quantity: 1.
- Jumper wires with alligator clips on the ends. Quantity: 2.

Procedure

You may be able to make this experiment work with the spool of hookup wire, depending on the size of the spool relative to the size of your magnet, but as the results are more likely to be better with the magnet wire, I'll assume that you're using that—initially, at least. The advantage of the magnet wire is that its very thin insulation allows the coils to be closely packed, increasing their inductance.

First peek into the hollow center of the spool to see if the inner end of the wire has been left accessible, as is visible in Figures 5-18 and 5-19. If it hasn't, you have to unwind the wire onto any large-diameter cylindrical object, then rewind it back onto the spool, this time taking care to leave the inner end sticking out.

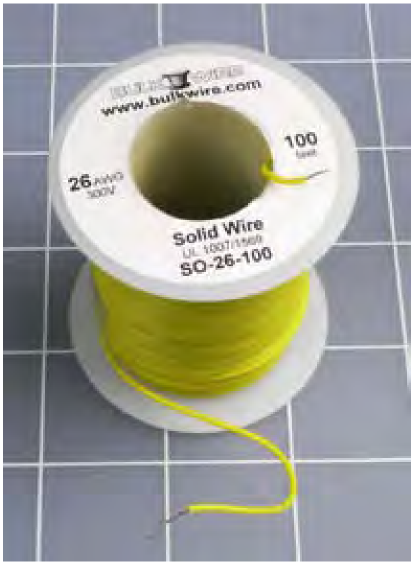

Figure 5-18. *An everyday 100-foot spool of hookup wire is capable of demonstrating the inductive power of a coil.*

Scrape the transparent insulation off each end of the magnet wire with a utility knife or sandpaper, until bare copper is revealed. To check, attach your meter, set to measure ohms, to the free ends of the wire. If you make a good contact, you should measure a resistance of 30 ohms or less.

Place the spool on a nonmagnetic, nonconductive surface such as a wooden, plastic, or glass-topped table. Attach the LED between the ends of the wire using jumper wires. The polarity is not important. Now take a cylindrical neodymium magnet of the type shown in Figure 5-20 and push it quickly down into the hollow core, then pull it quickly back out. See Figure 5-21. You should see the LED blink, either on the down stroke or the up stroke.

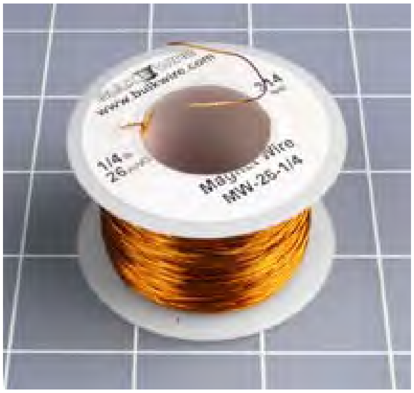

Figure 5-19. *Magnet wire has thinner insulation than hookup wire, allowing the turns to be more densely packed, inducing a more powerful magnetic field.*

The same thing may or may not happen if you use 100 feet of 26-gauge hookup wire. Ideally, your cylindrical magnet should fit fairly closely in the hollow center of the spool. If there's a big air gap, this will greatly reduce the effect of the magnet. Note that if you use a weaker, old-fashioned iron magnet instead of a neodymium magnet, you may get no result at all.

Blood Blisters and Dead Media

Neodymium magnets can be hazardous. They're brittle and can shatter if they slam against a piece of magnetic metal (or another magnet). For this reason, many manufacturers advise you to wear eye protection.

Because a magnet pulls with increasing force as the distance between it and another object gets smaller, it closes the final gap very suddenly and powerfully. You can easily pinch your skin and get blood blisters.

If there's an object made of iron or steel anywhere near a neodymium magnet, the magnet will find it and grab it, with results that may be unpleasant, especially if the object has sharp edges and your hands are in the vicinity. When using a magnet, create a clear area on a nonmagnetic surface, and watch out for magnetic objects underneath the surface. My magnet sensed a steel screw embedded in the underside of a kitchen countertop, and slammed itself into contact with the countertop unexpectedly.

Be aware that magnets create magnets. When a magnetic field passes across an iron or steel object, the object picks up some magnetism of its own. Be careful not to magnetize your watch!

Don't use magnets anywhere near a computer, a disk drive, credit cards with magnetic stripes, cassettes of any type, and other media. Also keep magnets well away from TV screens and video monitors (especially cathode-ray tubes). Last but not least, powerful magnets can interfere with the normal operation of cardiac pacemakers.

Figure 5-20. *Three neodymium magnets, 1/4-, 1/2-, and 3/4-inch in diameter. I would have preferred to photograph them standing half-an-inch apart, but they refused to permit it.*

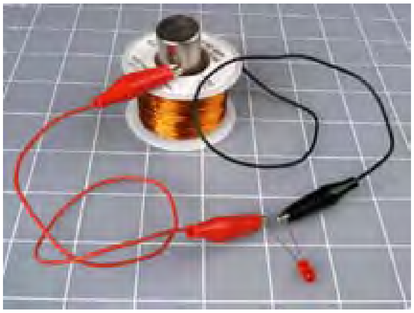

Figure 5-21. *By moving a magnet vigorously up and down through the center of a coil, you generate enough power to make the LED flash brightly.*

Here's another thing to try. Disconnect the LED and connect a 100 μF electrolytic capacitor in series with signal diode, as shown in Figure 5-23. Attach your meter, measuring volts, across the capacitor. If your meter has a manual setting for its range, set it to 20V DC. Make sure the positive (unmarked) side of the diode is attached to the negative (marked) side of the capacitor, so that positive voltage will pass through the capacitor and then through the diode.

Now move the magnet vigorously up and down in the coil. The meter should show that the capacitor is accumulating charge, up to about 10 volts. When you stop moving the magnet, the voltage reading will gradually decline, mostly because the capacitor discharges itself through the internal resistance of your meter.

This experiment is more important than it looks. Bear in mind that when you push the magnet into the coil, it induces current in one direction, and when you pull it back out again, it induces current in the opposite direction. You are actually generating alternating current.

The diode only allows current to flow one way through the circuit. It blocks the opposite flow, which is how the capacitor accumulates its charge. If you jump to the conclusion that diodes can be used to change alternating current to direct current, you're absolutely correct. We say that the diode is "rectifying" the AC power.

Experiment 24 showed that voltage can create a magnet. Experiment 25 has shown that a magnet can create voltage. We're now ready to apply these concepts to the detection and reproduction of sound.

Figure 5-22. *Because inductance increases with the diameter of a coil and with the square of the number of turns, your power output from moving a magnet through the coil can increase dramatically with scale. Those wishing to live "off the grid" may consider this steam-powered configuration, suitable for powering a three-bedroom home.*

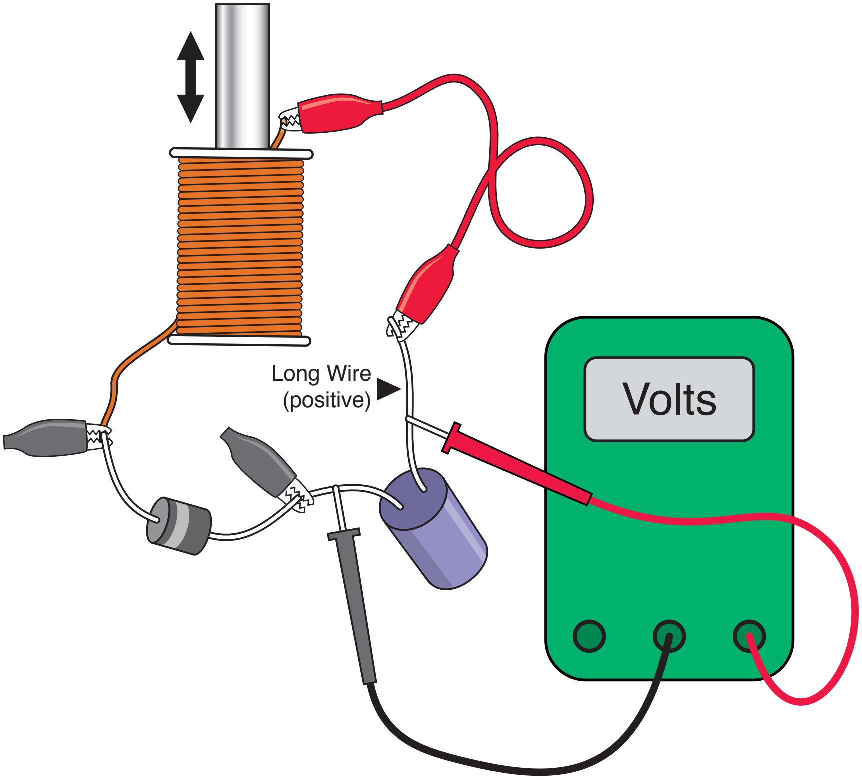

Figure 5-23. *Using a diode in series with a capacitor, you can charge the capacitor with the pulses of current that you generate by moving the magnet through the center of the coil. This demo illustrates the principle of rectifying alternating current.*

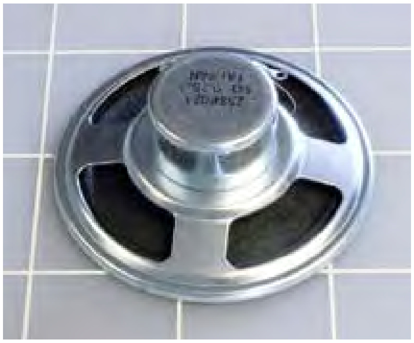

Figure 5-24. *A 2-inch loudspeaker can be instructively destroyed with a utility knife or X-Acto blade.*

Experiment 27: Loudspeaker Destruction

I'd like you to sacrifice a 2-inch loudspeaker, even though it means wasting the $5 or so that it probably costs. Actually, I don't consider this a waste, because if you want to learn how a component works, there's no substitute for actually seeing inside it. You might also have such a speaker already, part of a piece of cast-off personal electronics or toy you have in your basement.

You will need:

- Cheapest possible 2-inch loudspeaker. Quantity: 1. Figure 5-24 shows a typical example.

Procedure

Turn the loudspeaker face-up (as shown in Figure 5-25) and cut around the edge of its cone with a sharp utility knife or X-Acto blade. Then cut around the circular center and remove the ring of black paper that you've created. The result should look like Figure 5-26: you should see the flexible neck of the loudspeaker, which is usually made from a yellow weave. If you cut around its edge, you should be able to pull up the hidden paper cylinder, which has the copper coil of the loudspeaker wound around it. In Figure 5-27, I've turned it over so that it is easily visible. The two ends of this copper coil normally receive power through two terminals at the back of the speaker. When it sits in the groove visible between the inner magnet and the outer magnet, the coil reacts to voltage fluctuations by exerting an up-and-down force in reaction to the magnetic field. This vibrates the cone of the loudspeaker and creates sound waves.

Large loudspeakers in your stereo system work exactly the same way. They just have bigger magnets and coils that can handle more power (typically, as much as 100 watts).

Whenever I open up a small component like this, I'm impressed by the precision and delicacy of its parts, and the way it can be mass-produced for such a low cost. I imagine how astonished the pioneers of electrical theory (such as Faraday and Henry) would be, if they could see the components that we take for granted today. Henry spent days and weeks winding coils by hand to create electromagnets that were far less efficient than this cheap little loudspeaker.

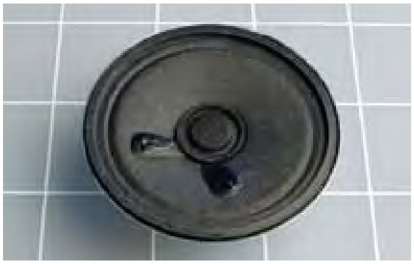

Figure 5-25. *Loudspeaker ready for creative destruction.*

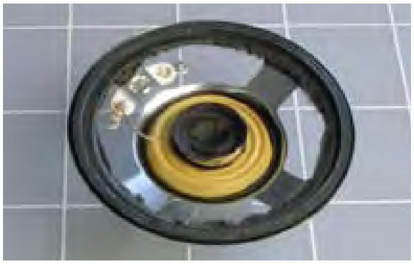

Figure 5-26. *The cone has been removed.*

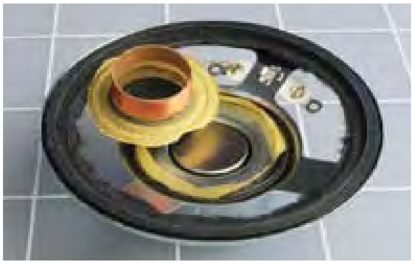

Figure 5-27. *The neck of the cone has been pulled out. Note the coil of copper wire, which fits precisely in the groove between two magnets in the base of the speaker.*

BACKGROUND

Origins of loudspeakers

Loudspeakers utilize the fact that if you run a varying electrical current through a coil situated in a magnetic field, the coil will move in response to the current. This idea was introduced in 1874 by Ernst Siemens, a prolific German inventor. (He also built the world's first electrically powered elevator in 1880.) Today, Siemens AG is one of the largest electronics companies in the world.

When Alexander Graham Bell patented the telephone in 1876, he used Siemen's concept to create audible frequencies in the earpiece. From that point on, sound-reproduction devices gradually increased in quality and power, until Chester Rice and Edward Kellogg at General Electric published a paper in 1925 establishing basic principles that are still used in loudspeaker design today.

At *http://www.radiolaguy.com/Showcase/Gallery-HornSpkr.htm* you'll find photographs of very beautiful early loudspeakers, which used a horn design to maximize efficiency. As sound amplifiers became more powerful, speaker efficiency became less important compared with quality reproduction and low manufacturing costs. Today's loudspeakers convert only about 1% of electrical energy into acoustical energy.

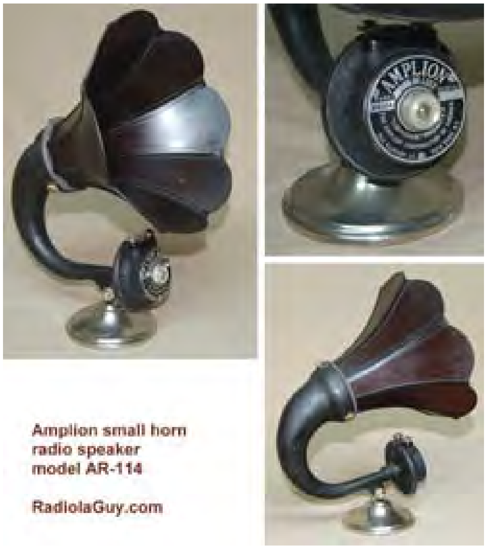

Figure 5-28. *This beautiful Amplion AR-114x illustrates the efforts of early designers to maximize efficiency in an era when the power of audio amplifiers was very limited. Photos by "Sonny, the RadiolaGuy." Many early speakers are illustrated at www.radiolaguy.com. Some are for sale.*

THEORY

Sound, electricity, and sound

Time now to establish a clear idea of how sound is transformed into electricity and back into sound again.

Suppose someone bangs a gong with a stick. The flat metal face of the gong vibrates in and out, creating sound waves. A sound wave is a peak of higher air pressure, followed by a trough of lower air pressure.

The wavelength of the sound is the distance (usually ranging from meters to millimeters) between one peak of pressure and the next peak.

The frequency of the sound is the number of waves per second, usually expressed as hertz.

Suppose we put a very sensitive little membrane of thin plastic in the path of the pressure waves. The plastic will flutter in response to the waves, like a leaf fluttering in the wind. Suppose we attach a tiny coil of very thin wire to the back of the membrane so that it moves with the membrane, and let's position a stationary magnet inside the coil of wire. This configuration is like a tiny, ultra-sensitive loudspeaker, except that instead of electricity producing sound, it is configured so that sound produces electricity. Sound pressure waves make the membrane move to and fro along the axis of the magnet, and the magnetic field creates a fluctuating voltage in the wire.

This is known as a *moving-coil* microphone. There are other ways to build a microphone, but this is the configuration that is easiest to understand. Of course, the voltage that it generates is very small, but we can amplify it using a transistor, or a series of transistors. Then we can feed the output through the coil around the neck of a loudspeaker, and the loudspeaker will recreate the pressure waves in the air. Figures 5-29 through 5-32 illustrate this sequence.

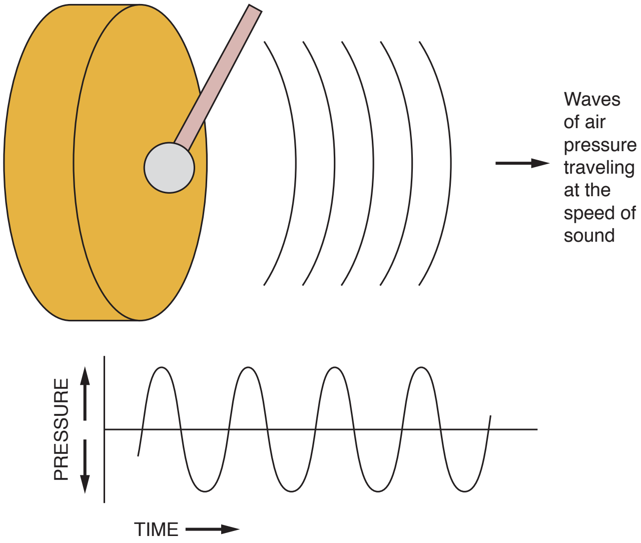

Figure 5-29. *Step 1 in the process of converting sound to electricity, and back again. When the hammer hits the gong, the face of the gong vibrates, creating pressure waves that travel through the air.*

THEORY

Sound, electricity, and sound (continued)

Somewhere along the way, we may want to record the sound and then replay it. But the principle remains the same. The hard part is designing the microphone, the amplifier, and the loudspeaker so that they reproduce the waveforms *accurately* at each step. It's a significant challenge, which is why accurate sound reproduction can be elusive.

Time now to think about what happens inside the wire when it generates a magnetic field. Obviously, some of the power in the wire is being transformed into magnetic force. But just what exactly is going on?

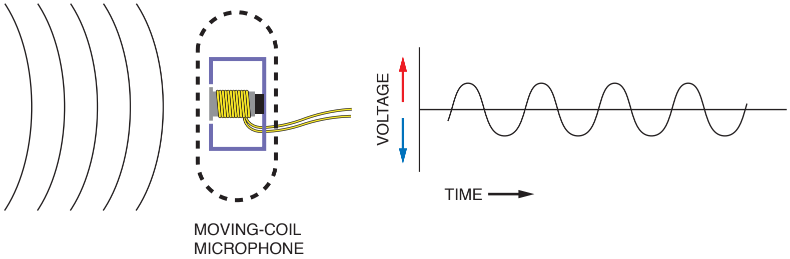

Figure 5-30. *Step 2: the pressure waves penetrate the perforated shell of a microphone and cause a diaphragm to vibrate in sympathy. The diaphragm has a coil attached to it. When the coil vibrates to and fro, a magnet at its center induces alternating current.*

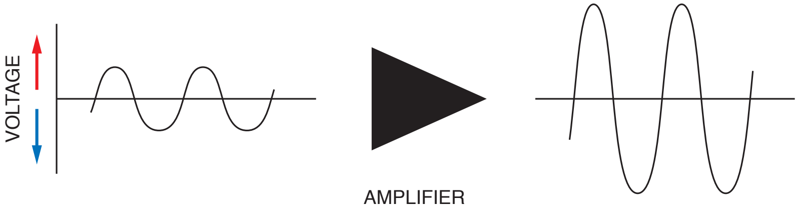

Figure 5-31. *Step 3: the tiny signals from the microphone pass through an amplifier, which enlarges their amplitude while retaining their frequency and the shape of their waveform.*

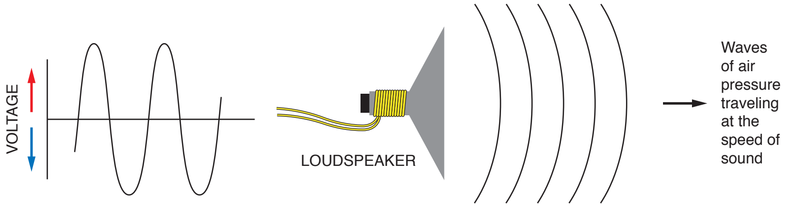

Figure 5-32. *Step 4: the amplified electrical signal is passed through a coil around the neck of a loudspeaker cone. The magnetic field induced by the current causes the cone to vibrate, reproducing the original sound.*

Experiment 28: Making a Coil React

A capacitor will absorb some DC current until it is fully charged, at which point it blocks the flow. There's another phenomenon that I haven't mentioned so far, which is the exact opposite of capacitance. It's known as *self-inductance*, and you find it in any coil of wire. Initially it blocks DC current (it reacts against it), but then its opposition gradually disappears. Here are a few definitions:

Resistance

Constrains current flow and drops voltage.

Capacitance

Allows current to flow initially and then blocks it. This behavior is properly known as capacitive reactance.

Self-Inductance

Blocks the flow of current initially and then allows it. This is also often referred to as *inductive reactance*. In fact, you may find the term "reactance" used as if it means the same thing, but since self-inductance is the correct term, I'll be using it here.

In this experiment, you'll see self-inductance in action.

You will need:

- LEDs, low-current type. Quantity: 2.
- Spool of hookup wire, 26-gauge, 100 feet. Quantity: 1.
- Resistor, 220Ω, rated 1/4 watt or higher. Quantity: 1.
- Capacitor, electrolytic, 2,000 µF or larger. Quantity: 1.
- SPST tactile switch. Quantity: 1.

Procedure

Take a look at the schematic in Figure 5-33. At first it may not make much sense. The curly symbol is a coil of wire—nothing more than that. So apparently the voltage will pass through the 220Ω resistor, and then through the coil, ignoring the two LEDs, because the coil obviously has a much lower resistance than either of them (and one of them is upside-down anyway).

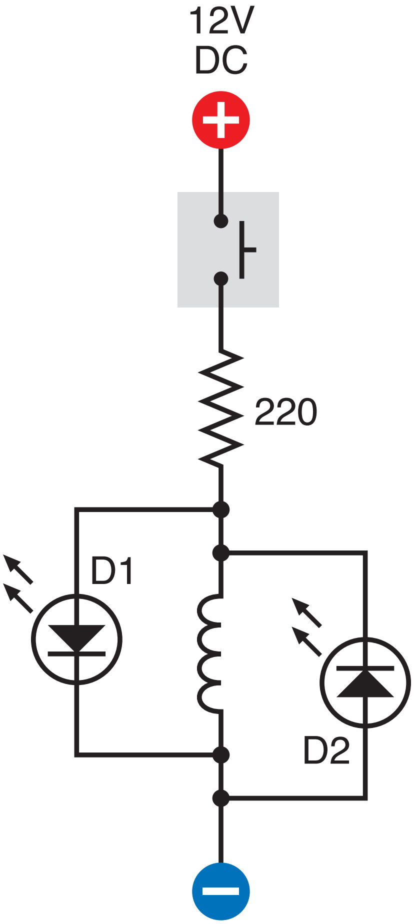

Figure 5-33. *In this demonstration of self-inductance, D1 and D2 are light-emitting diodes. When the switch is closed, D1 flashes briefly because the coil obstructs the initial flow of electricity. When the switch is opened, D2 flashes as the collapsing magnetic field induced by the coil releases another short burst of current.*

Is that what will happen? Let's find out. The coil can be a spool of 100 feet of 26-gauge (or smaller) hookup wire, although the spool of magnet wire listed in Experiment 25 will work better, if you have that. Once again, you will need access to both ends of the wire, and if the inner end is inaccessible, you'll need to rewind the coil, leaving the end sticking out.

Now that you have a coil, you can hook it up on your breadboard as shown in Figure 5-34, where the green circle is a tactile switch and the two circular red objects are LEDs. Make sure that you use low-current LEDs (otherwise, you may not see anything) and make sure that one of them is negative-side-up, positive-side-down and the other is positive-side-up, negative-side-down. Also, the 220Ω resistor should be rated at 1/4 watt or higher, if possible (see the following caution).

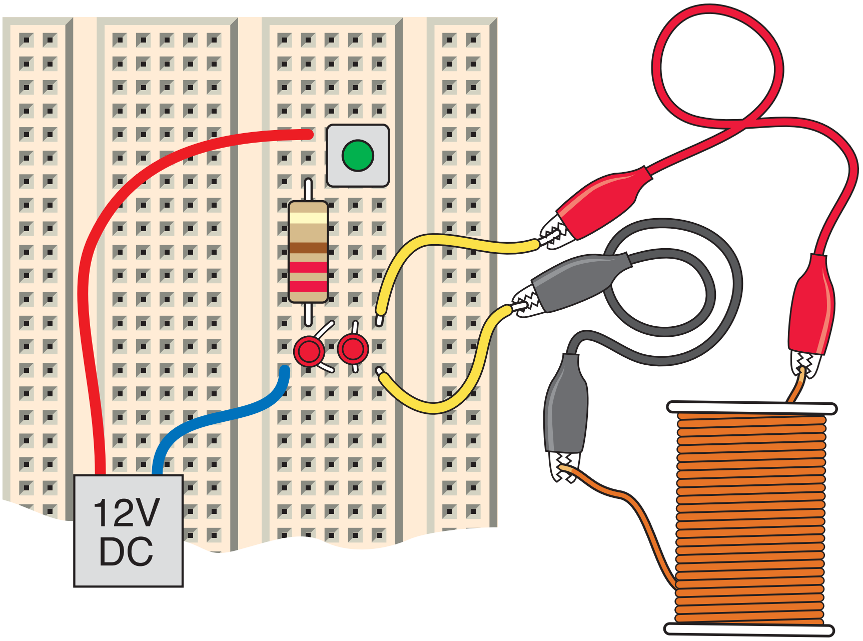

Figure 5-34. *The breadboarded version of the schematic in Figure 5-33 shows a simple way to set it up for a quick demo. The green button is a tactile switch. The two red LEDs should be placed so that the polarity of one is opposite to the polarity of the other.*

When you press the button, one LED should flash briefly. When you release the button, the other LED should flash.

What's happening here? The coil possesses self-inductance, which means that it reacts against any sudden change in the flow of electricity. First it fights it, and during that brief moment, it blocks most of the current. Consequently, the current looks for an alternative path and flows through D1, the lefthand LED in the schematic. (D2 doesn't respond, because it can pass current only in the opposite direction.)

Meanwhile, the voltage pressure overcomes the coil's self-inductance. When the self-inductance disappears, the resistance of the coil is no more than 10 ohms—so now the electricity flows mostly through the coil, and because the LED receives so little, it goes dark.

When you disconnect the power, the coil reacts again. It fights *any* sudden changes. After the flow of electricity stops, the coil stubbornly sustains it for a moment, because as the magnetic field collapses, it is turned back into electricity. This residual flow of current depletes itself through D2, the LED on the right.

In other words, the coil stores some energy in its magnetic field. This is similar to the way a capacitor stores energy between two metal plates, except that the coil blocks the current initially and then lets it build up, whereas the capacitor sucks up current initially, and then blocks it.

The more turns of wire you have in your coil, the more self-inductance the coil will have, causing your LEDs to flash more brightly.

Hot Resistors

You'll be passing about 50mA through the 220Ω resistor, while the current is flowing. At 12 volts, this works out at 0.6 watts. If you use a 1/8-watt resistor, you will be overloading it, and it will get quite hot and may burn out. If you use a 1/4-watt resistor, it will still get hot, but is unlikely to burn out, as long as you don't press the button for more than a second or two.

Don't run the circuit without the coil of wire; you'll be trying to pass more than 50mA through the LEDs.

Here's one last variation on this experiment to test your understanding of electrical fundamentals. Remove the 220Ω resistor, and substitute a 1K resistor (to protect your LED from sustained current). Remove the coil, and substitute a very large capacitor—ideally, about 4,700 µF. (Be careful to get its polarity the right way around.) What will you see when you press the button? Note that you will have to hold it down for a couple of seconds to get a result. And what will you see when you release the button? Remember: the behavior of capacitance is opposite to the behavior of self-inductance.

THEORY

Alternating current concepts

Here's a simple thought experiment. Suppose you set up a 555 timer to send a stream of pulses through a coil. This is a primitive form of alternating current.

We might imagine that the self-inductance of the coil will interfere with the stream of pulses, depending how long each pulse is, and how much inductance the coil has. If the pulses are too short, the self-inductance of the coil will tend to block them. Maybe if we can time the pulses exactly right, they'll synchronize with the time constant of the coil. In this way, we can "tune" a coil to allow a "frequency" to pass through it.

What happens if we substitute a capacitor? If the pulses are too long, compared with the time constant of the capacitor, it will tend to block them, because it will have enough time to become fully charged. But if the pulses are shorter, the capacitor can charge and discharge in rhythm with the pulses, and will seem to allow them through.

I don't have space in this book to get deeply into alternating current. It's a vast and complicated field where electricity behaves in strange and wonderful ways, and the mathematics that describe it can become quite challenging, involving differential equations and imaginary numbers. However, we can easily demonstrate the audio filtering effects of a loudspeaker and a coil.

Experiment 29: Filtering Frequencies

In this experiment, you'll see how self-inductance and capacitance can be used to filter audio frequencies. You're going to build a crossover network: a simple circuit that sends low frequencies to one place and high frequencies to another.

You will need:

- Loudspeaker, 8Ω, 5 inches in diameter. Quantity: 1. Figure 5-35 shows a typical example.
- Audio amplifier, STMicroelectronics TEA2025B or similar. Quantity: 1. See Figure 5-36.

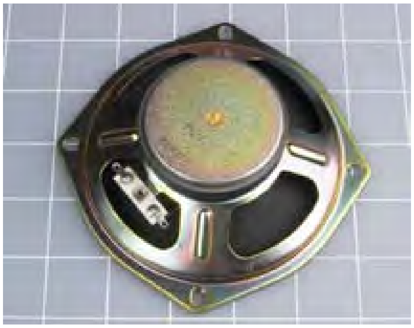

Figure 5-35. *To hear the effects of audio filters using coils and capacitors, you'll need a loudspeaker capable of reproducing lower frequencies. This 5-inch model is the minimum required.*

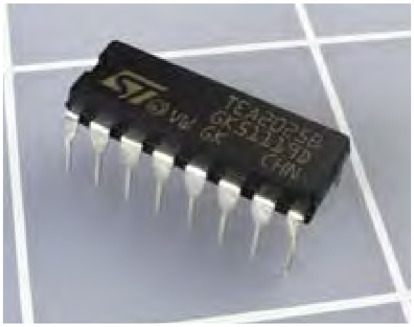

Figure 5-36. *This single chip contains a stereo amplifier capable of delivering a total of 5 watts into an 8Ω speaker when the two channels are combined.*

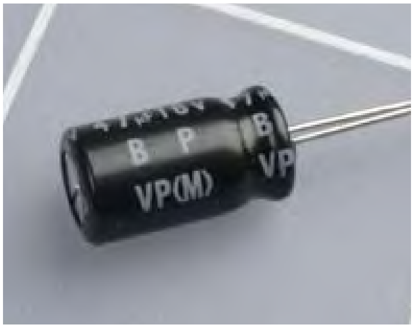

Figure 5-37. *A nonpolarized electrolytic capacitor, also known as a bipolar capacitor, looks just like an electrolytic capacitor, except that it will have "NP" or "BP" printed on it.*

- Nonpolarized electrolytic capacitors (also known as bipolar). 47 µF. Quantity: 2. A sample is shown in Figure 5-37. They should have "NP" or "BP" printed on them to indicate "nonpolarized" or "bipolar."
- Nonpolarized electrolytic capacitors (also known as bipolar). 100 µF. Quantity: 5. (Because you'll be working with audio signals that alternate between positive and negative, you can't use the usual polarized electrolytic capacitors. If you want to avoid the trouble and expense of ordering nonpolarized capacitors, you can substitute two regular electrolytics in series, facing in opposite directions, with their negative sides joined in the middle. Just remember that when you put capacitors in series, their total capacitance is half that of each individual component. Therefore, you would need two 220 µF electrolytics in series to create 110 µF of capacitance. See Figure 5-38.)
- Potentiometer, with audio taper if possible. 100K. Quantity: 1.
- Coil, for crossover network. Quantity: 1. You can search a source such as eBay for keywords "crossover" and "coil," but if you can't find one at a reasonable price, you can make do with a spool of 100 feet of 20-gauge hookup wire.
- Plastic shoebox. Quantity: 1.

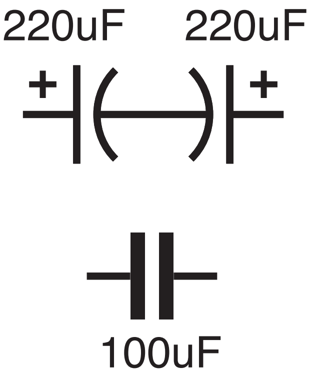

Figure 5-38. *You can make a nonpolarized electrolytic capacitor by putting two regular electrolytics in series. (In fact, that's what you'd find if you opened a real nonpolarized capacitor.) The symbol at the bottom is roughly equivalent to the pair of symbols at the top; bear in mind that two capacitors in series have a total capacitance that is half that of each of them.*

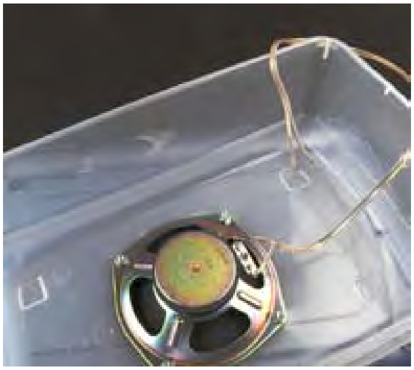

Figure 5-39. *A resonant enclosure is necessary if you want to hear some bass (lower frequencies) from your speaker. A cheap plastic shoebox is sufficient for demo purposes.*

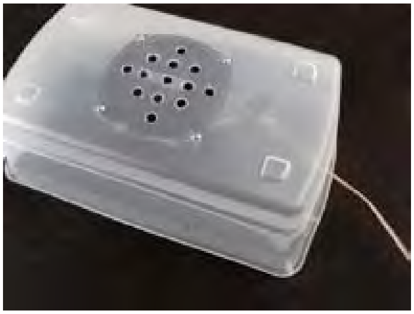

Figure 5-40. *Drill some half-inch holes in the bottom of the box, then bolt the speaker in place, running a wire out through a hole in one end. Snap on the lid, and you're ready for not-quite-high-fidelity audio.*

Procedure

The purpose of the audio amplifier chip is to provide enough power to get a decent amount of sound out of your loudspeaker. The purpose of using a 5-inch speaker is to enable you to hear lower-frequency sounds than the baby speakers that we have used previously. Bass notes have long wavelengths that small speakers are not able to generate effectively.

Maybe you remember from building the intrusion alarm that a speaker makes much more noise if you prevent the sound waves from the back of the cone from cancelling the sound waves from the front of the cone. The obvious way to achieve this is by enclosing the speaker in a box. I suggest a plastic box, because they're cheap, and we don't care too much about sound quality as long as we can hear at least some of the low frequencies. Figure 5-39 shows the speaker bolted into the bottom of a plastic box, and Figure 5-40 shows the box turned upside-down after snapping its lid into place.

Normally, a speaker should be mounted in a cabinet of heavy, thick material that has a very low resonant frequency—below the limits of human hearing. To minimize the resonance of the shoebox, you can put some soft, heavy fabric inside it before you snap the lid on. A hand towel or some socks should be sufficient to absorb some of the vibration.

Adding an Amplifier

Back in the 1950s, you needed vacuum tubes, transformers, and other power-hungry heavyweight components to build an audio amplifier. Today, you can buy a chip for about $1 that will do the job, if you add a few capacitors around it, and a volume control. The TEA2025B that I'm recommending is intended for use in cheap portable cassette players and CD players, and can work in stereo or mono mode, from a power supply ranging from 3 to 9 volts. With 9 volts and the two sides of the chip bridged together to drive one 8Ω speaker, it can generate 5 watts of audio power. That doesn't sound much compared with a typical home theater system rated at 100 watts per channel, but because loudness is a logarithmic scale, 5 watts will be quite enough to irritate any family members in the same room—and possibly even in other rooms.

If you can't find the TEA2025B chip, you can use any alternative listed as an audio amplifier. Try to find one that is designed to drive an 8Ω speaker with up to 5 watts in mono mode. Check the manufacturer's data sheet to see where you attach capacitors around it. Note carefully whether some of the capacitors have no polarity marked, even though they have fairly high values, such as 100 µF. These capacitors must function regardless of which way the alternating current is flowing, and I've marked them "NP" in my schematic in Figure 5-41, meaning "nonpolarized." (You may find them identified as "bipolar" or "BP" in parts catalogs.) As noted in the shopping list, you can put two 220 µF capacitors in series, negative-to-negative, to get the same effect as a single 100 µF nonpolarized capacitor.

For this project, it's essential to include the regular 100 µF electrolytic smoothing capacitor across the power supply. Otherwise, the amplifier will pick up and—yes, amplify—small voltage spikes in the circuit.

Input from headphone jack on audio device

Figure 5-41. *The audio amplifier chip should be wired with capacitors around it as shown, "NP" denoting the ones that are not polarized. The acronym "BP," meaning bipolar, is also often used to mean the same thing. The output from pins 2 and 15 of the chip can be passed through a coil or a 10 μF capacitor to demonstrate audio filtering.*

The input shown in the schematic can receive a signal from a typical media player, such as a portable MP3 player, CD player, or cassette player. To connect its headphone jack to the breadboard, you can use an adapter that converts it to a pair of RCA-type audio jacks, and then stick a wire into one of them as shown in Figure 5-42. The wire will connect to the 33K resistor on the breadboard circuit. The chromed neck of the RCA jack (which is sometimes gold-plated, or at least gold-colored) *must* be connected with the negative side of your power supply on the breadboard; otherwise, you won't hear anything. You can ignore the second output on the adapter, because we're working in mono, here, not stereo.

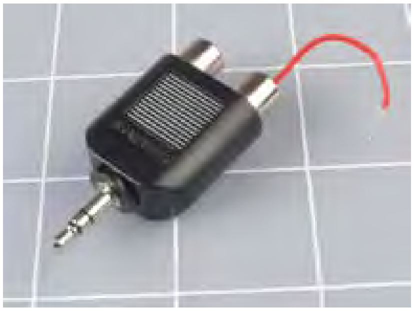

Figure 5-42. *To sample the output from the headphone socket of a music player, you can use this adapter and push the stripped end of a piece of hookup wire into one of the sockets. Then use alligator clips on a jumper wire to connect the audio to your breadboarded circuit. Don't forget to use an additional jumper wire to connect the outside of the socket to the negative side of the power supply on the breadboard. Because we're only using one speaker, the amplifier is connected to only one of the stereo outputs from your player. The other is ignored.*

The 33K resistor is necessary to protect the amplifier from being overdriven. If you don't get enough volume using your music player, decrease the 33K value. If the music is too loud and distorted, increase the value. You can also try omitting or increasing the 10K resistor next to it, which is included in an effort to reduce background hum noise.

I've shown two switches at the top of the schematic: one to bypass a coil, the other to bypass a capacitor. You can use alligator clips instead, as long as you can easily compare the sound when each of the components is inserted into the circuit.

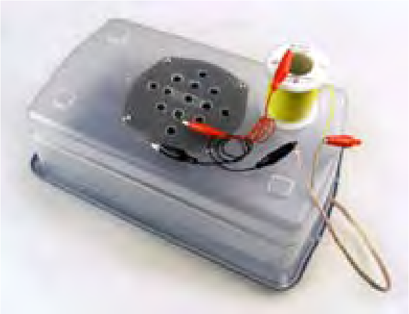

Figure 5-43. *The red and black alligator clips, lying on top of the shoebox, should connect with the output from your amplifier chip. The red jumper wire passes the signal through a coil of hookup wire on its way to the speaker. Note the change in sound when you short out the coil.*

Figure 5-43 shows a coil consisting of a spool of hookup wire being used. The red and black alligator clips resting loose on top of the shoebox will go to the output from the chip (on pins 2 and 15). There is no polarity; it doesn't matter which clip goes to which pin.

Begin by turning the volume control on your music source *all the way down* before you apply power. Don't be surprised if you hear humming or crackling noises when you activate the amplifier; it will pick up any stray voltages, because in this simple experiment, I haven't suggested that you should shield the input, and the amplifier circuit can pick up noise, as its wires can act like antennas.

Note that you may also get additional unwanted sound if you use the amplifier on a conductive desktop surface. Remove any aluminum foil or conductive foam for this project.

Make sure that your player is playing music, and slowly turn up its volume control until you hear it. If you don't hear anything, you'll have to check for circuit errors.

Now comes the interesting part. Insert the 100-foot spool of hookup wire between one output from the amplifier, and one input of the speaker (it doesn't matter which one), or if you used switches, open the switch that bypasses the coil. You should find that the music loses all its high-end response. By comparison, if you disconnect the coil and substitute a 10 µF capacitor, you should find that the music sounds "tinny," meaning that it loses all its low range, leaving only the high frequencies.

You've just tested two very simple filters. Here's what they are doing:

- The coil is a low-pass filter. It passes low frequencies but blocks high frequencies, because brief audio cycles don't have time to overcome the coil's self-inductance. A bigger coil eliminates a wider range of frequencies.
- The capacitor is a high-pass filter. It passes high frequencies and blocks low frequencies because longer audio cycles can fill the capacitance, at which point the capacitor stops passing current. A smaller capacitor eliminates a wider ranger of frequencies.

You can go a lot farther into filter design, using complex combinations of coils and capacitors to block frequencies at any point in the audible spectrum. Search online for audio filter schematics—you'll find hundreds of them.

Crossover Networks

In a traditional audio system, each speaker cabinet contains two drivers—one of them a small speaker called a *tweeter*, which reproduces high frequencies, the other a large speaker known as a *woofer*, which reproduces low frequencies. (Modern systems often remove the woofer and place it in a separate box of its own that can be positioned almost anywhere, because the human ear has difficulty sensing the direction of low-frequency sounds.)

The schematic that you just looked at and may have constructed is known as a "crossover network," and truly hardcore audiophiles have been known make their own (especially for use in car systems) to go with speakers of their choice in cabinets that they design and build themselves.

If you want to make a crossover network, you should use high-quality polyester capacitors (which have no polarity, last longer than electrolytics, and are better made) and a coil that has the right number of turns of wire and is the right size to cut high frequencies at the appropriate point. Figure 5-44 shows a polyester capacitor.

Figure 5-45 shows an audio crossover coil that I bought on eBay for $6. I was curious to find out what was inside it, so I bought two of them, and took one apart.

First I peeled away the black vinyl tape that enclosed the coil. Inside was some typical magnet wire—copper wire thinly coated with shellac or semitransparent plastic, as shown in Figure 5-46. I unwound the wire and counted the number of turns. Then I measured the length of the wire, and finally used a micrometer to measure the diameter of the wire, after which I checked online to find a conversion from the diameter in mils (1/1,000 of an inch) to American wire gauge.

As for the spool, it was plain plastic with an air core—no iron or ferrite rod in the center. Figure 5-47 shows the spool and the wire.

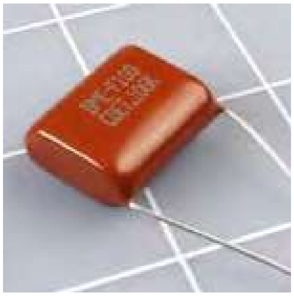

Figure 5-44. *Some nonelectrolytic capacitors have no polarity, such as this high-quality polyester film capacitor. However, they tend to be much more expensive, and are hard to find in values higher than 10 μF.*

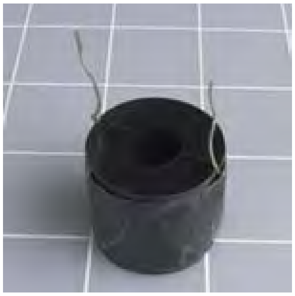

Figure 5-45. *What exotic components may we find inside this high-end audio component that's used with a subwoofer to block high frequencies?*

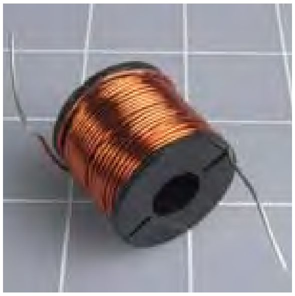

Figure 5-46. *The black tape is removed, revealing a coil of magnet wire.*

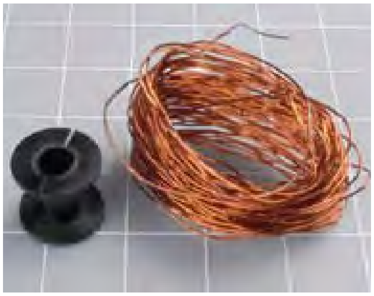

Figure 5-47. *The audio crossover coil consists of a plastic spool and some wire. Nothing more.*

So here's the specification for this particular coil in an audio crossover network. Forty feet of 20-gauge copper magnet wire, wrapped in 200 turns around a spool of 1/16–inch-thick plastic with a hub measuring 7/8 inch in length between the flanges and 1/2-inch external diameter. Total retail cost of materials if purchased separately: probably about $1, assuming you can find or make a spool of the appropriate size.

Conclusion: there's a lot of mystique attached to audio components. They are frequently overpriced, and you can make your own coil if you start with these parameters and adjust them to suit yourself.

Suppose you want to put some thumping bass speakers into your car. Could you build your own filter so that they only reproduce the low frequencies? Absolutely—you just need to wind a coil, adding more turns until it cuts as much of the high frequencies as you choose. Just make sure the wire is heavy enough so that it won't overheat when you push 100 or more audio watts through it.

Here's another project to think about: a color organ. You can tap into the output from your stereo and use filters to divide audio frequencies into three sections, each of which drives a separate set of colored LEDs. The red LEDs will flash in response to bass tones, yellow LEDs in response to the mid-range, and green LEDs in response to high frequencies (or whatever colors you prefer). You can put signal diodes in series with the LEDs to rectify the alternating current, and series resistors to limit the voltage across the LEDs to, say, 2.5 volts (when the music volume is turned all the way up). You'll use your meter to check the current passing through each resistor, and multiply that number by the voltage drop across the resistor, to find the wattage that it's handling, to make sure the resistor is capable of dissipating that much power without burning out.

Audio is a field offering all kinds of possibilities if you enjoy designing and building your own electronics.

THEORY

Waveforms

If you blow across the top of a bottle, the mellow sound that you hear is caused by the air vibrating inside the bottle, and if you could see the pressure waves, they would have a distinctive profile.

If you could slow down time and draw a graph of the alternating voltage in any power outlet in your house, it would have the same profile.

If you could measure the speed of a pendulum swinging slowly to and fro in a vacuum, and draw a graph of the speed relative to time, once again it would have the same profile.

That profile is a *sine wave*, so called because you can derive it from basic trigonometry. In a right-angled triangle, the sine of an angle is found by dividing the length of the side opposite the angle by the length of the hypoteneuse (the sloping side of the triangle).

To make this simpler, imagine a ball on a string rotating around a center point, as shown in Figure 5-48. Ignore the force of gravity, the resistance of air, and other annoying variables. Just measure the vertical height of the ball and divide it by the length of the string, at regular instants of time, as the ball moves around the circular path at a constant speed. Plot the result as a graph, and there's your sine wave, shown in Figure 5-49. Note that when the ball circles below its horizontal starting line, we consider its distance negative, so the sine wave becomes negative, too.

Why should this particular curve turn up in so many places and so many ways in nature? There are reasons for this rooted in physics, but I'll leave you to dig into that topic if it interests you. Getting back to the subject of audio reproduction, what matters is this:

- Any sound can be broken down into a mixture of sine waves of varying frequency and amplitude.

Or, conversely:

- If you put together the right mix of audio sine waves, you can create *any sound at all*.

Suppose that there are two sounds playing simultaneously. Figure 5-50 shows one sound as a red curve, and the other as pale blue. When the two sounds travel either as pressure waves through air or as alternating electric currents through a wire, the amplitudes of the waves are added together to make the more complex curve, which is shown in black. Now try to imagine dozens or even hundreds of different frequencies being added together, and you have an idea of the complex waveform of a piece of music.

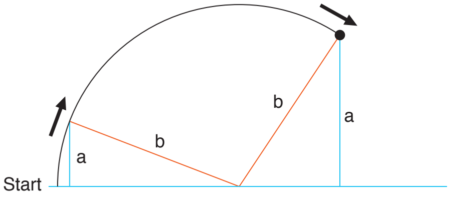

Figure 5-48. *If a weight on the end of a string (length b, in the diagram) follows a circular path at a steady speed, the distance of the weight from a horizontal center line (length a, in the diagram) can be plotted as a graph relative to time. The graph will be a sine wave, so called because in basic trigonometry, the ratio of a/b is the sine of the angle between line b and the horizontal baseline, measured at the center of rotation. Sinewaves occur naturally in the world around us, especially in audio reproduction and alternating current.*

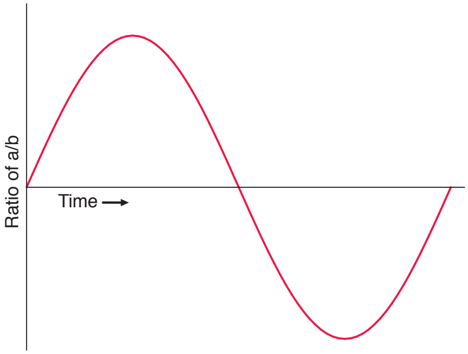

Figure 5-49. *This is what a "pure" sinewave looks like.*

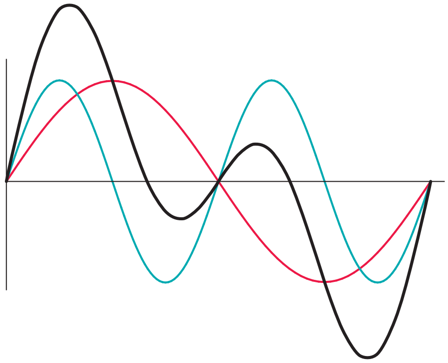

Figure 5-50. *When two sinewaves are generated at the same time (for instance, by two musicians, each playing a flute), the combined sound creates a compound curve. The blue sinewave is twice the frequency of the red sinewave. The compound curve (black line) is the sum of the distances of the sinewaves from the baseline of the graph.*

THEORY

Waveforms (continued)

You can create your own waveform as an input for your audio amplifier with the basic astable 555 timer circuit shown in Figure 5-51. You have to be careful, though, not to overload the amplifier input. Note the 680K series resistor on the output pin of the timer. Also note the 500Ω potentiometer.

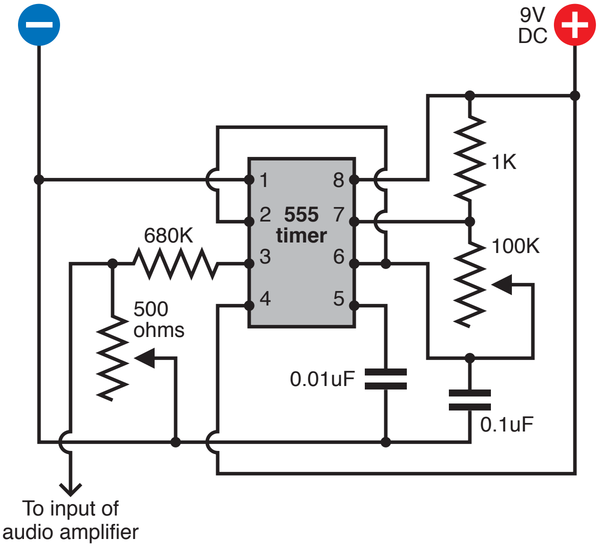

Figure 5-51. *A 555 timer is wired in astable mode using the component values shown here to generate a wide range of audible frequencies when the 100K potentiometer is adjusted. After the output is reduced in power, it can feed into the amplifier chip that was used previously.*

Disconnect your music player and connect the output from the 555 circuit to the input point (the 33K resistor) in the amplifier circuit shown earlier in Figure 5-41. You don't have to worry about a separate connection on the negative side as long as the 555 timer shares the same breadboard and the negative side of its power supply.

Make sure that the 500Ω potentiometer is turned all the way to short the output from the timer to the negative side of the power supply. This functions as your volume control. Also make sure the 100K potentiometer is in the middle of its range. Switch on the power and slowly turn up the 500Ω potentiometer until you hear a tone.

Now adjust the 100K potentiometer to create a low-pitched note. You'll find that it doesn't have a "pure" sound. There are some buzzing overtones. This is because the 555 timer is generating square waves such as those shown in Figure 5-52, not sine waves, and a square wave is actually a sum of many different sine waves, some of which have a high frequency. Your ear hears these harmonics, even though they are not obvious when you look at a square-shaped waveform.

Route one of the connections to your loudspeaker through your spool of hookup wire, and now you should hear a much purer tone, as the buzzing high frequencies are blocked by the self-inductance of the coil. Remove the coil and substitute the 10 µF capacitor, and now you hear more buzzing and less bass.

You've just taken a small step toward sound synthesis. If this subject interests you, you can go online and search for oscillator circuits. For a thorough understanding of the relationship between waveforms and the sounds you hear, you'll really need an oscilloscope, which will show you the shape of each waveform that you generate and modify.

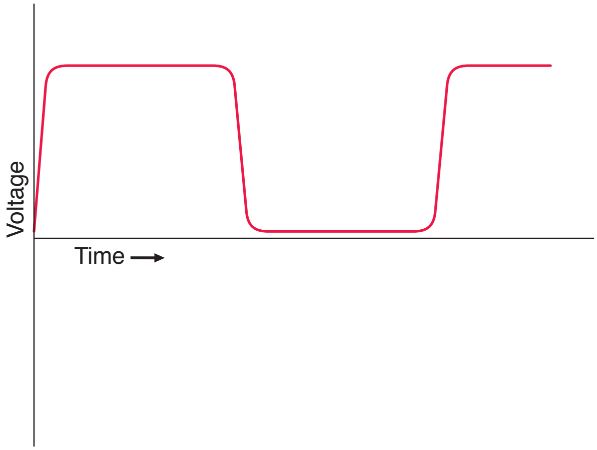

Figure 5-52. *The output from a 555 timer is either "on" or "off," with a very fast transition between those two states. The result is an almost perfect square wave. Theoretically, this can be disassembled into a complex set of sine waves that have many different frequencies. The human ear hears the high frequencies as harsh overtones.*

Experiment 30: Fuzz

Let's try one more variation on the circuit in Experiment 28. This will demonstrate another fundamental audio attribute: distortion.

You will need:

- One more 100K potentiometer.
- Generic NPN transistors: 2N2222 or similar. Quantity: 2.
- Various resistors and capacitors.

BACKGROUND

Clipping

In the early days of "hi-fi" sound, engineers labored mightily to perfect the process of sound reproduction. They wanted the waveform at the output end of the amplifier to look identical with the waveform at the input end, the only difference being that it should be bigger, so that it would be powerful enough to drive loudspeakers. Even a very slight distortion of the waveform was unacceptable.

Little did they realize that their beautifully designed tube amplifiers would be abused by a new generation of rock guitarists whose intention was to create as much distortion as possible.

The most common form of waveform abuse is technically known as "clipping." If you push a vacuum tube or a transistor to amplify a sine wave beyond the component's capabilities, it "clips" the top and bottom of the curve. This makes it look more like a square wave, and as I explained in the section on waveforms, a square wave has a harsh, buzzing quality. For rock guitarists trying to add an edge to their music, the harshness is actually a desirable feature.

Figure 5-53. *This Vox Wow-Fuzz pedal was one of the early stomp boxes, which deliberately induced the kind of distortion that audio engineers had been trying to get rid of for decades.*

The first gadget to offer this on a commercial basis was known as a "fuzz box," which deliberately clipped the input signal. An early fuzz box is shown in Figure 5-53. The clipping of a sine wave is shown in Figure 5-54.

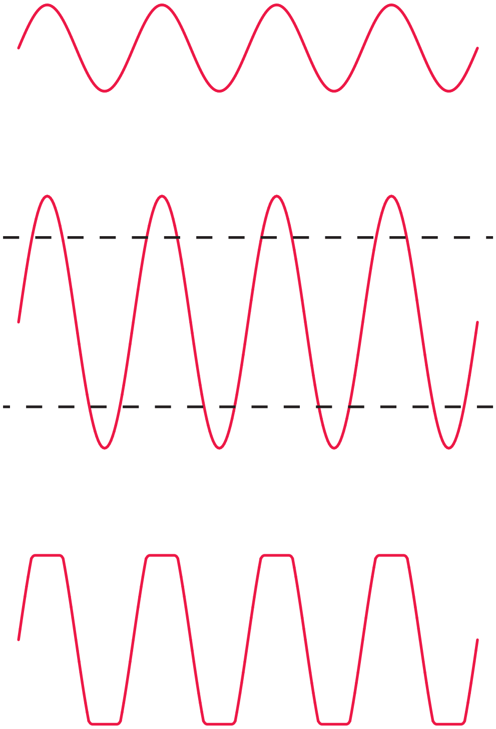

Figure 5-54. *When a sinewave (top) is passed through an amplifier which is turned up beyond the limit of its components (shown as dashed lines, center), the amplifier chops the wave (bottom) in a process known as "clipping." The result is close to a square wave and is the basic principle of a fuzz box commonly used to create a harsh guitar sound.*

Schematic

The output from the 555 timer is a square wave, so it already sounds quite "fuzzy," but we can make it more intense to demonstrate the clipping principle. I've redrawn the whole circuit in Figure 5-55, as several components have changed. The principal alteration is the addition of two NPN transistors.

If you assemble this circuit on your breadboard, note carefully that the 33K and 10K resistors at the bottom of the amplifier chip have been removed, and there's now just an 820Ω resistor in that location. The bottom of the adjacent 0.22 µF capacitor is still the input point for the amplifier, and if you follow the connection around to the middle of the schematic, you'll find it leading to a 100K potentiometer. This is your "fuzz adjuster."

The two NPN transistors are arranged so that the one on the left receives output from the 555 timer. This signal controls the flow of electricity through the transistor from a 33K resistor. This flow, in turn, controls the base of the righthand transistor, and the flow of current through that is what ultimately controls the amplifier.

When you power up the circuit, use the 100K potentiometer attached to the 555 timer to adjust the frequency (as before) and crank the "fuzz adjuster" potentiometer to hear how it adds increasing "bite" to the sound until ultimately it becomes pure noise.

The two transistors act as amplifiers. Of course, we didn't need them for that purpose—the input level for the amplifier chip was already more than adequate. The purpose of the lefthand transistor is simply to overload the righthand transistor, to create the "fuzz" effect. And when you turn up the output from the transistors with the "fuzz adjuster," eventually they overload the input of the amplifier chip, creating even more distortion.

If you want to tweak the output, try substituting different values for the 1K resistor and the 1 µF capacitor that are positioned between the emitter of the righthand transistor and the negative side of the power supply. A larger resistor should overload the transistor less. Different capacitor values should make the sound more or less harsh.

You can find literally thousands of schematics online for gadgets to modify guitar sound. The circuit I've included here is one of the most primitive. If you want something more versatile, you should search for "stomp box schematics" and see what you can find.

Figure 5-55. *For a quick demo of clipping, insert a couple of transistors between the output from the 555 timer and the input of the amplifier chip. One transistor overdrives the other, so that when you adjust the potentiometer at the center of the circuit, you hear an increasingly harsh, distorted sound.*

BACKGROUND

Stomp-box origins

The Ventures recorded the first single to use a fuzz box, titled "The 2,000 Pound Bee," in 1962. Truly one of the most awful instrumentals ever made, it used distortion merely as a gimmick and must have discouraged other musicians from taking the concept seriously.

Ray Davies of the Kinks was the first to embody distortion as an integral part of his music. Davies did it initially by plugging the output from one amp into the input of another, supposedly during the recording of his hit "You Really Got Me." This overloaded the input and created clipping—the basic fuzz concept. From there it was a short step to Keith Richards using a Gibson Maestro Fuzz-Tone when the Rolling Stones recorded "(I Can't Get No) Satisfaction" in 1965.

Today, you can find thousands of advocates promoting as many different mythologies about "ideal" distortion. In Figure 5-56, I've included a schematic from Flavio Dellepiane, a circuit designer in Italy who gives away his work (with a little help from Google AdSense) at *http://www.redcircuits.com*. Dellepiane is self-taught, having gained much of his knowledge from electronics magazines such as the British *Wireless World*. In his fuzz circuit, he uses a very high-gain amplifier consisting of three field-effect transistors (FETs), which closely imitate the rounded square-wave typical of an overdriven tube amp.

Dellepiane offers dozens more schematics on his site, developed and tested with a dual-trace oscilloscope, low-distortion sinewave oscillator (so that he can give audio devices a "clean" input), distortion meter, and precision audio volt meter. This last item, and the oscillator, were built from his own designs, and he gives away their schematics, too. Thus his site provides one-stop shopping for home-audio electronics hobbyists in search of a self-administered education.

Before fuzz, there was tremolo. A lot of people confuse this with vibrato, so let's clarify that distinction right now:

- Vibrato applied to a note makes the frequency waver up and down, as if a guitarist is bending the strings.
- Tremolo applied to a note makes its volume fluctuate, as if someone is turning the volume control of a guitar up and down very quickly.

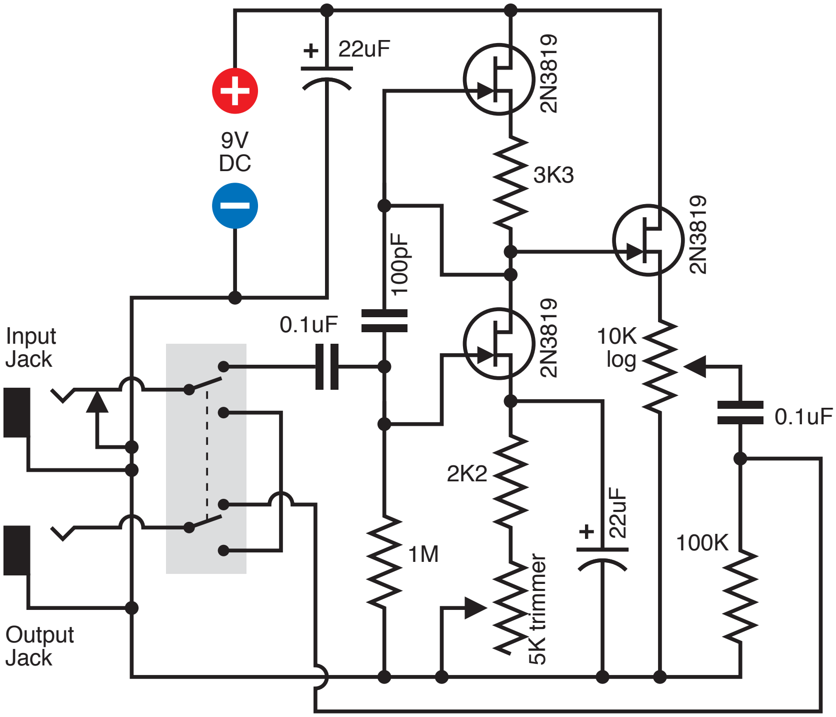

Figure 5-56. *This circuit designed by Flavio Dellepiane uses three transistors to simulate the kind of distortion that used to be created by overloading the input of a tube amplifier.*

BACKGROUND

Stomp-box origins (continued)

Harry DeArmond sold the first tremolo box, which he named the Trem-Trol. It looked like an antique portable radio, with two dials on the front and a carrying handle on top. Perhaps in an effort to cut costs, DeArmond didn't use any electronic components. His steam-punkish Trem-Trol contained a motor fitted with a tapered shaft, with a rubber wheel pressing against it. The speed of the wheel varied when you turned a knob to reposition the wheel up and down the shaft. The wheel, in turn, cranked a little capsule of "hydro-fluid," in which two wires were immersed, carrying the audio signal. As the capsule rocked to and fro, the fluid sloshed from side to side, and the resistance between the electrodes fluctuated. This modulated the audio output.

Today, Trem-Trols are an antique collectible. When industrial designer Dan Formosa acquired one, he put pictures online at *http://www.danformosa.com/dearmond.html*. And Johann Burkard has posted an MP3 of his DeArmond Trem-Trol so you can actually hear it: *http://johannburkard.de/blog/music/effects/DeArmond-Tremolo-Control-clip.html*.

The idea of a mechanical source for electronic sound mods didn't end there. The original Hammond organs derived their unique, rich sound from a set of toothed wheels turned by a motor. Each wheel created a fluctuating inductance in a sensor like the record head from a cassette player.

It's easy to think of other possibilities for motor-driven stomp boxes. Going back to tremolo: imagine a transparent disc masked with black paint, except for a circular stripe that tapers at each end. While the disc rotates, if you shine a bright LED through the transparent stripe toward a light-dependent resistor, you would have the basis for a tremolo device. You could even create never-before-heard tremolo effects by swapping discs with different stripe patterns. Figures 5-57 and 5-58 show the kind of thing I have in mind. For a real fabrication challenge, how about an automatic disc changer?

Today's guitarists can choose from a smorgasbord of effects, all of which can be home-built using plans available online. For reference, try these special-interest books:

- *Analog Man's Guide to Vintage Effects* by Tom Hughes (For Musicians Only Publishing, 2004). This is a guide to every vintage stomp box and pedal you can imagine.
- *How to Modify Effect Pedals for Guitar and Bass* by Brian Wampler (Custom Books Publishing, 2007). This is an extremely detailed guide for beginners with little or no prior knowledge. Currently it is available only by download, from sites such as *http://www.openlibrary.org*, but you may be able to find the previous printed edition from secondhand sellers, if you search for the title and the author.

Of course, you can always take a shortcut by laying down a couple hundred dollars for an off-the-shelf item such as a Boss ME-20, which uses digital processing to emulate distortion, metal, fuzz, chorus, phaser, flanger, tremolo, delay, reverb, and several more, all in one convenient multi-pedal package. Purists, of course, will claim that it "doesn't sound the same," but maybe that's not the point. Some of us simply can't get no satisfaction until we build our own stomp box and then tweak it, in search of a sound that doesn't come off-the-shelf and is wholly our own.

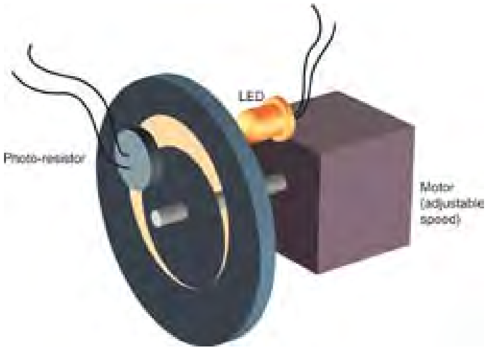

Figure 5-57. *Although electromechanical audio devices are obsolete now, some unexplored possibilities still exist. This design could create various tremolo effects, if anyone had the patience to build it.*

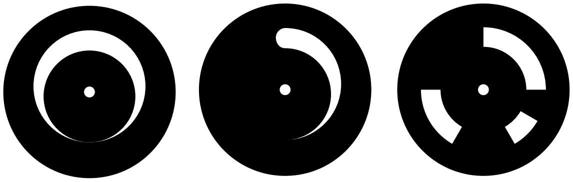

Figure 5-58. *Different stripe patterns could be used in conjunction with the imaginary electromechanical device in Figure 5-57 to create various tremolo effects.*

Experiment 31: One Radio, No Solder, No Power

Time now to go back one more time to inductance and capacitance, and demonstrate an application which also makes use of the way that waveforms can be added to each other. I want to show you how a simple circuit with no power supply at all can receive AM radio signals and make them audible. This is often known as a crystal radio, because the circuit includes a germanium diode, which has a crystal inside it. The idea dates back to the dawn of radio, but if you've never tried it, you've missed an experience that is truly magical.

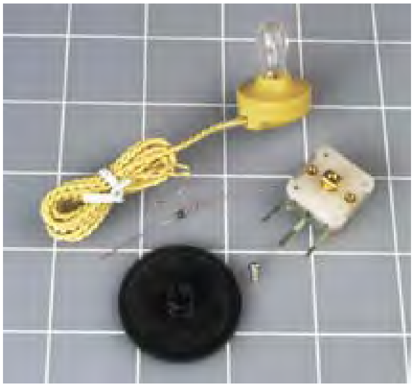

Figure 5-59. *Just add wire and a coil, and this is all you need to receive AM radio signals. The black disc becomes the tuning dial, after it is screwed onto the variable capacitor (right). This is actually an optional extra. A germanium diode (center) rectifies the radio signal. The high-impedance earphone (top) creates a barely audible sound.*

You will need:

- Rigid cylindrical object, such as a vitamin bottle. Quantity: 1.
- 22-gauge hookup wire, solid-core. Quantity: 60 feet.
- 16-gauge wire, stranded. Quantity: 100 feet.
- Polypropylene rope ("poly rope") or nylon rope. Quantity: 10 feet.
- Germanium diode. Quantity: 1.
- High-impedance headphone. Quantity: 1.

The diode and headphone can be ordered from *http://www.scitoyscatalog.com*. You cannot use a modern headphone of the type you wear with an MP3 player.

Some of these items are shown in Figure 5-59.

First, you need to make a coil. It should be about 3 inches in diameter, and you can wind it around any empty glass or plastic container of that size, so long as it's rigid. A soda bottle or water bottle isn't suitable, because the cumulative squeezing force of the turns of wire can deform the bottle so that it isn't circular anymore.

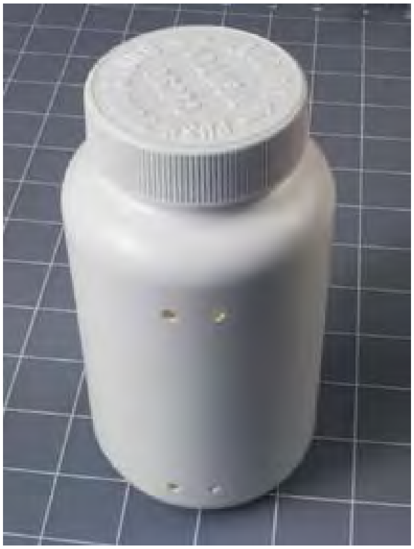

Figure 5-60. *A large, 3-inch diameter empty vitamin bottle makes an ideal core for a crystal radio coil. The drilled holes will anchor wire wrapped around the bottle.*

I chose a vitamin bottle that just happened to be exactly the right size. To remove the label, I softened its adhesive with a heat gun (lightly, to avoid melting the bottle) and then just peeled it off. The adhesive left a residue, which I removed with Xylol (also known as Xylene). This is a handy solvent to have around, as it can remove "permanent" marker stains as well as sticky residues, but you should always use latex or nitrile gloves to avoid getting it on your skin, and minimize your exposure the fumes. Because Xylol will dissolve some plastics, clearly it's not good for your lungs.

After you prepare a clean, rigid bottle, drill two pairs of holes in it, as shown in Figure 5-60. You'll use them to anchor the ends of the coil.

Now you need about 60 feet of 22-gauge solid-core wire. If you use magnet wire, its thin insulation will allow the turns of the coil to be more closely spaced, and the coil may be slightly more efficient. But everyday vinyl-insulated wire will do the job, and is much easier to work with.

Begin by stripping the first 6 inches of insulation from the end of the wire. Now measure 50 inches along the insulated remainder and apply your wire strippers at that point, just enough to cut the insulation without cutting the wire. Use your two thumb nails to pull the insulation apart, revealing about a half-inch of bare wire, as shown in Figure 5-61. Bend it at the center point and twist it into a loop, as shown in Figure 5-62.

You just made a "tap," meaning a point where you will be able to tap into the coil after you wind it. You'll need another 11 of these taps, all of them spaced 50 inches apart. (If the diameter of the bottle that you'll be using as the core of your coil is not 3 inches, multiply its diameter by 16 to get the approximate desired spacing of taps.)

After you have made 12 taps, cut the wire and strip 6 inches off that end. Now bend the end into a U shape about a half-inch in diameter, so that you can hook it through the pair of holes that you drilled at one end of the bottle. Pull the wire through, then loop it around again to make a secure anchor point.

Now wind the rest of the wire around the bottle, pulling it tightly so that the coils stay close together. When you get to the end of the wire, thread it through the remaining pair of holes to anchor it as shown in Figure 5-63. The completed coil is shown in Figure 5-64.

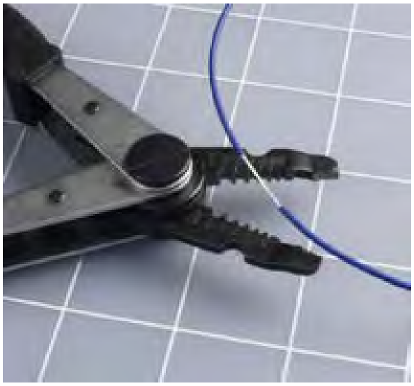

Figure 5-61. *Wire strippers expose the solid conductor at intervals along a 22-gauge wire.*

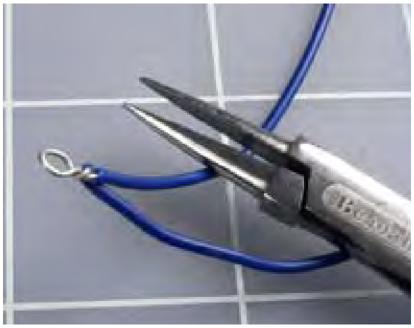

Figure 5-62. *Each exposed section of wire is twisted into a loop using sharp-nosed pliers.*

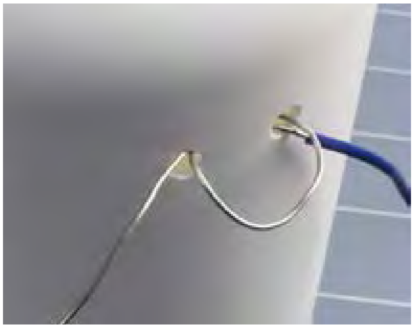

Figure 5-63. *The stripped end of the wire is secured through the holes drilled in the bottle.*

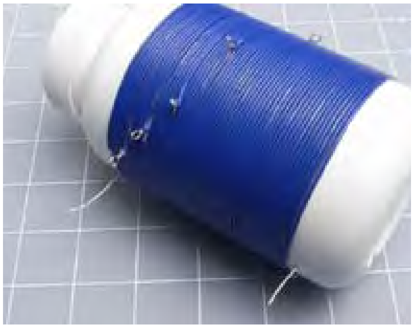

Figure 5-64. *The completed coil, wrapped tightly around the bottle.*

Your next step is to set up an antenna. If you live in a house with a yard outside, this is easy: just open a window, toss out a reel of 16-gauge wire while holding the free end, then go outside and string up your antenna by using polypropylene rope ("poly rope") or nylon rope, available from any hardware store, to hang the wire from any available trees, gutters, or poles. The total length of the wire should be about 100 feet. Where it comes in through the window, suspend it on another length of poly rope. The idea is to keep your antenna wire as far away from the ground or from any grounded objects as possible.

If you live in an apartment where you don't have access to a yard outside, you can try stringing your antenna around the room, hanging the wire from more pieces of poly rope. The antenna should still be about 100 feet long, but obviously it won't be in a straight line.

Hook the free end of your antenna to one end of your coil. At this point, you also need to add a germanium diode, which functions like a silicon-based diode but is better suited to the tiny voltages and currents that we'll be dealing with. The other end of the diode attaches to one of the wires leading to a high-impedance

High Voltage!

The world around us is full of electricity. Normally we're unaware of it, but a thunderstorm is a sudden reminder that there's a huge electrical potential between the ground below and the clouds above.

If you put up an outdoor antenna, never use it if there is any chance of a lightning strike. This can be extremely dangerous. Disconnect the indoor end of your antenna, drag it outside, and push the end of the wire into the ground to make it safe.

earphone. *A normal modern earphone or headphone will not work in this circuit.* The return wire from the headphone is connected to a jumper wire, the other end of which can be clipped to any of the taps in your coil.

One last modification, and you'll be ready to tune in. You have to ground the jumper wire. By this I mean connect it to something that literally goes into the ground. A cold-water pipe is the most commonly mentioned option, but (duh!) this will work only if the pipe is made of metal. Because a lot of plumbing these days is plastic, check under the sink to see if you have copper pipes before you try using a faucet for your ground.

Another option is to attach the wire to the screw in the cover plate of an electrical outlet, as the electrical system in your house is ultimately grounded. But the sure-fire way to get a good ground connection is to go outside and hammer a 4-foot copper-clad grounding stake into reasonably moist earth. Any wholesale electrical supply house should be able to sell you a stake. They're commonly used to ground welding equipment.

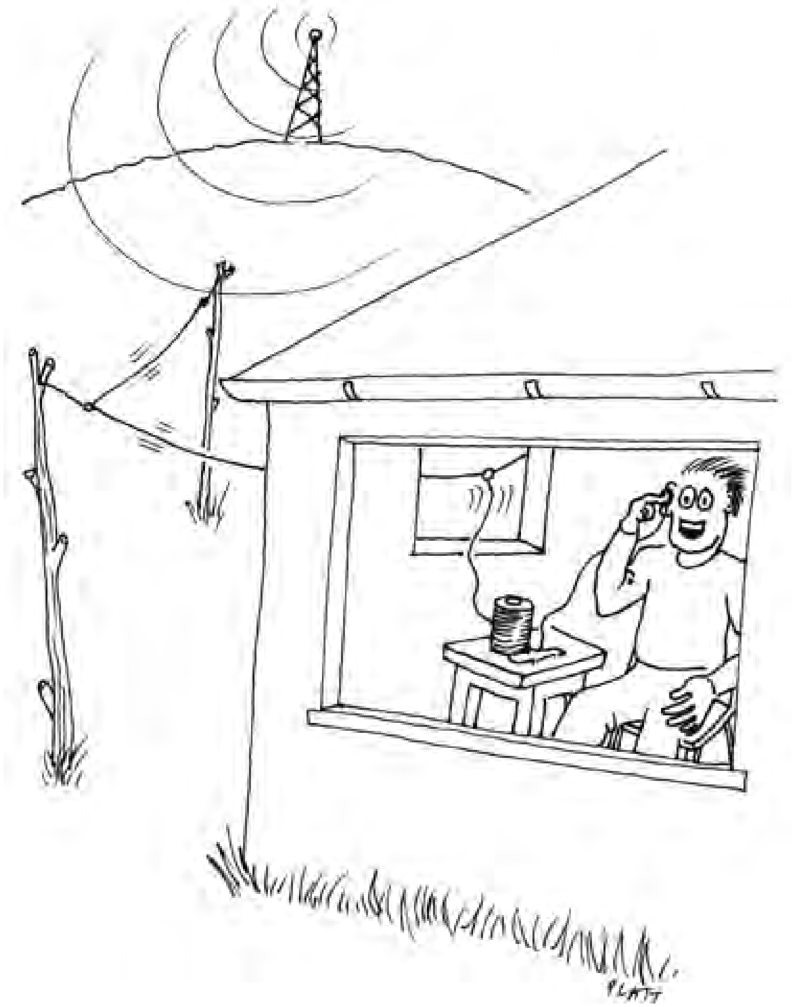

Figure 5-85. *The simple pleasure of picking up a radio signal with ultra-simple components and no additional power.*

Figures 5-66 and 5-67 show the completed radio.

If you've managed to follow these instructions (one way or another), it's time to tune your radio to the nearest station. Move the alligator clip at the end of your patch cord from one tap to another on your coil. Depending on where you live, you may pick up just one station, or several, some of them playing simultaneously.

It may seem that you're getting something for nothing here, as the earphone is making noise without any source of power. Really, though, there is a source of power: the transmitter located at the radio station. A large amplifier pumps power into the broadcasting tower, modulating a fixed frequency. When the combination of your coil and antenna resonates with that frequency, you're sucking in just enough voltage and current to energize a high-impedance headphone.

The reason you had to make a good ground connection is that the radio station broadcasts its signal at a voltage relative to ground. The earth completes the circuit between you and the transmitter. For more information on this and other concepts relating to radio, see the upcoming section "Theory: How radio works."

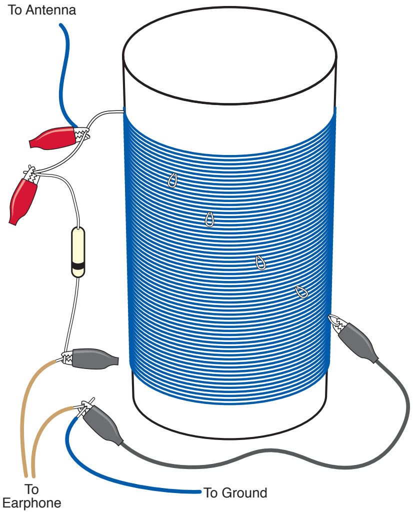

Figure 5-66. *A signal from the antenna can pass through the coil to ground. If the jumper wire is attached to an appropriate tap on the coil, it resonates with the radio signal, just powerfully enough to energize the earphone which is wired in series with a diode.*

Enhancements

The higher your antenna is, the better it should work. In my location, this is a major problem, as I live in a desert area without any trees. Still, just stringing the wire out of my window and tethering it (with rope) to the front bumper of my car enabled me to pick up a faint radio signal.

To improve the selectivity of your radio, you can add a variable capacitor, as shown in the following section. This allows you to "tune" the resonance of your circuit more precisely. Variable capacitors are uncommon today, but you can find one at the same specialty source that I recommended for the earphone and the germanium diode: the Scitoys Catalog (*http://www.scitoyscatalog.com*).

This source is affiliated with a smart man named Simon Quellan Field, whose site suggests many fun projects that you can pursue at home. One of his clever ideas is to remove the germanium diode from your radio circuit and substitute a low-power LED in series with a 1.5-volt battery. This didn't work for me, because I live 40 miles from the nearest AM broadcaster. If you're closer to a transmitter, you may be able to see the LED varying in intensity as the broadcast power runs through it.

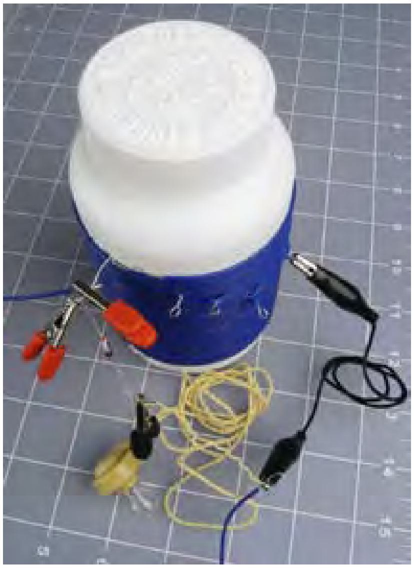

Figure 5-67. *The real-life version of Figure 5-66.*

THEORY

How radio works

When electrical frequencies are very high, the radiation they create has enough energy to travel for miles. This is the principle of radio transmission: A high-frequency voltage is applied to a broadcasting antenna, relative to the ground.

When I say "ground" in this instance, I literally mean the planet beneath us. If you set up a receiving antenna, it can pick up a faint trace of the transmission relative to the ground—as if the earth is one huge conductor. Actually the earth is so large and contains so many electrons, it can function as a common sink, like a gigantic version of the file cabinet that I suggested you should touch to get rid of static electricity in your body before touching a CMOS logic chip.

To make a radio transmitter, I could use a 555 timer chip running at, say, 850 kHz (850,000 cycles per second), and pass this stream of pulses through an amplifier to a transmission tower; if you had some way to block out all the other electromagnetic activity in the air, you could detect my signal and reamplify it.

This was more or less what Marconi (shown in Figure 5-68) was doing in 1901, after he had purchased rights to Edison's wireless telegraphy patent, although he had to use a primitive spark gap, rather than a 555 timer, to create the oscillations. His transmissions were of limited use, because they had only two states: on or off. You could send Morse code messages, and that was all.

Figure 5-68. *Marconi, the great pioneer of radio (photograph from Wikimedia Commons).*

Five years later, the first true audio signal was transmitted by imposing lower audio frequencies on the high-frequency carrier wave. In other words, the audio signal was "added" to the carrier frequency, so that the power of the carrier varied with the peaks and valleys of the audio.

At the receiving end, a very simple combination of a capacitor and a coil detected the carrier frequency out of all the other noise in the electromagnetic spectrum. The values of the capacitor and the coil were chosen so that their circuit would "resonate" at the same frequency as the carrier wave. Figures 5-69 and 5-70 illustrate these concepts.

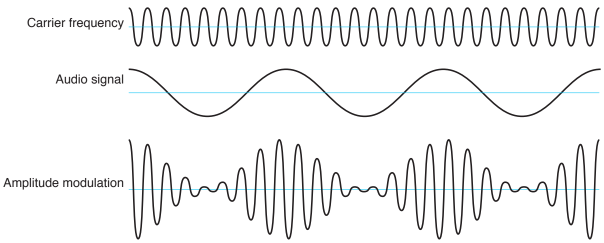

Figure 5-69. *When an audio signal (middle) is combined electronically with a high carrer frequency (top), the result looks something like the compound signal at the bottom. In actuality, the carrier frequency would be much higher compared with the audio frequency, by a radio of perhaps 1,000:1.*

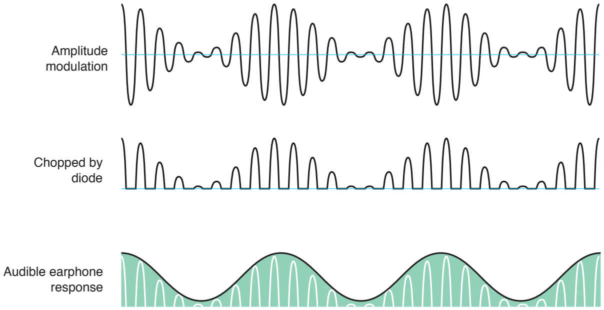

Figure 5-70. *When the compound signal is passed through a diode, only the upper half remains. An earphone cannot react fast enough to reproduce the high carrier frequency, so it "rides" the peaks and thus reproduces the audio frequency.*

The schematic in Figure 5-71 shows the simple circuit that you built by wrapping a coil around an empty vitamin bottle. When a positive pulse was received by the antenna, it resonated with the antenna and the coil, provided that the antenna was long enough and the coil was tapped at the appropriate number of turns.

THEORY

How radio works (continued)

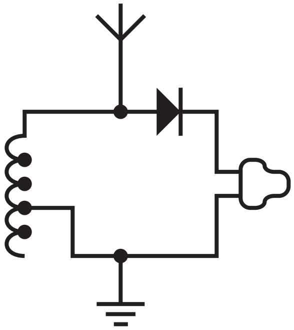

Figure 5-71. *An antenna at the top of the schematic picks up faint electromagnetic radiation from a distant transmitter. The coil at the left side is tapped at intervals so that its resonance can be adjusted to match the carrier frequency of the radio signal. Other frequencies are grounded (at the bottom of the schematic). The diode passes the "top half" of the signal to the earphone at the right, which is incapable of responding fast enough to reproduce the carrier frequency, and thus filters it out, leaving only the audio frequencies that were superimposed on it.*

By adding a capacitor, you can tune the circuit. Now an incoming pulse from the transmitter is initially blocked by the self-inductance of the coil, while it charges the capacitor. If an equally negative pulse is received after an interval that is properly synchronized with the values of the coil and the capacitor, it coincides with the capacitor discharging and the coil conducting. In this way, the right frequency of carrier wave makes the circuit resonate in sympathy. At the same time, audio-frequency fluctuations in the strength of the signal are translated into fluctuations in voltage in the circuit.

What happens to other frequencies pulled in by the antenna? The lower ones pass through the coil to ground; the higher ones pass through the capacitor to ground. They are just "thrown away."

The righthand half of the circuit samples the signal by passing it through a germanium diode and an earphone. The power from the transmitter is just sufficient to vibrate the diaphragm in the earphone, after the diode has subtracted the negative half of the signal.

Look back at the diagram of the amplitude-modulated signal. You'll see that it fluctuates up and down so rapidly, the earphone cannot possibly keep up with the positive-negative variations—hence the need for the diode. It will remain hesitating at the midpoint between the highs and lows, producing no sound at all. The diode solves this problem by subtracting the lower half of the "audio envelope," leaving just the positive spikes of voltage. Although these are still very small and rapid, they are now all pushing the diaphragm of the earphone in the same direction, so that it averages them out, approximately reconstructing the original sound wave.

Figure 5-72 shows how the circuit can be enhanced with a variable capacitor, to tune it without needing to tap the coil at intervals.

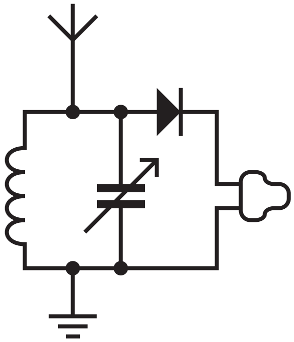

Figure 5-72. *By adding a capacitor to the circuit, its resonance can be tuned more precisely. The diagonal arrow indicates that a variable capacitor is used.*

The radio can pull in the stations on the AM (amplitude-modulated) waveband that happen to be most powerful in your area. The waveband ranges from 300 kHz to 3 MHz. If you find yourself interested in radio, your next step could be to build a powered radio using a couple of transistors. Alternatively you could build your own (legal) low-power AM transmitter. There's an ultra-simple kit available from *http://www.scitoys.com* consisting of just two principal components: a crystal oscillator, and a transformer, shown in Figure 5-73. That's all it takes.

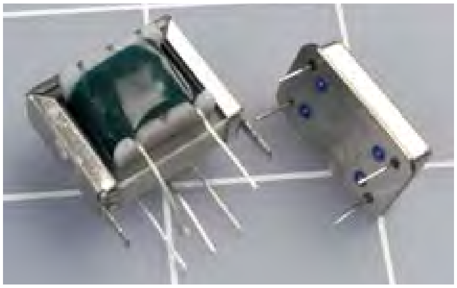

Figure 5-73. *An AM radio transmitter can be made from just two components: a transformer (left) and a crystal oscillator (right), available from http://www.scitoys.com.*

Experiment 32: A Little Robot Cart

Robotics is another application of electronics that deserves a book in itself—or several books. So, once again, I'm going to give you an introduction followed by some points that you can follow if you want to go further. As always, I will start with the simplest possible device, which in the world of robotics is a cart that finds its way around your living room.

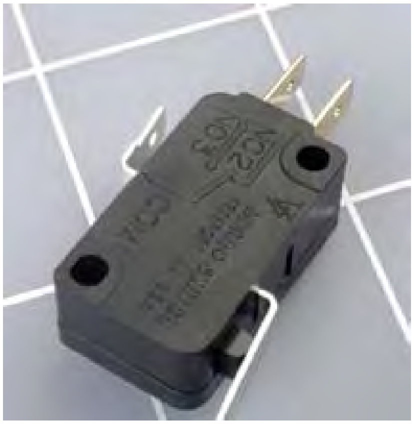

Figure 5-74. *A microswitch has a small button (at the front, righthand side in this picture) that is often actuated by a pivoted metal lever. The switch can respond to a very light pressure, but can handle relatively high currents.*

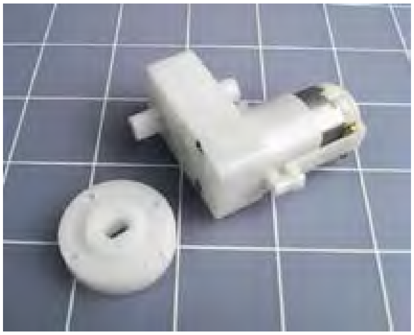

Figure 5-75. *For the Little Robot Cart, I found this 5-volt motor, which is supplied with a disc that fits its output shaft. The combination cost less than $10.*

You will need:

- SPST or SPDT microswitches requiring minimal pressure to activate them. A force between 0.02 and 0.1 newtons would be ideal. Quantity: 2. See Figure 5-74.
- DC gear-motor, rated for any voltage between 5 and 12, drawing a maximum of 100mA in its free-running state, output shaft turning between 30 and 60 RPM. Quantity: 1. A motor is shown in Figure 5-75.
- Disc or arm that fits securely onto your motor shaft. Quantity: 1.
- 555 timer. Quantity: 1.
- DPDT nonlatching relay rated for the same voltage as your motor. Quantity: 1.
- 1/4-inch plywood or plastic, one piece about 2 feet square.
- #4 sheet-metal screws, 5/8 inch or 3/4 inch long. Quantity: 2 dozen.
- #6 bolts, 3/4 inch long, with nylon-insert lock nuts. Quantity: 2 dozen.
- 1/4-inch bolts, 1 inch long, with nuts, to mount the wheels. Quantity: 4.

I'm not specifying one particular motor, because if I did, it might not be available by the time you read this. Motors aren't like logic chips, which have retained their basic function throughout various improvements over a period of several decades. Motors come and go, and many that you may run across will be surplus parts that will never been seen again. Search online for "gearmotor" or "gearhead motor" and find one as close as possible to the specification that I have provided. The mechanical power output of the motor shouldn't be important, because we won't be requiring it to do much work.

The important consideration when you buy your motor is that you should also obtain something that fits onto its output shaft. Typically, this will be a disk or arm that can be screwed into place. To this you can then add a larger wheel of your own, which you can cut with a hole saw or make from the screw-on lid of a jar, or anything else circular that you may find in the house.

A larger wheel will make your cart move faster than a smaller wheel, but will reduce its torque, thus limiting its power to overcome obstacles.

This brings me to my next topic: fabrication. Although this is an electronics book, motors are electromechanical devices, and you have to be able to install them in some kind of a machine to get any interesting results. You can use plywood to complete the two little robotics projects here (ideally, the kind of thin, high-quality plywood sold by hobby stores) but I recommend something that looks better and is easier to work with: ABS plastic. Before you start on the robotic cart, you may want to check the section "Fundamentals: All about ABS."

FUNDAMENTALS

All about ABS

Unless you think the steampunk movement isn't going back far enough, you probably don't want your autonomous robot cart to resemble a relic from before the 1800s. Therefore, wood may not be the best construction material. Metal can look nice, but is not easy to work with. For quick results that have a twentieth-century look (maybe even a 21st-century look), plastic is the obvious choice, and I feel that ABS is the best type of plastic to use, because it provides such quick, easy results. ABS stands for "acrylonitrile butadiene styrene." Lego® blocks are made of ABS. Car-stereo installers and model-railroad buffs use it. You can use it, too. You can saw it, drill it, sand it, whittle it, and drive screws into it, and it won't warp, split, or splinter. It's washable, doesn't need to be painted, and will last almost forever.

Delrin is another type of plastic, but tends to cost more and is a little tougher to drill and cut. It's a matter of personal preference. ABS machines fairly well, but when you drill it, for example, it can "catch" on the bit and the piece will spin with the bit due to the way that plastic chips off with the bit. Delrin is self-lubricating and has better melting properties under the heat of machining, so it drills and cuts much more cleanly and easily than ABS.

Where to find ABS

Pieces of ABS a couple of feet square are available from online sources such as *http://hobbylinc.com* or estreetplastics (an eBay store), but you'll save money if you can truck on down to your nearest plastic supply house and buy it like plywood, in sheets measuring 4 by 8 feet. To discover whether you have a nearby plastic supply house, search for "plastic supply" in your yellow pages or Google Local.

Piedmont Regal Plastics has many supply centers around the nation, but you'll have to collect it yourself, and they may not be willing to cut small pieces. You can check online at *http://www.piedmontplastics.com* for their locations.

Stock colors of ABS include black, white, and "natural," which is beige. Sheets usually are textured on one side, which is the side that should face outward, as it is more scratch-resistant than the smooth side.

Because you won't be adding paint or other finishes, you'll have to be careful not to scuff the plastic or scratch it while working. Clean your bench thoroughly before you begin, taking special care to remove any metal particles, which tend to become embedded in the plastic. Use wooden shims in the jaws of your vise, and avoid resting the plastic accidentally on any sharp tools or screws. Working with ABS requires a clean environment and a very gentle touch.

Cut with Care

You can saw ABS, but if you use a table saw, the plastic will tend to melt and stick to the blade. These smears will get warm and sticky when you feed the next piece of plastic into the saw, and the result will be extremely unpleasant. The whirling blade will grab the plastic and hurl it at you powerfully enough to break bones. This is known as "kickback" and is a very serious risk when sawing plastic.

If you have extensive experience using a table saw, you are actually more vulnerable, because the reflexes and cautions you have developed while dealing with wood will not be adequate for working with plastic. Please take this warning seriously!

Your first and most obvious precaution is to use a plastic-cutting blade, which has a larger number of thicker teeth to absorb the heat. The blade I have used is a Freud 80T, but there are others. If you use a blade that is not suitable, you will see it starting to accumulate sticky smears. This is the only warning you will get. Clean that blade with a solvent such as acetone, and never use it for ABS again.

Regardless of other precautions, always wear gloves and eye protection when using a table saw, and stand to one side when feeding materials into it. Personally, after one episode of kickback that I thought had broken my arm, I prefer not to use a table saw on plastic at all.

For long, straight cuts, the alternatives include:

- *Panel saw (big and expensive, but safe and accurate).*
- *Miniature handheld circular saw with a blade around 4 inches in diameter, guided with a straight edge clamped to the sheet.*
- *Hand saw. This is my old-school preference. My favorite is a Japanese pull-to-cut saw, which makes very clean cuts: the Vaughan Extra-Fine Cross-Cut Bear Saw, 9-1/2 inches, 17 tpi (teeth per inch). If you use one of these, be careful to keep your free hand out of the way, as the saw can easily jump out of the cut. Because it is designed to cut hard materials such as wood, it has no difficulty cutting soft flesh. Gloves are strongly recommended.*

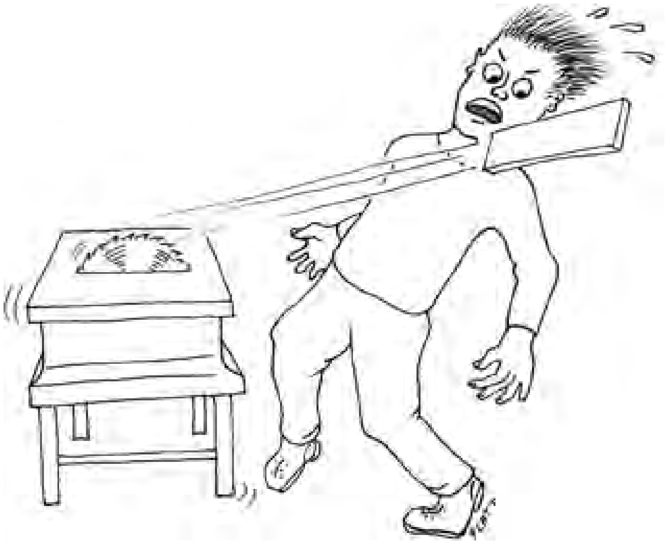

Figure 5-76. *The perils of kickback. Plastic easily sticks to the blade of a table saw, which will hurl it at you unexpectedly. Use other tools to cut plastic.*

Curving Cuts

Curving cuts involve relatively little danger, although eye protection and gloves are still advisable. My preferred tools:

- Band saw with a 3/8- or 1/4-inch blade designed for thin wood or plywood.
- Jigsaw. I have a special liking for the DeWalt XRP using Bosch blades that are designed for hardwood or plastic. This will cut complex curves in ABS as easily as scissors cutting paper.

No matter what type of saw you use, you'll have to clean ragged bits of plastic off the cut afterward, and the absolutely necessary item for this purpose is a deburring tool, available from *http://www.mcmaster.com* and most other online hardware sources. A belt sander or disc sander is ideal for rounding corners, and a metal file can be used to remove bumps from edges that are supposed to be straight.

Figures 5-77 through 5-80 show various cutting tools. Figure 5-81 shows a deburring tool, and Figure 5-82 shows a disc sander.

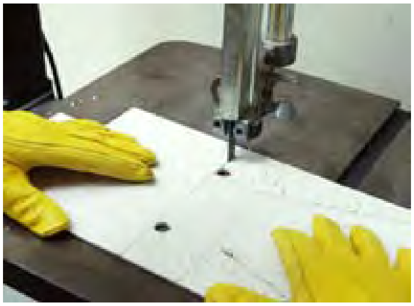

Figure 5-77. *A band saw is an ideal tool for cutting complex shapes out of ABS plastic. You can often find them secondhand for under $200.*

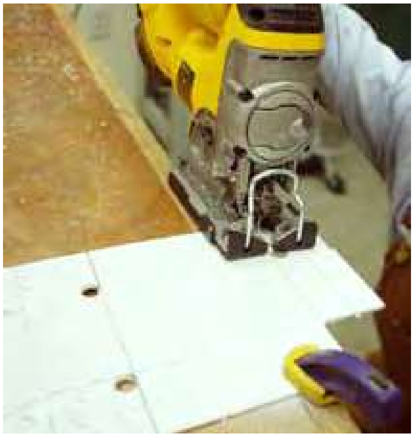

Figure 5-80. *This DeWalt jigsaw can run at very slow speeds, enabling precise and careful work with plastic.*

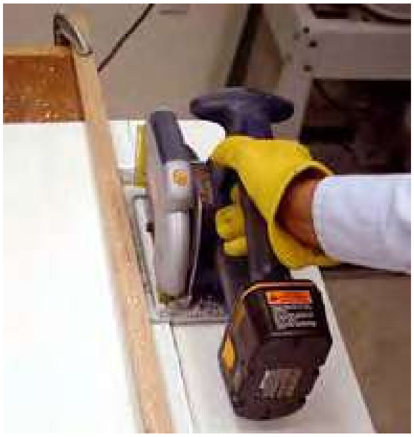

Figure 5-78. *A handheld circular saw, running along a straight-edge, is much safer than a table saw for cutting plastic, and can produce comparable results.*

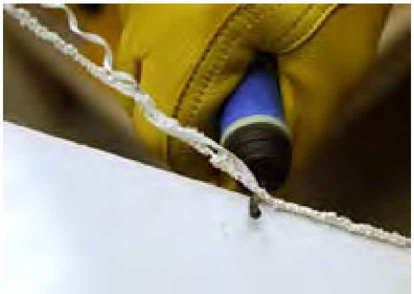

Figure 5-81. *A deburring tool will clean and bevel the sawn edge of a piece of plastic in just a couple of quick strokes.*

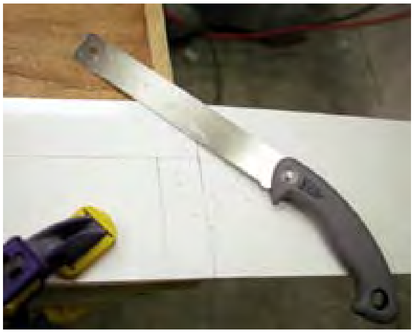

Figure 5-79. *This Japanese-style saw cuts when you pull it, rather than when you push it. After some practice, you can use it to make very accurate cuts. Because ABS is so soft, minimal muscle-power is required.*

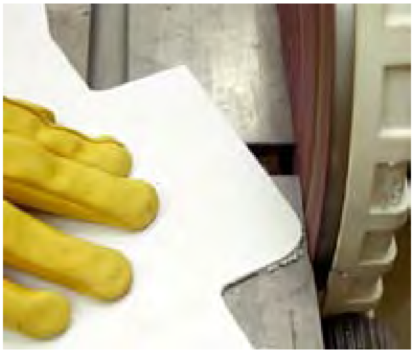

Figure 5-82. *A belt sander or disc sander is the ideal tool for rounding corners when working with ABS plastic.*

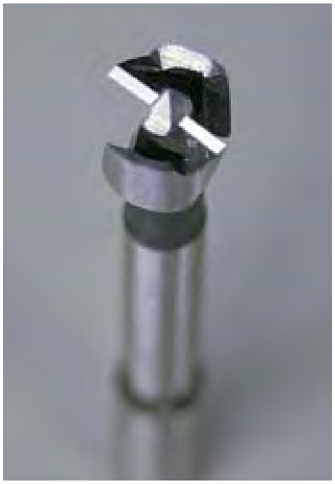

Figure 5-83. *A Forstner drill bit makes clean, precise holes; a large regular drill bit will chew up ABS plastic and make a mess.*

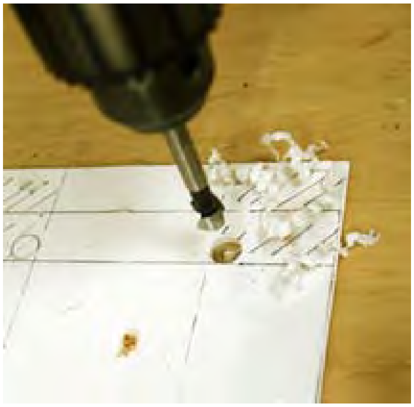

Figure 5-84. *By drilling holes at any location where two bends intersect, you reduce the risk of the plastic fissuring.*

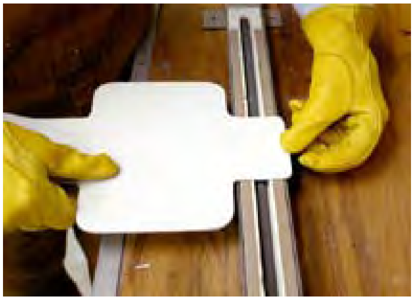

Figure 5-85. *Making clean, precise bends in ABS is simply a matter of resting the plastic over a bender that consists of an electric heating element.*

Making Plans

I like to use drawing software to create plans, and I try to print them at actual scale. I tape them to the smooth side of a piece of white or natural-color ABS, then use an awl to prick through the plan into the soft surface beneath. I remove the paper and connect the awl marks by drawing onto the plastic using a pencil or a fine-point water-soluble pen. Its lines can be wiped away later with a damp cloth. Don't use a permanent marker, as the solvents that you will need to clean it may dissolve the plastic.

Because ABS will tend to open a fissure when you bend it at any inside corner where you don't have a smooth radius, you need to drill holes at these locations, as shown in the cart plans in Figure 5-92 on page 275.

A regular half-inch drill bit is too aggressive; it will tend to jam itself into the plastic within one turn of the drill. Use Forstner bits (shown in Figures 5-83 and 5-84) to cut nice smooth circles.

Note that the heat from bending will tend to make any marks on the plastic permanent.

Bending It

A big advantage of plastic over wood is that you can make complex shapes by bending them, instead of cutting separate pieces and joining them with nails, screws, or glue. Unfortunately, bending does require an appropriate bender: an electric heating element mounted in a long, thin metal enclosure that you place on your workbench. The bender I use is made by FTM, a company that offers all kinds of neat gadgets for working with plastic. Their cheapest bender, shown in Figure 5-85, is just over $200 with a 2-foot element. You can get a 4-foot model for about $50 more. Check them out at *http://thefabricatorssource.com*.

Avoid Burns While Bending

A plastic bender will inflict serious burns if you happen to rest your hand on it accidentally, and because it has no warning light, you can easily forget that you have left it plugged in. Use gloves!

To bend plastic, lay it over the hot element of a plastic bender for a brief time (25 to 30 seconds for 1/8-inch ABS, 40 to 45 seconds for 3/16-inch, and up to a minute for 1/4-inch). If you overheat the plastic, you'll smell it, and when you turn it over you'll find it looks like brown melted cheese. Naturally you should learn to intervene before the plastic reaches that point.

ABS is ready to bend when it yields to gentle pressure. Take it off the bender and bend it *away* from the side that you heated. If you bend it toward the hot side, the softened plastic will bunch up inside the bend, which doesn't look nice.

You can work with it for about half a minute, and when you have it the way you want it, spray or sponge water onto it to make it set quickly. Alternatively, if you need more time, you can reheat it. The amount of force necessary to bend the sheet increases in proportion with the length of the bend, so a long bend can be difficult, and I usually insert it into a loose vise, push it a bit, move it along to the next spot, and push it again.

Because plastic bending is very similar to making shapes in origami, it's a good idea to model your projects in paper before you commit yourself to ABS.

If you decide that you don't want to spend money on a bender, don't abandon plastic just yet—you can use screws to assemble separate sections with greater ease and convenience than if you were working with wood.

Making 90-Degree Joints

Driving screws into the edge of a piece of plywood will almost always separate its layers, but ABS has no layers (or grain, either), and never splits or shatters. This means that you can easily join two pieces at 90° using small screws (#4 size, 5/8-inch long).

Figures 5-86 through 5-90 show the procedure for joining 1/8-inch (or thicker) ABS to 1/4-inch ABS, which I regard as the minimum thickness when you're inserting screws into its edge:

1. Mark a guideline on the thinner piece of plastic, 1/8 inch from its edge. For #4 screws, drill holes using a 7/64-inch bit. If you're using flat-headed screws, countersink the holes very gently.

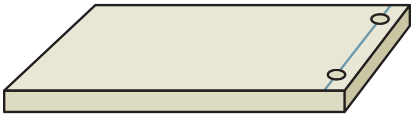

Figure 5-86

2. Hold or clamp the pieces in place and poke a pen or pencil through the holes to mark the edge of the 1/4-inch plastic beneath.
3. Remove the thin plastic, clamp the 1/4-inch plastic in a vise, and drill guide holes for the screws at each mark, centered within the thickness of the plastic. Because ABS does not compress like wood, the holes must be larger than you may expect; otherwise, the plastic will swell around the screw. A 3/32-inch bit is just right for a #4 screw.
4. Assemble the parts. Be careful not to overtighten the screws; it's easy to strip the threads that they cut in the soft plastic.

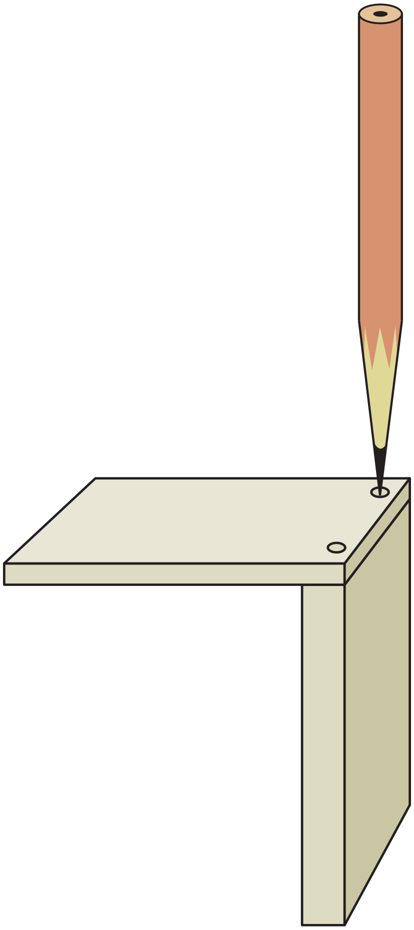

Figure 5-87

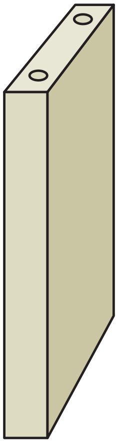

Figure 5-88

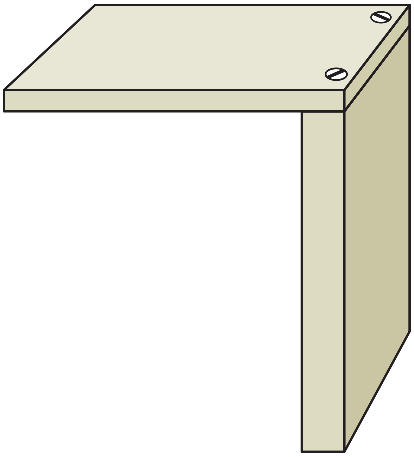

Figure 5-89. *Figures 5-86 through 5-89 illustrate four steps to join two pieces of ABS using #4 sheet-metal screws. Cut 7/64-inch holes on a line 1/8 inch from the edge of the first piece, then mark through the holes to the edge of the second piece. Drill 3/32-inch holes that are precisely centered in the edge, then screw the pieces together.*

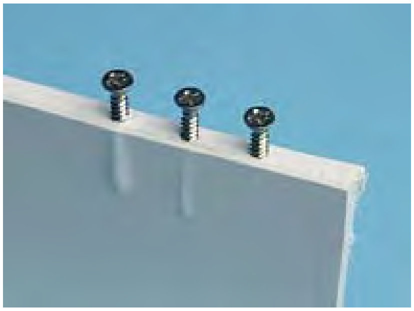

Figure 5-90. *Three #4 screws driven into the edge of ABS, using a 1/16-inch guide hole, a 5/64-inch guide hole, and a 3/32-inch guide hole. respectively Because the first two guides holes were too small, the plastic swelled around the screw (but did not break).*

Framing Your Cart

For reasons that will soon be apparent, I've chosen an unusual diamond-shaped configuration of wheels. In the rendering shown in Figure 5-91, the front wheel (at the far end of the cart) applies power, the rear wheel (at the near end of the cart) steers the cart when backing up, and the side wheels prevent it from falling over.

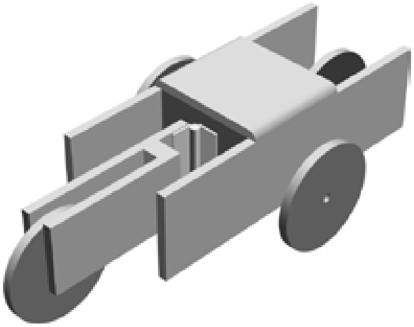

Figure 5-91. *If you have 3D rendering software, it can be a great way to test the feasibility of a construction project before you start cutting materials and trying to fit pieces together. This rendering was a proof-of-concept for the Little Robot Cart.*

Depending on the type of motor that you buy, you'll have to improvise a way to mount it in the front section of the cart. Don't be afraid to use kludges such as cable ties, duct tape, or even rubber bands to attach the motor to the frame. We're making a rough prototype, here, not a thing of beauty (although if you decide you like the cart, you can always rebuild it beautifully later).

The plan in Figure 5-92 shows the pieces that you will need. Part A is the body of the cart. If you're going to bend it from ABS, you should drill half-inch holes, with a forstner bit, at the four inside corners, so that these corners have rounded edges. If you simply saw the plastic to make sharp 90° corners, the plastic may develop fissures at the corners when you bend it. If you don't have a plastic bender and don't feel inclined to buy one, you can make Part A from three separate rectangles and then screw them together.

Figure 5-92. *These sections of 1/4-inch plastic can be assembled to create the simple cart described in Experiment 31.*

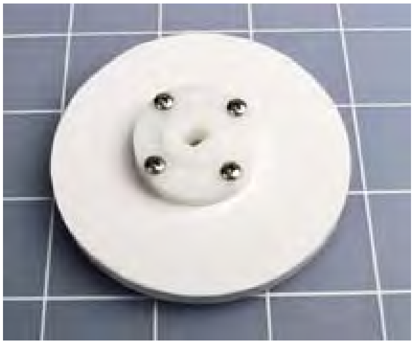

Figure 5-93. *A 3-inch wheel is screwed to the disc that mates with the drive shaft of the motor.*

Part B is a wheel, of which you will need four. I cut them using a 3-inch hole saw. The front wheel is screwed to whatever disc or arm you obtained to mate with the shaft of your motor. See Figure 5-93.

Parts C, D, and E assemble to form a yoke in which the rear wheel is mounted. I used a 2-inch hinge to pivot the yoke. The hinge is mounted on Part F, which is a partition located midway in the frame of the cart. The photographs in Figures

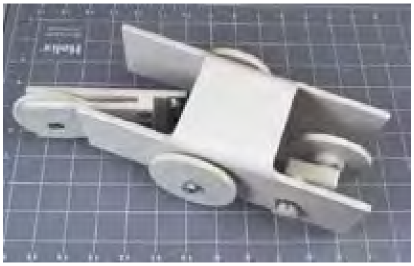

Figure 5-94. *The assembled body of the cart, before adding control electronics. The wheel at the righthand end will pull the cart from left to right. The hinged trailing wheel will allow the cart to move in a relatively straight line when it moves forward, but will tend to turn it when it backs up.*

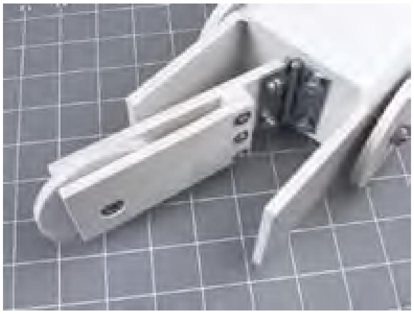

Figure 5-95. *A closeup of the hinged trailing wheel, which rotates freely and can flip from side to side with minimal friction.*

5-94 and 5-95 will help to make this clear. Initially, when you install Part F, use only two screws, one each side, so that you can adjust its angle a little. This will be necessary to optimize the contact of the wheels with the floor.

The side wheels and rear wheel must spin freely, but on the other hand, they shouldn't wobble. I simply tightened the nuts on the bolts that serve as axles for the wheels, until there was maybe half a millimeter of clearance. I added a drop of Loctite to stop the nuts from getting loose.

The plans don't show precisely where to drill holes for the axle bolts, because the location will depend on the size of your wheels. You can figure this out as you go along. Just make sure that the side wheels aren't mounted too low. We don't want them to lift the front wheel or the rear wheel off the floor. If the side wheels are a fraction higher off the ground than the front and rear wheels, that's good.

If you have tile or wood floors, your cart may acquire better traction if you wrap a thick rubber band around each disc that you use for the drive wheel and the steering wheel.

The most important aspect of the construction is to place microswitches where they'll be triggered when the cart runs into something. I placed mine at the front corners, as shown in Figures 5-96 and 5-97. And that brings me to the electronics.

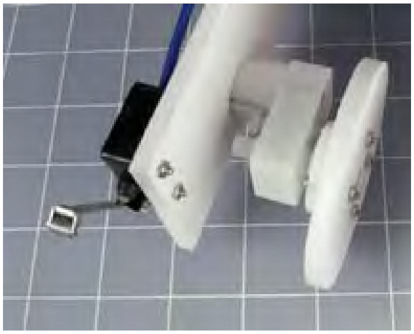

Figure 5-96

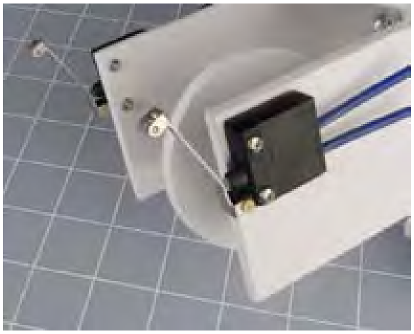

Figure 5-97. *Two microswitches with metal arms are mounted on each side of the cart, where they will sense any obstacle.*

The Circuit

The schematic is very, very simple, with only four principal components: two microswitches that sense obstacles in front of the cart, one relay, and one 555 timer. You will also need a small power switch, a battery or battery pack, and a resistor, and capacitors to go with the timer. A trimmer potentiometer will allow you to adjust the "on" time of the 555 timer, which will determine how long the cart takes to back up. See Figure 5-98.

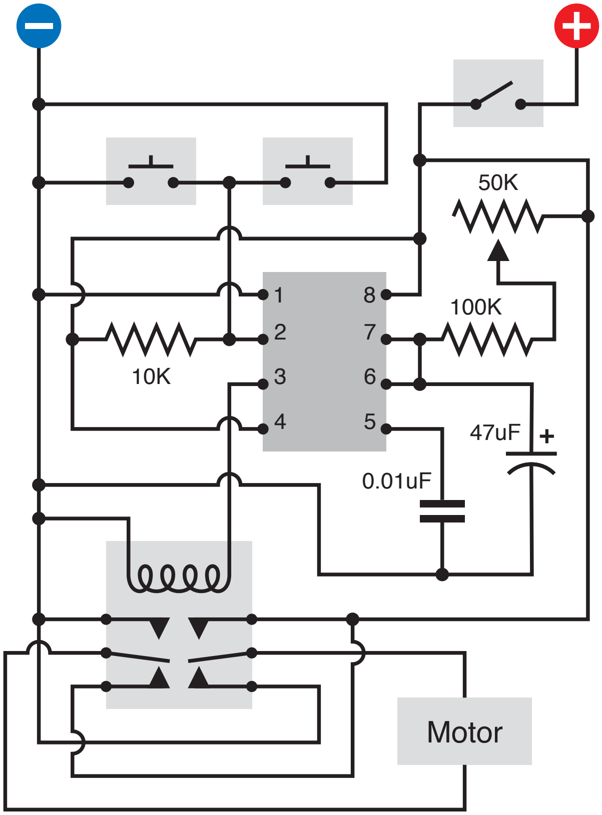

Figure 5-98. *This ultrasimple schematic is all the cart needs to enable it to back up when it hits an obstacle.*

The motor I chose requires 5 volts, so I had to use a voltage regulator with a 9-volt battery. If your motor uses 6 volts, you can wire four AA batteries to it directly. If you have a 12-volt motor, you can use two 9-volt batteries in series, supplying power through a 12-volt voltage regulator.

Assemble the components, mount them on the cart, and switch it on, and it should move forward slowly in a more-or-less straight line. If it moves backward, reverse your connection to the terminals on the motor.

When the cart bumps into something, either of the microswitches will connect negative voltage to the input pin of the 555 timer. This triggers the timer, which runs in monostable mode, generating a single pulse lasting about 5 seconds, which closes the relay, which is wired so that it reverses the voltage to the motor.

When the voltage is reversed to a simple DC motor, it runs backward. So the cart backs up. Because the rear wheel is mounted in a yoke that pivots, the yoke will tend to flip one way or the other, causing the cart to describe an arc as it moves backward. At the end of the timer cycle, the relay relaxes and the cart starts moving forward again. In forward mode, the rear wheel just follows along without applying any steering force, so the cart tends to follow a straight line—until it hits another obstacle, at which point it backs up, and tries another path.

FUNDAMENTALS

All about limit switches

The most obvious enhancement for your cart would be a better steering mechanism. You could use another motor to take care of this, with a pair of limit switches. Because limit switches are a basic, important idea in conjunction with motors, I'll explain them in detail.

Figure 5-99 shows three successive views of a motor with an arm attached to it, which can press either a lower pushbutton or an upper pushbutton. Both of the pushbuttons are normally closed, but will open when pressed by the motor arm. These buttons are the limit switches. Typically you would use microswitches for this purpose, just like the ones that I suggested as barrier-sensors at the front of the cart.

In addition, there's a DPDT relay that is activated by a simple on/off switch at the righthand side. On the cart, the 555 timer takes the place of the on/off switch, by feeding power to the relay.

Suppose that the motor begins with the arm pointing downward, as shown in the top view in Figure 5-99, and the motor is wired so that when it receives negative voltage at its lower terminal and positive at its upper terminal, it rotates counter-clockwise. This is what happens when the on/off switch closes and sends power to the DPDT relay. Positive voltage from the relay contacts cannot pass through the upper diode, but can pass through the upper limit switch, which is closed. Negative voltage cannot pass through the lower limit switch, because it's open, but can pass through the lower diode. So, the motor starts to turn counterclockwise. During the midpoint of its arc, it receives power through both of the limit switches.

Finally, the motor arm reaches the upper switch, and opens it. This prevents positive voltage from reaching the motor through that switch, and the positive voltage is also blocked by the upper diode. So, at this time, the motor stops.

Now suppose that the on/off switch is opened, as in the top view in Figure 5-100. The relay loses its power, so its contacts relax. The voltage to the motor is now reversed. Negative voltage passes through the upper diode, while positive voltage reaches the motor through the lower limit switch. The motor starts running clockwise, until its arm hits the lower switch, opening it and cutting off power to the motor.

Limit switches are necessary, because if you continue to apply voltage to a simple DC motor that is unable to turn, the motor sucks more current, gets hot, and may burn out.

You can easily see how this kind of system could be used to control the cart's steering. Even though the motor has only two positions, these are sufficient to make the cart turn when going backward, and proceed straight ahead when going forward.

To reduce power consumption, the DPDT relay could be replaced with a two-coil latching relay. The circuit would then have to be revised so that the relay is flipped to and fro by a pulse to each of its coils.

FUNDAMENTALS

All about limit switches (continued)

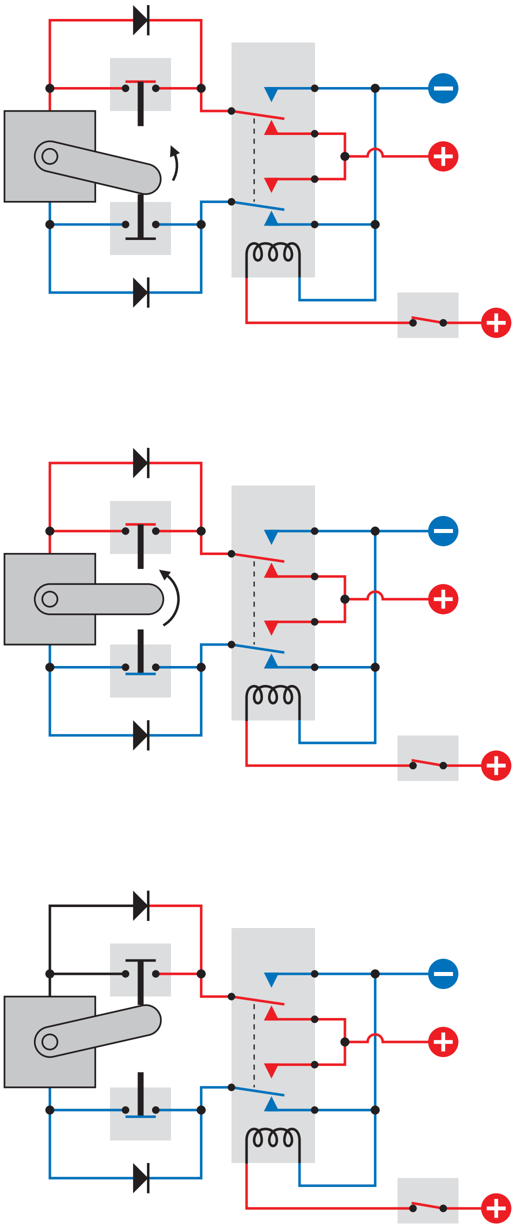

Figure 5-99. *The three diagrams, from top to bottom, show three snapshots of a motor controlled by a DPDT relay and two limit switches. When the on/off switch at bottom-right sends power to the relay, the lower relay contacts cause the motor to run counterclockwise until it stops itself as its arm opens the upper limit switch.*

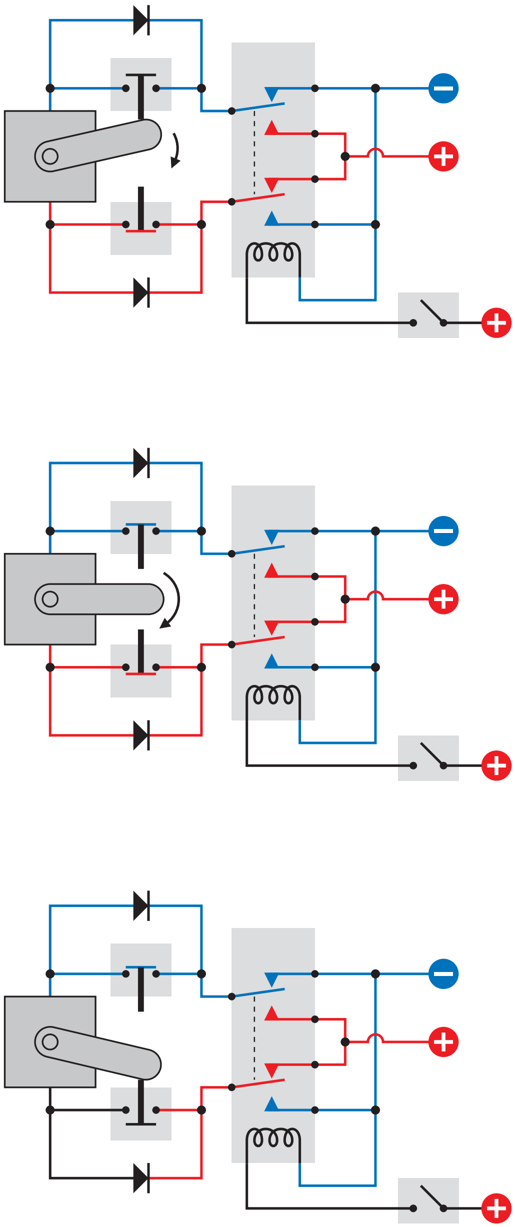

Figure 5-100. *When the on/off switch at bottom-right opens, the relay connects its upper contacts. This causes the motor to run clockwise until its arm opens the lower limit switch. Limit switches avoid the overheating and possible damage that are likely when power is delivered to a motor that is prevented from turning.*

FUNDAMENTALS

All about motors

Brushed DC motor

This is the oldest, simplest design for an electric motor, shown in very simplified form in Figure 5-101. Coils are attached to a shaft where they can interact with stationary magnets around them. The magnetic attraction turns the shaft a little, at which point the next coil on the shaft is energized to turn the shaft a little more, and then the next coil—and so on. To make this happen, electricity has to be fed into the coils by "brushes," often consisting of soft carbon pads that conduct power to a hub, known as a commutator, divided into sections, each of which is connected to a separate coil.

This basic design has several advantages if we want to build a small motorized gadget, such as a miniature robot or even a model airplane:

- Widely available
- Low cost
- Simple
- Reliable
- Will run in reverse when voltage reverses

In addition, brushed motors are often sold with reduction gearing built in. Such units are known as *gearhead motors* or *gear motors*. They free you from the need to use your own gears or belts to adjust the output speed yourself. You simply choose the motor that fits your specification.

DC stepper motor

This requires a controller, consisting of some electronics to tell the motor to rotate its shaft in small, discrete steps. The advantages of a stepper motor are:

- Precise positioning of the shaft
- Precise speed adjustment

Stepper motors are ideal for devices such as computer printers, where the paper has to roll up by a precise distance and the print head has to move laterally by an equally precise distance, but they are also useful in robots. If the motor is small enough to draw less than 200mA and will run on 12 volts or less, you can control it with pulses from a 555 timer. I'll describe stepper motors in more detail in Experiment 33.

Servo motor

This is generally used in conjunction with a programmable microcontroller, which sends instructors to rotate the motor shaft to a specific position and then hold it there. I'll mention servo motors when I introduce you to microcontrollers, but we won't be dealing with them in detail.

Other types of motors exist, including brushless DC motors (which require a different type of controller and are found in computer disk drives and CD players), and AC motors (including synchronous motors, which synchronize their rotation with the frequency of AC voltage, and were used extensively in clocks, before clocks mostly became digital).

In this book, I'll be talking mostly about brushed DC motors and DC stepper motors.

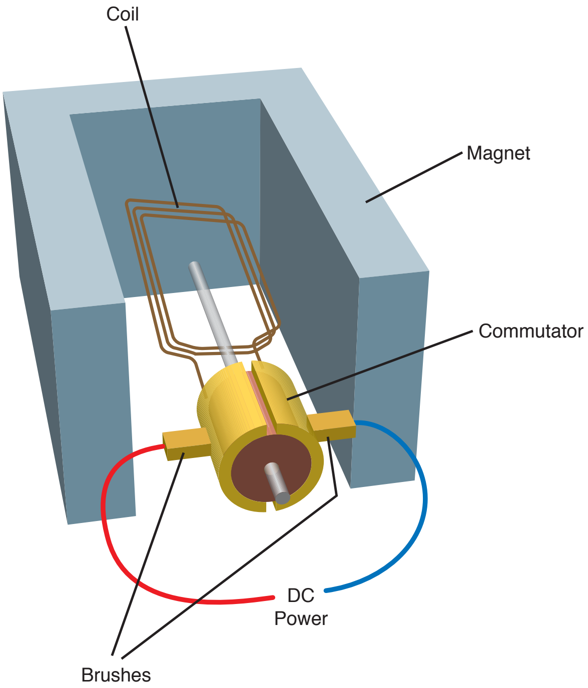

Figure 5-101. *The basic principle of a simple DC motor. The commutator passes electricity through a coil, creating a magnetic field that interacts with a magnet around the motor. The coil turns, and the commutator turns with it, until the electric field through the coil is reversed. This causes the process to repeat. In reality, a motor is likely to have a commutator formed from multiple segments, connected with multiple coils. The principle, however, remains the same.*

Take-home messages from this experiment include the following:

- You can buy simple DC motors with reduction gearing built in, providing your choice of RPM. Literally hundreds of websites will sell you small motors for robotics projects.
- When you reverse the voltage to a DC motor, the motor runs in reverse.
- A DPDT relay can be wired so that when it closes its contacts, it reverses a power supply to a motor.
- You can use two limit switches and a pair of diodes to stop a motor at two positions. In each of its stopping positions, the motor consumes no power and you won't have the risk of it burning out.

What other projects can you imagine using this simple set of techniques?

Mechanical Power

In the United States, the turning force, or torque, of a motor is usually measured in pound-feet or ounce-inches. In Europe, the metric system is used to measure torque in dynes.

A pound-foot is easy to understand. Imagine a lever pivoted at one end, as shown in Figure 5-102. If the lever is one foot long, and you hang a one-pound weight at the end of it, the turning force is one pound-foot.

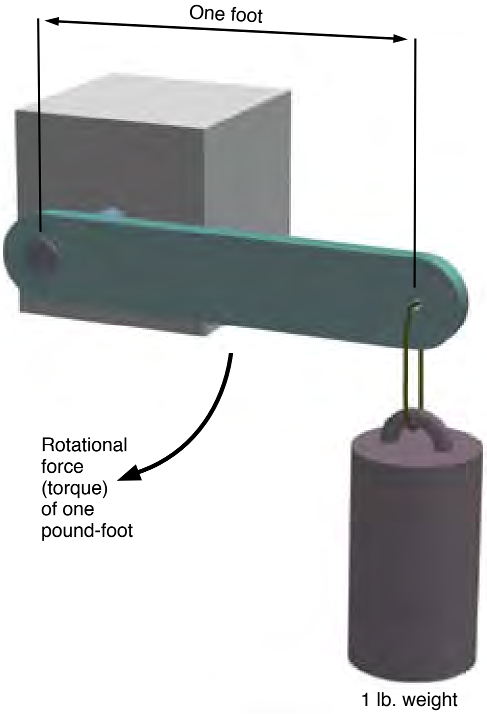

Figure 5-102. *The rotational force created by a motor is known as "torque," and in the United States it is measured in pound-feet (or ounce-inches, for small motors). In the metric system, torque is measured in dynes. Note that the torque created by a motor will vary according to the speed at which the motor is running.*

FUNDAMENTALS

Wire gauges

If you're going to power larger motors, or other components that take more current than LEDs or small relays, you really need to know about wire gauges. In particular, what's the relationship between wire thickness and AWG (American Wire Gauge)? And what gauge of wire should you use for any given current?

You can find numerous charts and tables if you go online, but many of these sources contradict each other, especially on the topic of how much current is safe to run through each gauge of wire.

After making several comparisons (and testing some wire samples myself), I've compiled the table in Figure 5-103, which I recommend as a compromise. Note the following:

- This table applies to solid-core copper wire.
- For stranded wire, or copper that has been tinned (giving it a silver appearance), the number of ohms per foot will *increase*, the number of feet per ohm will *decrease*, and the maximum amperage will *decrease*, probably by around 20%.

The maximum amperage assumes that the wire is insulated, preventing it from radiating heat as effectively as a bare conductor. I am also assuming that the wire is likely to be at least partially enclosed, inside a box or cabinet. At the amperages listed for each gauge of wire, you should expect the wire to become noticeably warm, and personally I would tend to use thicker wire instead of the maximums indicated in the table.

Most tables of this type only tell you the resistance of each gauge of wire in ohms per 1,000 feet. I have included that number but have also expressed the function the other way around, as the number of feet per ohm, as this doesn't require you to do so much arithmetic with decimals.

AWG		Diameter in inches	Ohms per 1,000 ft	Feet per ohm	Maximum amps (insulated)
0000	●	0.46	0.049	20,400	225
000	●	0.41	0.062	16,200	200
00	●	0.365	0.078	12,800	175
0	●	0.325	0.098	10,200	150
1	●	0.289	0.124	8,070	125
2	●	0.258	0.156	6,400	100
3	●	0.229	0.197	5,080	90
4	●	0.204	0.249	4,020	80
5	●	0.182	0.313	3,190	70
6	●	0.162	0.395	2,510	60
7	●	0.144	0.498	2,010	51
8	●	0.128	0.628	1,590	44
10	●	0.102	0.999	1,000	32
12	●	0.081	1.59	630	23
14	●	0.064	2.53	396	17

Figure 5-103. *American wire gauges (AWG) and their properties.*

THEORY

Calculating voltage drop

Another fact that you often need to know is how much of a voltage drop a particular length of wire will introduce in a circuit. If you want to get maximum power from a motor, you don't want to lose too much voltage in the wires that go to and from the motor.

Voltage drop is tricky, because it depends not only on the wire, but also on how heavily the circuit is loaded. Suppose that you are using 100 feet of 22-gauge wire, which has a resistance of about 1.5 ohms. If you attach it to a 12-volt battery and drive an LED and a series resistor offering a total effective resistance of about 1,200 ohms, the resistance of the wire is trivial by comparison. According to Ohm's Law:

amps = volts / ohms

so the current through the circuit is only about 10mA.

Again, by Ohm's Law:

volts = ohms × amps

so the wire with resistance of 1.5 ohms imposes a voltage drop of 1.5 × 0.01 = 0.015 volts.

Now suppose you're running a motor. The coils in the motor create impedance, rather than resistance, but still if we measure how much current is going through the circuit, we can establish its effective resistance. Suppose the current is 1 amp. Repeating the second calculation:

volts = ohms × amps

So the voltage drop in the wire is now 1.5 × 1 = 1.5 volts! This is illustrated in Figure 5-104.

Bearing these factors in mind, I have compiled a table for you. I've rounded the numbers to just two digits, as variations in the wire that you use make any pretense of greater accuracy unrealistic.

To use this table, you need to know how much current is passing through your circuit. You can calculate it (by adding up all the resistances and dividing it into the voltage that you are applying) or you can simply measure the current with a meter. Just make sure that your units are consistent (all in ohms, amps, and volts, or milliohms, milliamps, and millivolts).

In the table, I have arbitrarily assumed a length of 10 feet of wire. Naturally you will have to make allowances for the actual length of wire in your circuit. The shorter the wire, the less the loss will be. A circuit with only 5 feet of wire, and the same amperage and voltage, will suffer half of the percentage loss shown in the table. A circuit with 15 feet of wire, and the same amperage and voltage, will suffer 1.5 times the percentage loss. So, to use the table:

1. Divide your length of wire by 10. (Make sure that you measure the length in feet.)
2. Use the result to multiply the number in the table.

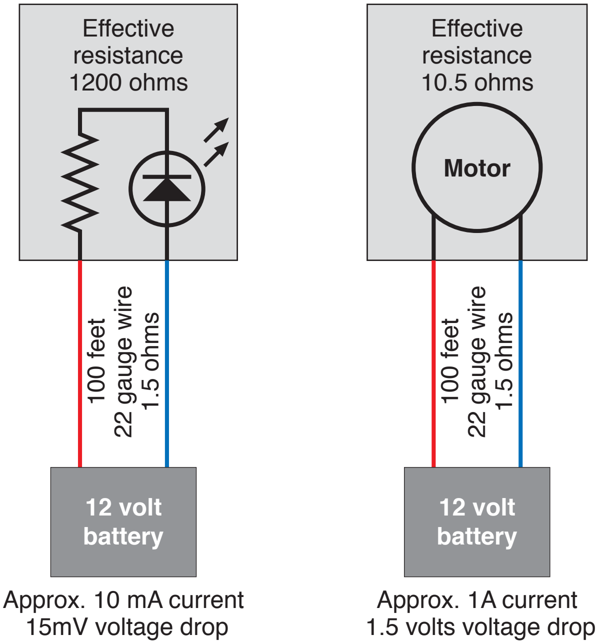
The table also arbitrarily assumes that you have a 12-volt supply. Again, you will have to make allowances if you are using a different voltage. So, to use the table:

1. Divide 12 by the actual voltage of your power supply.
2. Use the result to multiply the number in the table.

I can summarize those two steps like this:

Percent voltage lost = P × (12 / V) × (L / 10)

where P is the number from the table, V is your power-supply voltage, and L is the length of your wire.



Effective resistance 1200 ohms
100 feet 22 gauge wire 1.5 ohms
12 volt battery
Approx. 10 mA current 15mV voltage drop
Effective resistance 10.5 ohms
Motor
100 feet 22 gauge wire 1.5 ohms
12 volt battery
Approx. 1A current 1.5 volts voltage drop

Figure 5-104. *The voltage drop imposed by wiring will depend on the current and the resistance in the circuit. The drop will be greatest when the resistance of the circuit is low and the amperage is high.*

THEORY

Calculating voltage drop (continued)

This table shows the percent voltage lost in a circuit with 10-foot wire at 12 volts.

Wire Gauge	Amperes									
	1	2	3	4	5	6	7	8	9	10
10	0.08	0.17	0.25	0.33	0.42	0.50	0.58	0.67	0.75	0.83
12	0.13	0.27	0.40	0.53	0.66	0.80	0.93	1.1	1.2	1.3
14	0.21	0.42	0.63	0.84	1.1	1.3	1.4	1.5	1.9	2.1
16	0.33	0.67	1.0	1.3	1.7	2.0	2.3	2.7	3.0	3.4
18	0.53	1.1	1.6	2.1	2.7	3.2	3.7	4.3	4.8	5.3
20	0.85	1.7	2.6	3.4	4.3	5.1	6.0	6.8	7.7	8.5
22	1.3	2.7	4.0	5.4	6.7	8.1	9.4	11	12	13
24	2.1	4.3	6.4	8.6	11	13	15	17	19	21
26	3.4	6.8	10	14	17	20	24	27	31	34
28	5.4	11	16	22	27	32	38	43	49	54
30	8.6	17	26	34	43	52	60	69	77	86

Remember, though, that the wire resistance will be higher if you are using stranded copper wire or tinned copper wire, and this will increase the percentage of voltage lost.

Experiment 33: Moving in Steps

Time now to build something more sophisticated: a cart that orients itself toward a light source. I'm going to tell you all you need to get started on this project, but this time I won't go all the way to the end in exhaustive detail. I want you to get into the habit of figuring out the details, improving on plans, and eventually inventing things for yourself.

You will need:

- 555 timers. Quantity: 8.
- Trimmer potentiometer, 2K linear. Quantity: 2.
- LEDs. Quantity: 4. If you get tired of using series resistors to protect LEDs in a 12-volt circuit, consider buying 12-volt LEDs such as Chicago Miniature 606-4302H1-12V, which contain their own resistors built in. However, the schematic in Figure 5-108 assumes that you will use regular 2V or 2.5V LEDs.
- Stepper motor: Unipolar, four-phase, 12-volt. Parallax 27964 or similar, consuming 100mA maximum. Quantity: 2.
- Photoresistors, ideally 500 to 3,000Ω range. Quantity: 2.

- ULN2001A or ULN2003A Darlington arrays by STMicroelectronics. Quantity: 2.
- CMOS octal or decade counter. Quantity: 2.
- Various resistors and capacitors.

Exploring Your Motor

I've specified a unipolar, four-phase, 12-volt motor because this is a very common type. A typical sample is shown in Figure 5-105. If you can't easily find the one that I've listed, you should feel safe in buying any other that has the same generic description. "Unipolar" means that you don't have to switch the power supply from positive to negative and back to positive again, to run the motor. Four-phase means that the pulses that run the motor must be applied in sequence to four separate wires. Because you will be running your motor directly from 555 timers, the lower its power consumption, the better.

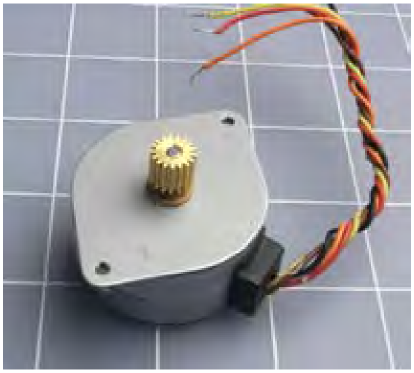


Figure 5-105. *A typical stepper motor. The shaft rotates in steps when negative pulses are applied to four of the wires in sequence, the fifth wire being common-positive.*

First, though, we can apply voltage to the motor without using any other components at all. Most likely it will have five wires already attached, with the ends stripped and tinned, so that you can easily insert them into holes in a breadboard, as shown in Figure 5-106. Check the data sheet for your motor; you should find that four of the wires are used to energize the motor and turn it in steps, while the fifth is the common connection. In many cases, the common connection should be hooked to the positive side of your power supply, while you apply negative voltage to the other four wires in sequence, one step at a time.

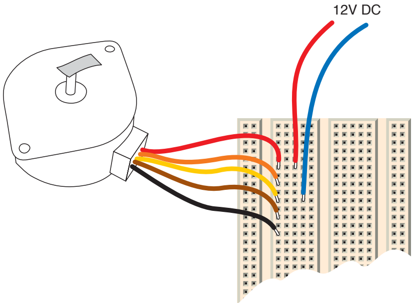

Figure 5-106. *The simplest test of a stepper motor is to apply voltage manually to each of its four control wires, while a piece of duct tape, attached to the output shaft, makes it easy to see how the motor responds.*

The data sheet will tell you in what sequence to apply power to the wires. You can figure this out by trial and error if necessary. One thing to bear in mind: a stepper motor is very tolerant. As long as you apply the correct voltage to it, you can't burn it out.

To see exactly what the motor is doing, stick a piece of duct tape to the end of the shaft. Then apply voltage to wires, one at a time, by moving your negative power connection from one to the next. You should see the shaft turning in little steps.

Inside the motor are coils and magnets, but they function differently from those in a DC motor. You can begin by imagining the configuration as being like the diagram in Figure 5-107. Each time you apply voltage to a different coil, the black quadrant of the shaft turns to face that coil. In reality, of course, the motor turns less than 90° from one coil to the next, but this simplified model is a good way to get a rough idea of what's happening. For a more precise explanation, see the upcoming section "Theory: Inside a stepper motor."

Bear in mind that as long as any of the wires of the motor are connected, it is constantly drawing power, even while sitting and doing nothing. Unlike a regular DC motor, a stepper motor is designed to do nothing for much of the time. When you apply voltage to a different wire, it steps to that position and then resumes doing nothing.

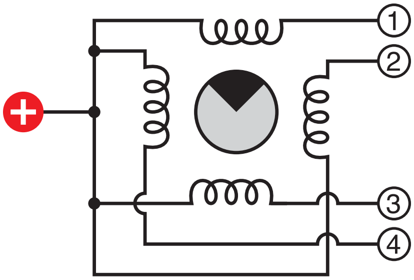

Figure 5-107. *This greatly simplified diagram helps in visualizing the way in which a stepper motor works. In reality, almost all motors rotate by less than 90° in response to each pulse.*

The coil inside the motor is holding the shaft in position, and the power that the motor draws will be dissipated as heat. It's quite normal for the motor to get warm while you're using it. The trouble is, if you use a battery to power it, and you forget that you have it connected, the battery will not hold its charge for long.

Quick Demo

Now that you've proved that your motor is functional, how can you actually run it? You need to send a pulse to each of the four wires in turn, in a rapidly repeating sequence. If you can also adjust the speed of the pulses, so much the better. I'm thinking that for a quick and simple demo, you can handle the challenge simply by using four 555 timers, all of them in monostable mode, with each one triggering the next.

The schematic in Figure 5-108 shows what I have in mind. It looks more complex than it really is. Each timer has the same pattern of components around it, so after you create the first module, you just make three copies of it.

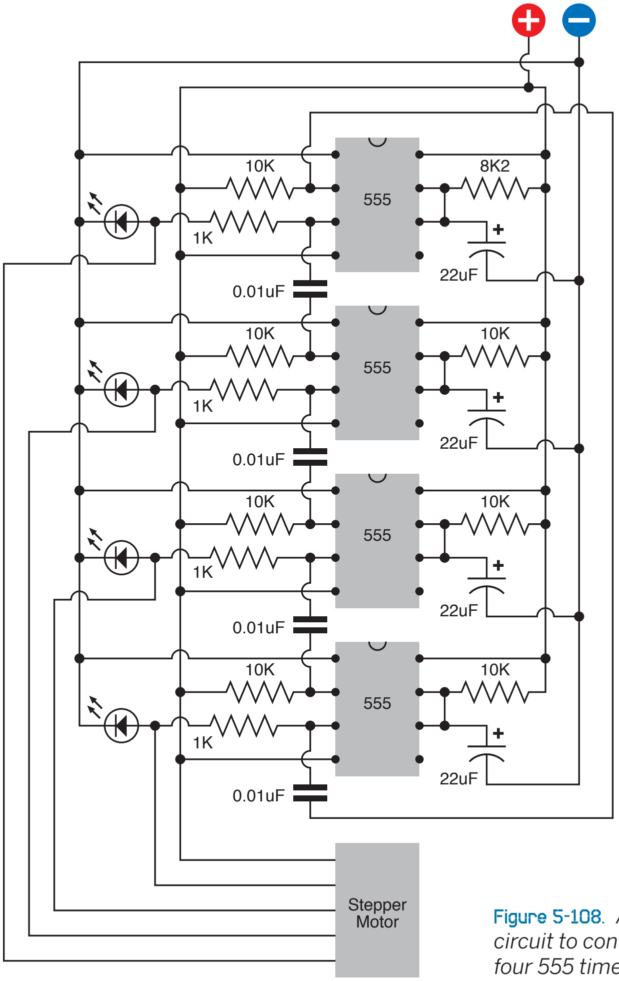

Figure 5-108. *A very quick and simple circuit to control a stepper motor uses four 555 timers, each in monostable mode, triggering each other in a repeating sequence.*

I've used a 10K resistor to pull up the input to each 555, so that the timers are naturally in their quiescent state. A 0.01 µF capacitor links the output from one timer to the input of the next so that they are electrically isolated from each other, and the capacitor just conveys a "spike" of voltage when one timer finishes its "on" cycle, and its output goes low, which triggers the next.

On the righthand side, I've used 10K resistors and 22 µF capacitors to generate a cycle of about a quarter of a second—except that the topmost timer has a 8K2 timing resistor. The reason for this is that when power is first applied, the timers will all be waiting for each other to begin, and timers 2 and 4 or 1 and 3 may fire together. By giving one timer a shorter cycle than the others, I minimize this problem.

The LEDs are included just to give you some visual verification of what's happening. Without them, if you make a wiring error, the motor may turn to and fro erratically, and you won't know why. Initially you can run your circuit with only the LEDs connected, just to make sure it works. Figure 5-109 shows the breadboarded circuit before the motor is plugged in. Then add the motor by plugging its wires into the breadboard, where you'll make connection with the outputs (pins 3) of the timers. See Figure 5-110.

Apply power, and you should see the motor turning in steps, in sequence with the LEDs. If the LED sequence isn't stable:

1. Connect a wire directly from the input (pin 2) of the topmost timer to the positive side of the voltage supply, and wait for the timers to calm down.
2. Restart the sequence by disconnecting the free end of this wire, or (if necessary) touch the free end of it briefly to the negative side of the supply, to trigger the first timer.

One thing you may have noticed, if you're paying very close attention: the common terminal of the motor is connected to positive. Therefore, when each timer flashes positive, that positive signal isn't actually powering the motor. The *low* outputs from the three timers that are *not* firing at any given moment are sinking current from the motor. It seems quite happy with this arrangement. You'll need some theory to understand why.

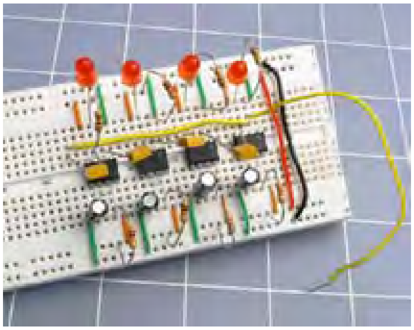

Figure 5-109. *To test the control circuit for errors, four LEDs show the outputs from the four 555 timers. The loose yellow wire at the righthand side connects to pin 2 of the first timer. Touch the free end of this wire to the positive side of the power supply to reset the timers, and then, if necessary, make a brief negative connection with the free end of the wire to restart their sequence.*

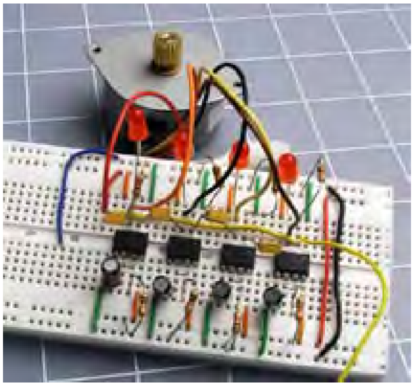

Figure 5-110. *After the circuit has been tested, the motor can be added by hooking its control wires to the outputs of the four 555 timers.*

THEORY

Inside a stepper motor

If you check the Wikipedia entry for stepper motors, you may see a very nice 3D rendering showing a toothed rotor and four coils arrayed around it. Maybe stepper motors used to be manufactured like this once upon a time, but not anymore.

Imagine two horizontal rows of coils. In the space between them is a series of little magnets, like a freight train, that can move left or right, as shown in Figures 5-111 and 5-112. Each coil has two windings, in opposite directions, so that current through one winding will create an upward magnetic force while current through the other will create a downward force. Each row of windings is connected in parallel, so that they switch on and off simultaneously.

In Step 1, the negative connection energizes the upper windings of the upper coils, which creates an upward magnetic force. I've shown this force using blue-green arrows so that you won't mistake it for a flow of electricity. It so happens that this force attracts the north poles of the magnets and repels the south poles, so if the magnets begin in the position shown in Step 1, they will want to move one step to the right.

This brings them to the position shown in Step 2. Now the upper windings of the lower coils are energized, and again, this produces an upward force, which again attracts the north poles and repels the south poles.

This advances the magnets to their location in Step 3. Now the lower windings of the upper coils are energized, producing a downward force. This repels the north poles of the magnets and attracts their south poles. So the magnets keep moving.

They reach the position shown in Step 4. The lower windings of the lower coils are energized, producing a downward force which continues to attract the south poles while repelling the north poles. So the magnets move a final step to the right—which leaves them in the same orientation shown in Step 1. And the process can repeat all over again.

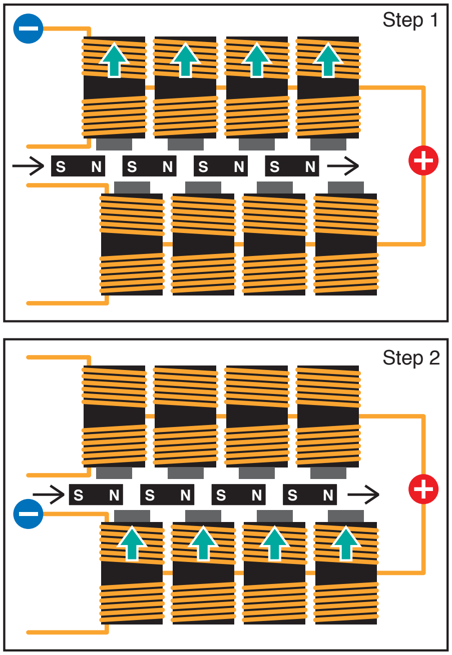

Figure 5-111. *This sequence shows the first two steps as the rotor of a stepper motor (shown as a series of north-south magnets) moves in response to pulses through electromagnets.*

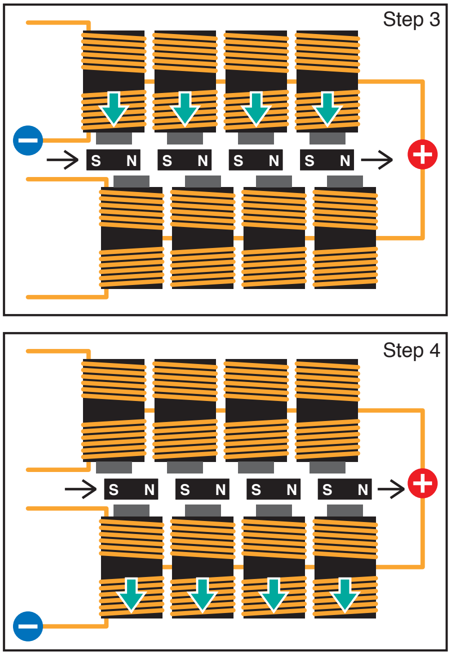

Figure 5-112. *After taking another two steps, the motor will be back where it started at Step 1 in Figure 5-111.*

THEORY

Inside a stepper motor (continued)

In reality, the magnets are not separate from each other. The edge of a rotor is magnetized in zones that alternate between south and north polarity. And instead of multiple coils, there are just four windings that go around all the magnetic cores. But the principle is exactly the same. The 3D rendering gives a general idea, and the photograph shows what I found when I cracked open a typical stepper motor.

Now bear in mind that when this device is driven by a set of 555 timers, we don't just connect negative to one wire at a time on the left, leaving the others floating. In reality, at any given moment, three of the timers have a negative output and the fourth has a positive output. The last diagram in Figure 5-112 shows this situation.

Suppose the top wire is positive while the other three are negative, as shown in Figure 5-113. The positive output does nothing, because it is balanced by the positive power on the other end of the coils. The two negatives attached to the bottom set of coils create equal and opposite forces that cancel each other out (while wasting some power). So the net result is the same as in Step 3.

In fact, you should find that you can disconnect the common wire completely while using the stepper motor with 555 timers, and the motor will still turn, because one of the timers is providing positive power while the others are negative. In fact, you'll be running them more efficiently this way.

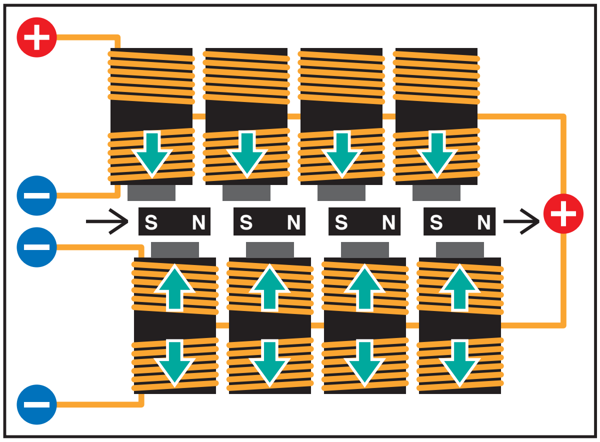

Figure 5-113. *When the motor is driven by four 555 timers, they are activating it by sinking positive voltage from it. The interior workings of the motor look something like this. It's not the most efficient way to do the job.*

Figures 5-114 and 5-115 may help to give you a clearer idea of what the motor actually looks like inside.

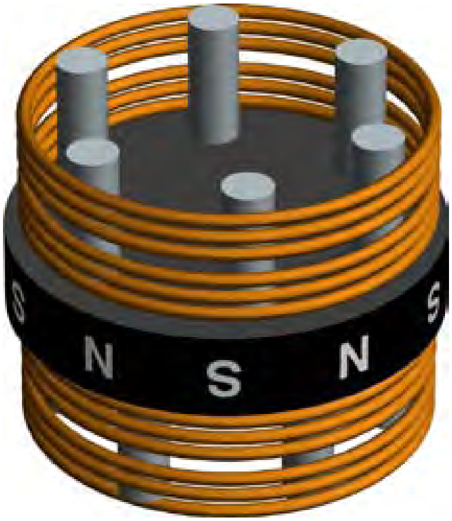

Figure 5-114. *This 3D rendering gives a better idea of what a typical stepper motor looks like inside. The copper coils and gray cylinders are stationary, while the black disc rotates between them.*

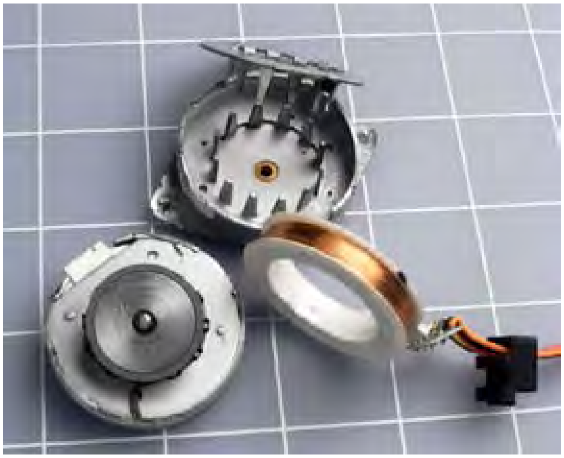

Figure 5-115. *When a stepper motor is broken open, this is what you're likely to find. On the left, the rotor of the motor, which has a magnetized band around its circumference, is still attached to the lower half of the casing. On the right, the upper half of the casing has been opened, and the coil has been removed (actually the winding you can see consists of two coils, wound in opposite directions). The spikes are the magnetic cores that exert force on the rotor.*

Speed Control

If you are a truly exceptionally observant, you may have noticed that I left pin 5 of each of the timers unconnected in the schematic for driving the stepper motor in Figure 5-108. Normally, pin 5 should be grounded through a capacitor to prevent it from picking up stray voltages which can affect the accuracy of the chip.

I left the pins unconnected because I had a plan for them. In fact, changing the timing of the chip is exactly what we want to do now, as a way to change the speed of the stepper motor.

If you tie pin 5 of all four timers together, as shown in Figure 5-116, and put a 2K trimmer potentiometer (shown in Figure 5-117) between them and the negative side of the power supply, you'll find that as you turn the trimmer to reduce its resistance, the timers start to run faster. Figure 5-118 shows the breadboard layout. Eventually, when the resistance goes below around 150 ohms, everything stops. The LEDs go dark, because you've reduced the voltage on pin 5 below the threshold level that the 555 timer finds acceptable.

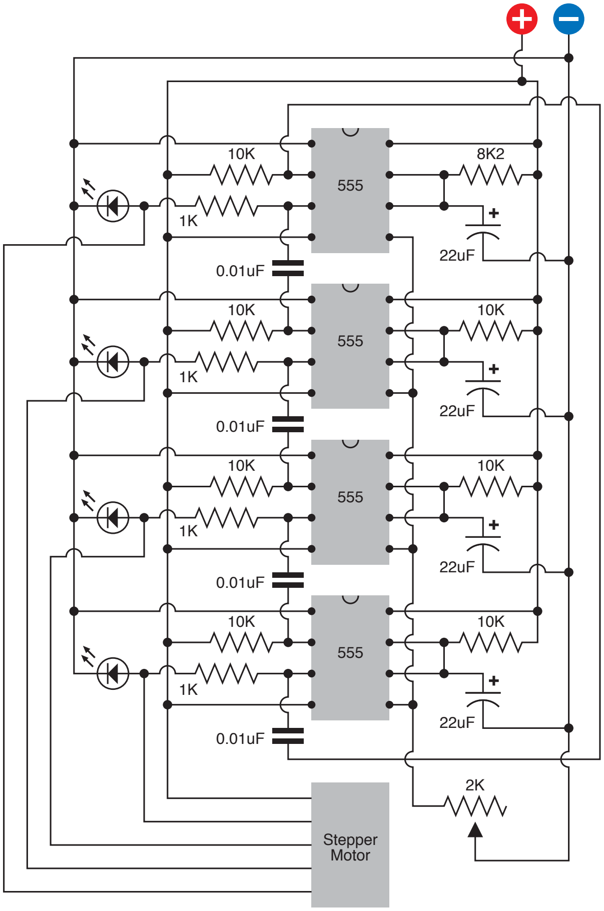

Figure 5-116. *To adjust the speed of the sequence of 555 timers, their control pins (pin 5 on each timer) are linked together and attached to a trimmer potentiometer that adjusts the resistance between the pins and the negative side of the power supply.*

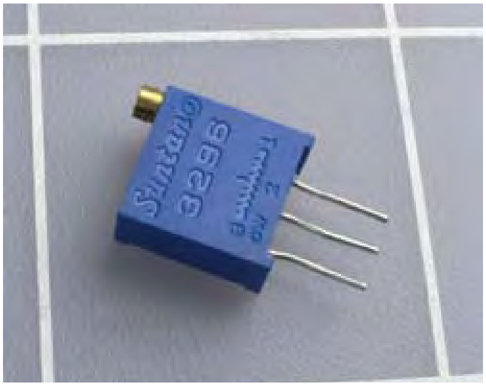

Figure 5-117. *Close-up of a trimmer potentiometer with pins spaced at 1/10 inch for insertion in a breadboard or perforated board. The brass screw, at top-left, turns a worm gear inside the unit, allowing precise adjustment of internal resistance.*

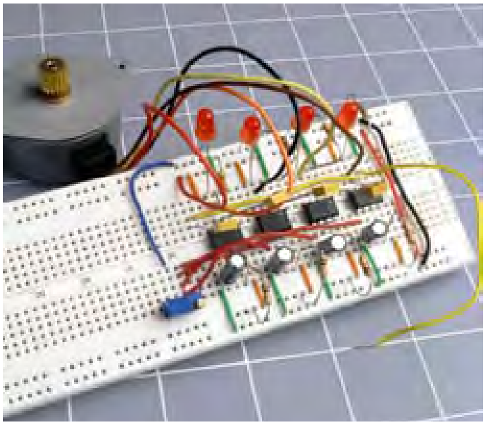

Figure 5-118. *The trimmer potentiometer has been added to the circuit, allowing motor speed control.*

Initially I suggested a step time of 1/4 second just so that you could see what was happening. When you're actually using this circuit, you'll never need it to run as slowly as that. So you can increase the entire range of speeds. Remove the 22 µF timing capacitors and substitute, say, 4.7 µF capacitors, or smaller. Now when you adjust the potentiometer, you'll get a useful range of speed.

Adding Autonomy

Currently, the circuit simply does what you tell it to do. The next step is to make it autonomous—in other words, give it the illusion of making up its own mind. I'm thinking that instead of a trimmer potentiometer, we could substitute a photocell, properly known as a photoresistor. Typically, the resistance of a cadmium sulfide photo resistor is highest in the dark, and lowest when light shines on it.

One problem with photoresistors is that they're not as widely available as many other types of electronic components. If you search Mouser.com, for instance, you'll find virtually nothing. Partly this is because the online search function at Mouser is the weakest feature of the site, and partly it's because Mouser is not oriented toward hobbyists. What you need to do is conduct a "product search." Go to *http://www.google.com/products*, enter the search terms "CdS" and "photocell," and you'll find a bunch of cheap cadmium sulfide components from places you may never have heard of.

Because photoresistors seem to come and go as erratically as DC motors, I am not offering any part numbers. You can buy any product that has an appropriate minimum resistance (in bright light) and maximum resistance (in the dark). If you find a component that ranges from 500 to 3,000Ω, that would be a good choice. If the only ones you can find have a higher minimum than 500Ω, you could consider putting a couple of them in parallel.

Setting Up Your Light Seeking Robot

Why would you want to control the speed of a stepper motor by using a photo resistor? Because the original objective was to build a robot that is attracted to light.

The idea is simple enough: use two stepper motors, each controlling the speed of one wheel of the cart. Use two photoresistors, each controlling the speed of the opposite stepper motor. When the righthand photoresistor picks up more light, its resistance lowers, causing the lefthand set of timers to run faster, which will make the lefthand wheel run faster. Thus, the cart will turn toward the light. Figure 5-119 illustrates the concept.

Before you start wiring more 555 timers, though, you might consider doing the job with a more appropriate component. The ULN2001A and ULN2003A are chips containing Darlington amplifiers specifically designed to deliver current to inductive loads such as solenoids, relays, and (you guessed it) motors. Each chip has seven inputs that require very little current, and seven outputs that can deliver 500mA each. The inputs are TTL and CMOS compatible (the 2001A has a wider tolerance for voltages than the 2003A) and each channel of

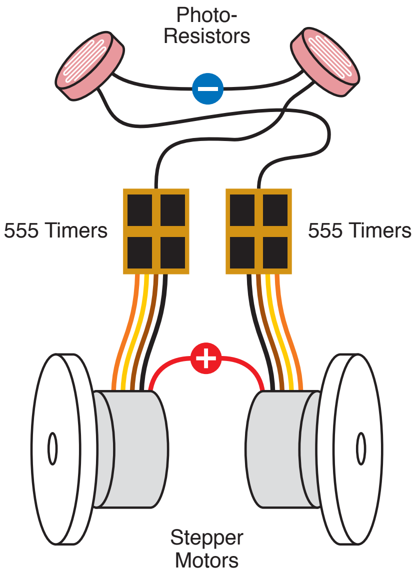

Figure 5-119. *If two photoresistors control the speed of two 555-timer arrays, the difference in speed between one wheel and the other can turn the cart toward a light source.*

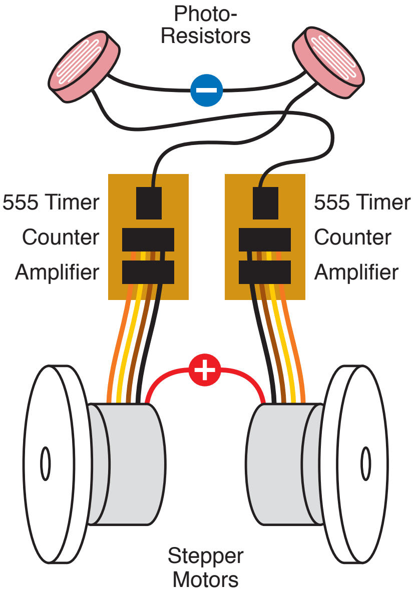

Figure 5-120. *A more efficient way to drive the motors is to use just one timer to set the speed of each, with a counter and amplifier (such as a Darlington array chip) sending the pulses down the wires. The principle is still the same, though.*

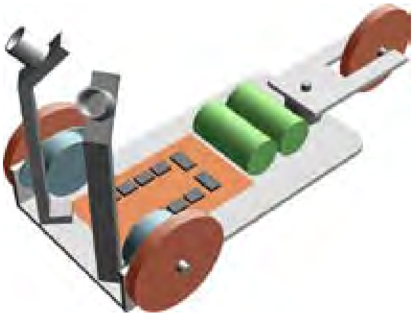

Figure 5-121. *This 3D rendering shows a possible configuration of the light-seeking cart, with two photoresistors enclosed in small tubes to restrict their response to light.*

the chip functions as an inverter, so that when the input goes high, the output goes low and sinks current. This is of course just what we need for our stepper motor that has a common positive connection.

The ULN2001A is only an amplification device, so you have to precede it with a counter that runs from 1 to 4 and then repeats. You can stick with your 555 timers, as you've already assembled them, or substitute almost any CMOS octal or decade counter that sends its output pulses to a series of pins. Just use the output from the fifth pin as the "carry" output to restart the counting sequence. I suggest a CMOS counter simply because it will run on 12 volts, so you can use the same power supply that suits your stepper motors.

If you switch to CMOS counters, you will still need a pair of 555 timers sending pulses to the counters. The timers will be free-running in astable mode, and your photoresistors will control their speed. Figure 5-120 shows the configuration.

One last item: you'll need a 12-volt battery. You can of course put eight AA cells together, but I think you should consider a rechargeable pack from a source such as *http://www.all-battery.com*, which has a section entirely devoted to "robot batteries."

If you put it all together, you should find that when you place your robot cart in a very dimly lit room, it will turn toward the beam from a bright, well-focused flashlight. To get reliable results, you may have to recess each of the photoresistors in little tubes, so that they receive much more light when they face your flashlight than when they face away from it. Figure 5-121 is a 3D rendering of the concept.

Another idea is to rewire your cart so that it actually runs away from the light. Can you imagine how this might be done?

Just one more thought: if you use infrared photoresistors, you can control your cart with beams from infrared LEDs, in normal room lighting. If you and a couple of friends all have infrared transmitters, you can get your cart to run from one of you to the next, like an obedient dog.

This takes us about as far as I'm going to go into robotics. I urge you to check out the sites online if you want to pursue the topic further. You can also buy a wide variety of robot kits, although of course I feel that it's more fun to invent or develop things for yourself.

All that's left now is to perform one last introduction: to a device that should make your life much easier, even though the device is much more complicated than anything we have dealt with so far.

Experiment 34: Hardware Meets Software

Throughout this book, in accordance with the goal of *learning by discovery*, I have asked you to do an experiment first, after which I've suggested the general principles and ideas that we can learn from it. I now have to change that policy, because the next experiment involves so much setup that it's only fair to tell you what to expect before you begin the preparations.

We are about to enter the realm of controller chips, often known as MCUs, which is an acronym for micro controller unit. An MCU contains some flash memory, which stores a program that you write yourself. The flash memory is like the memory in a portable media player, or the memory card that you use in a digital camera. It needs no electricity to power it. In addition, the chip has a processor which carries out the instructions in your program. It has RAM to store the values of variables on a temporary basis, and ROM, which tells it how to perform tasks such as sensing a varying voltage input and converting it into digital form for internal use. It also contains an accurate oscillator, so that it can keep track of time. Put it all together, and it's a tiny computer that you can buy for under $5.

Let's suppose that you have a greenhouse where the temperature must never fall below freezing. You set up a temperature sensor, and you have two different heaters. You want to switch on the first heater if the temperature falls below 38° Fahrenheit. But if, for some reason, that heater is broken, you want to switch on the second, backup heater when the temperature goes below 36° Fahrenheit.

Programming a MCU to take care of this can be very simple indeed. You could even add extra features, such as a second temperature sensor, just in case the first one fails, and you could tell the chip to use whichever sensor gives a lower reading.

Another application for a MCU would be in a fairly elaborate security system. The chip could monitor the status of various intrusion sensors, and can take various preprogrammed steps, depending on the sensors' status. You could include delay intervals, too.

Many MCUs have additional useful features built in, such as the ability to control servo motors that turn to a specific angle in response to a stream of pulses. Servos are widely used in radio-controlled model boats, airplanes, and hobby robotics.

Perhaps you are now wondering why, if MCUs can do all this, haven't we been using them all along? Why did I spend so much time describing the development of an alarm system using discrete components, if one chip could have done everything?

There are three answers:

1. MCUs cannot do everything. They need other components to help them interact with the world, such as transistors, relays, sensors, and amplifiers. You need to know how those things work, so that you can make intelligent use of them.
2. MCUs can introduce their own kinds of problems and errors, associated with using software in addition to hardware. I'll have more to say about this later.
3. MCUs have limits and restrictions, most obviously their requirement for a 5-volt regulated power supply, and their inability to source or sink much current from each pin. They also demand that you learn a programming language (which differs from one brand of MCU to the next). And to get the program into the chip, you have to be able to plug it into a computer and do a download, which is not always convenient.

In this experiment, you'll learn how to write a program for a small and simple MCU, and you'll transfer the program into it and see how it works.

BACKGROUND

Origins of programmable chips

In factories and laboratories, many procedures are repetitive. A flow sensor may have to control a heating element. A motion sensor may have to adjust the speed of a motor. Microcontrollers are perfect for this kind of routine task.

A company named General Instrument introduced an early line of MCUs in 1976, and called them PICs, meaning Programmable Intelligent Computer—or Programmable Interface Controller, depending which source you believe. General Instrument sold the brand to another company named Microchip Technology, which owns it today.

"PIC" is trademarked, but is sometimes used as if it's a generic term, like Scotch tape. In this book, I've chosen a range of controllers based on the PIC architecture. They are licensed by a British company named Revolution Education Ltd., which calls its range of chips the PICAXE, for no apparent logical reason other than that it sounds cool.

I like these microcontrollers because they were developed originally as an educational tool and because they are very easy to use. They're cheap, and some of them are quite powerful. Despite their odd name, I think they're the best way to get acquainted with the core concepts of MCUs.

After you play with the PICAXE, if you want to go farther into MCUs, I suggest the BASIC Stamp (which uses a very similar language, but with additional powerful commands) and the very popular Arduino (which is a more recent design, packed with powerful features, but requires you to learn a variant of C language to program it). I'll say more about these chips later.

If you search for "picaxe" on Wikipedia, you'll find an excellent introduction to all the various features. In fact, I think it's a clearer overview than you'll get from the PICAXE website.

Supplies

Figure 5-122 shows some of the chips in the PICAXE range. I'll be telling you how to use the smallest—the 08M—which costs less than $5 and is cheaper than any other MCU that I've found. It has only 256 bytes of memory to store a program (not gigabytes, megabytes, or kilobytes, just 256 bytes!), but you'll be surprised how many possibilities this amount allows for. Figure 5-123 shows a closeup of the 08M with its legs safely embedded in a piece of conductive foam.

In the United States, there are three distributors of this chip:

- *http://www.advancedmicrocircuits.com*
- *http://www.phanderson.com/picaxe*
- *http://www.sparkfun.com*

I like P. H. Anderson for its grass-roots hobbyist approach, and they have good prices if you want to buy multiple chips. But SparkFun Electronics offers other associated products that you may find interesting.

All the distributors will want to sell you "starter kits," such as the one in Figure 5-124, perhaps because the PICAXE itself is so cheap that it doesn't offer much of a profit margin. Still, for our purposes, you should buy the chip as a standalone item. And buy two of them, just in case you damage one (for example, by connecting voltage to it incorrectly).

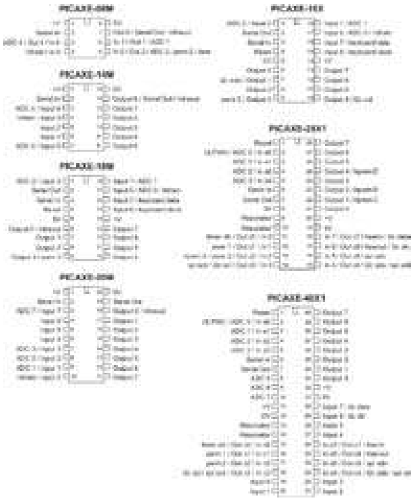

Figure 5-122. *A page from the PICAXE catalog lists only some of the chips that are available. What began as an educational aid has become a useful prototyping tool.*

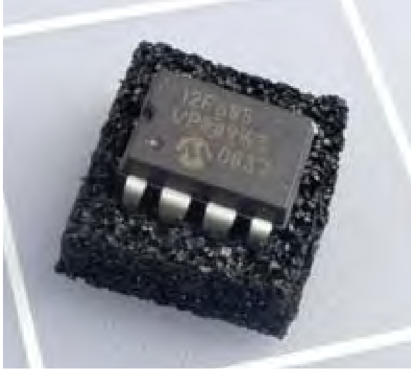

Figure 5-123. *When supplied by one of its American distributors, a PICAXE 08M arrives embedded in a little square of conductive foam. The chip is the same size as a 555 timer but has the power of a tiny computer.*

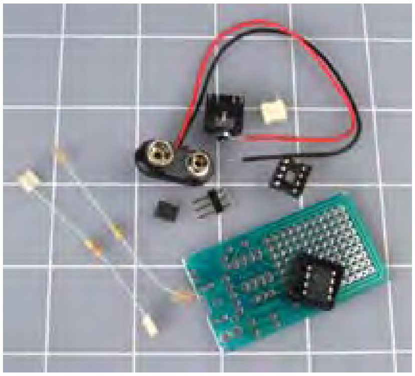

Figure 5-124. *A typical PICAXE kit includes a printed circuit board, which you may not really need, and some other not-entirely-essential items. But the 3.5-mm stereo jack socket (top, center) is absolutely necessary.*

To download your programming instructions into the chip, first you'll type the instructions on a computer, and then you'll feed them through a cable into the PICAXE memory. So you'll need to buy a cable, and you'll need software to help you to write the program.

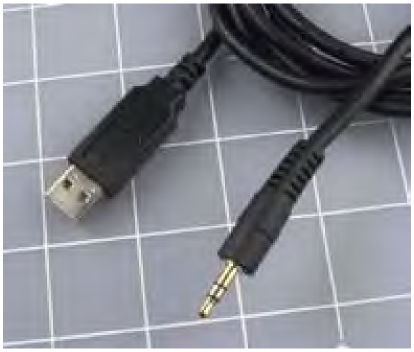

Figure 5-125. *The USB download cable made for use with the PICAXE terminates in a 3.5-mm audio plug. This should not be inserted in any audio device. It establishes a serial connection with a computer, allowing program code to be downloaded into the chip.*

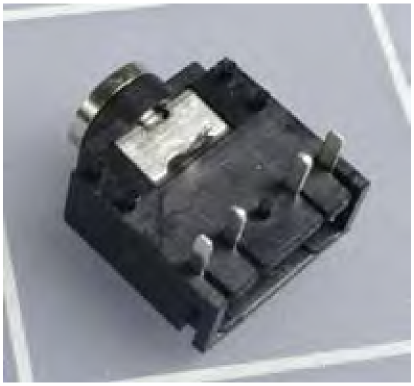

Figure 5-126. *Closeup of the 3.5-mm stereo socket that is used with the USB download cable.*

You can use the PICAXE with a serial cable, but I don't recommend it. The old RS-232 serial communications standard on PCs is pretty much obsolete, and PICAXE has recognized this by offering a USB cable (which contains a serial converter inside its plug). The USB cable is a little more expensive, but is also simpler and compatible with Apple computers. From any of the U.S. distributors, buy USB cable part AXE027, also sold as part PGM-08312 by *http://www.sparkfun.com* (quantity: 1). The cable is shown in Figure 5-125.

To write your software and send it down the wire to the chip, the PICAXE Programming Editor is the tool of choice. It comes in only a Windows version. For those who prefer Mac OS or Linux, you can get a free download of another piece of software known as AXEpad, which has fewer features, but will do the job. All the downloadable software is freely available from *http://www.rev-ed.co.uk/picaxe/software.htm*.

Finally, you need a 3.5-mm stereo audio socket with solder connections. The reason for this is that the manufacturers of the PICAXE have used a stereo audio plug on the free end of their USB cable, and you have to be able to plug it into something. The PICAXE breadboard adapter, SparkFun stock number DEV-08331, contains the necessary stereo socket in addition to a few other little items. Quantity: 1. See Figure 5-126.

Oddly enough, the USB cable is the most expensive item on the list, because of the electronics hidden inside it.

Software Installation and Setup

Now you have to go through a setup procedure. There is no way around this. Here is what you will be doing:

1. Install a driver so that your computer will recognize the special USB cable.
2. Install the Programming Editor software (or AXEpad for Mac/Linux) so that your computer will help you to write programs and then download them into the chip.
3. Mount the PICAXE on your breadboard and add the socket to receive downloads.

These steps are explained in the following sections.

The USB driver

Fair warning: If you go to the PICAXE website and try to use its search function, it probably won't find what you want. Search for "USB Driver," for instance, and it will pretend it has never heard of such a thing.

The PICAXE home page also has irritating drop-down menus that tend to disappear just when you're about to click on them, but at the time of writing, you can bypass these issues by going straight to the Software Downloads section at *http://www.rev-ed.co.uk/picaxe/software.htm*.

Scroll down past all the software until you get to Additional Resources. Look for the AXE027 PICAXE USB Download Cable. At first glance, it looks as if they want to sell you a cable, but in fact this is the list of drivers. Double-click the one appropriate to your computer, and choose a destination on your computer for the download—a place where you will find it easily, such as your desktop.

Be careful not to download the driver for the USB010 USB-Serial adapter by mistake. The USB-Serial adapter is something else entirely.

The download will leave you with a zipped file folder. You will have to unzip it. On Windows XP, right-click the folder and choose "Extract all." View the extracted files and you will find a PDF installation guide. Linux and Mac users can find instructions currently stashed at *http://www.rev-ed.co.uk/docs/AXE027.pdf*.

When installing the driver on a Windows platform, here are a few tips to minimize your exasperation level:

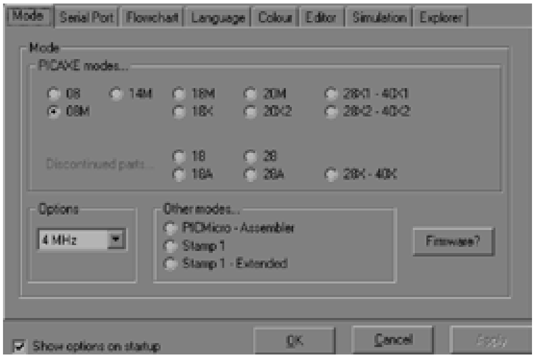
1. Remember, the special USB cable contains some electronics. It is not just a cable, but a device designed for interacting with a PICAXE chip. *Don't try to use it for anything else!*
2. You have to plug the cable into a USB port *before* you install the driver, because your computer will need to verify that the driver matches the cable.
3. You must not attach the PICAXE to the other end of the cable until *after* you have installed the driver.
4. Every USB port on your computer has a separate identity. Whichever one you choose when you first plug in the cable, you should use that port *every time in the future*. Otherwise, you will have to repeat the process of telling your computer what the cable is.
5. Bearing in mind Tip #4, you should avoid using the cable in a standalone USB hub.
6. The cable is fooling the PICAXE into thinking that it's talking to a serial port on your computer. Those "communication" ports are known as COM1, COM2, COM3, or COM4. When you install the driver, the installer will choose one of those COM ports for you, and later you will have to know which one it is. The PDF guide should help you through this procedure. Unfortunately, you cannot skip it.

The Programming Editor software

If you have come this far, you're ready for the next big step, which is much easier. You need the PICAXE Programming Editor, available for free on the Software Downloads web page where you found the USB driver. (If you are using a Mac or Linux, you will need AXEpad, which is on the same web page.)

Downloading and installing the Programming Editor should be simple and painless. Once you have done that, you should find that it has placed a shortcut on your desktop. Double-click it, go to View→Options, and in the window that opens (shown in Figure 5-127), click the Serial Port tab. You should see a dialog box like the one in Figure 5-128. Now make sure that the Programming Editor is looking at the same COM port that was chosen by the USB driver. Otherwise, the Programming Editor won't know where to find your PICAXE chip.

In the Programming Editor, go to View→Options and click the Mode tab, then click the button to select the 08M chip.



Mode

PICAXE modes...

○ 08 ○ 14M ○ 18M ○ 20M ○ 28X1 - 40X1

● 08M ○ 18X ○ 20X2 ○ 28X2 - 40X2

Discontinued parts... ○ 18 ○ 28

○ 18A ○ 28A ○ 28X - 40X

Options: 4 MHz

Other modes...

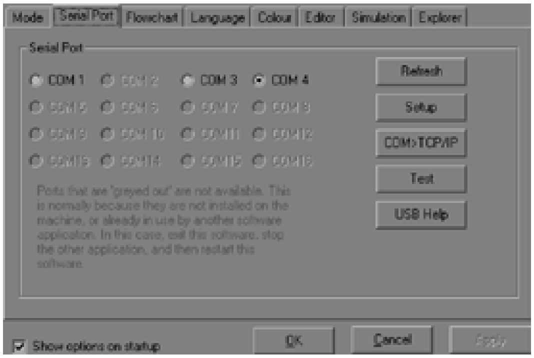
○ PICMicro - Assembler

○ Stamp 1

○ Stamp 1 - Extended

☑ Show options on startup

Figure 5-127. *This screenshot shows the options window of the PICAXE Program Editor, which you must use to select the type of chip that you intend to program (in our case, the 08M).*



Serial Port

○ COM 1 ○ COM 2 ○ COM 3 ● COM 4

○ COM 5 ○ COM 6 ○ COM 7 ○ COM 8

○ COM 9 ○ COM 10 ○ COM11 ○ COM12

○ COM13 ○ COM14 ○ COM15 ○ COM16

Ports that are "greyed out" are not available. This is normally because they are not installed on the machine, or already in use by another software application. In this case, exit this software, stop the other application, and then restart this software.

☑ Show options on startup

Figure 5-128. *Another screenshot of the options window shows the second essential choice that you must make: selection of the COM port that the installer chose on your computer.*

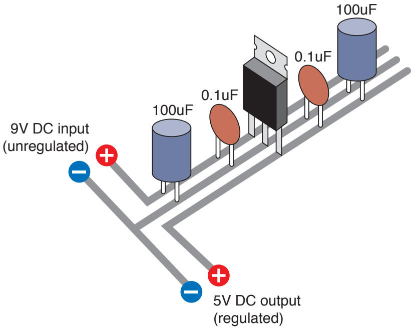


Figure 5-129. *PICAXE documentation specifies a 100 µF and 0.1 µF capacitor on the input side of a 5-volt regulator, and a similar pair of capacitors on its output side. On a breadboard, they can be arrayed like this.*

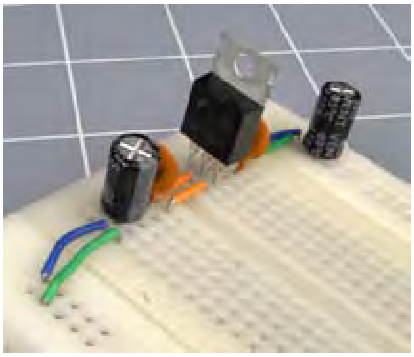

Figure 5-130. *The actual components for power regulation, applied to a breadboard, delivering 5 volts (positive and negative) down each side.*

Are we having fun yet? Obviously not, but you're through with software hassles for the time being. The last step before you're ready to use the PICAXE is to mount it, and its socket, on your breadboard.

Setting up the hardware

The PICAXE 08M looks like a 555 timer. (Other chips in the PICAXE range have more pins and more features.) It requires a properly regulated 5 volts, just like the logic chips you dealt with previously. In fact, the PICAXE people are rather emphatic about protecting it from voltage spikes. They want you to use two capacitors (one 100 µF, one 0.1 µF) on either side of an LM7805 regulator. This seems like overkill, but the PICAXE is more inconvenient to replace than a 555 timer. You certainly can't run down to RadioShack to buy one. So let's do what the manufacturer says, just in case, and set up a breadboard as shown in Figures 5-129 and 5-130.

Now for the chip itself. Note that the pins for positive and negative power are *exactly opposite* to those for the 555 timer, so be careful!

Set up your breadboard following the schematic shown in Figure 5-131. Note that I am showing the stereo socket on its underside, because I think that's how you'll have to use it with the breadboard. If you try to stick its pins into the holes in the board, they will fit, but when you insert the plug into the socket, the thickness of the plug will tend to raise the socket up so that it loses contact. I really think the way to go is to solder wires to the pins on the socket and push the wires into the breadboard. See Figure 5-133.

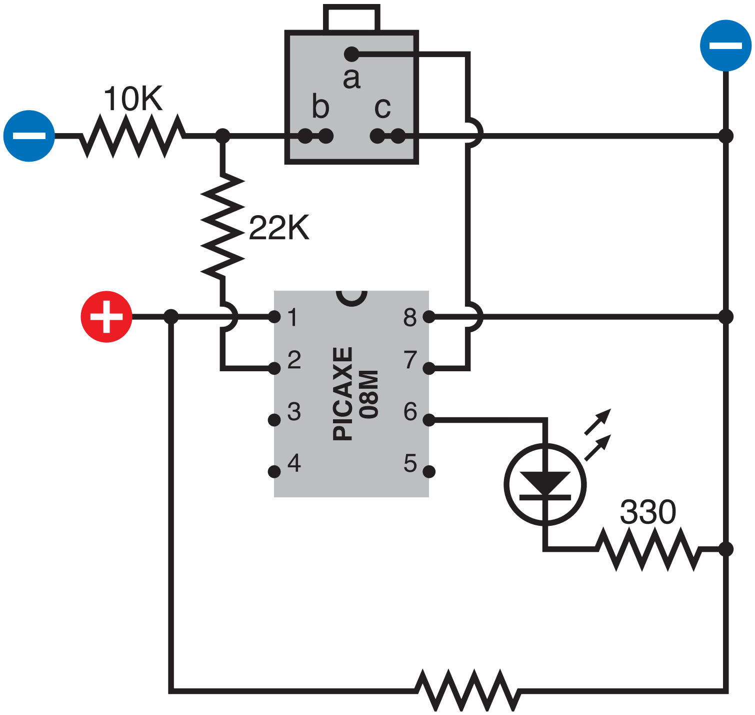

Figure 5-131. *The schematic of a test circuit for the PICAXE 08M shows the underside of the stereo socket, the essential 10K and 22K resistors on the input pin, and an LED to show an output from the chip.*

Be aware that the PICAXE manual shows things differently (although I have retained their labeling convention for the parts of the socket and the parts of the plug, identified as a, b, and c).

One little detail about the socket that is commonly supplied for use with the PICAXE: typically it has two *pairs* of contacts for the connections labeled b and c in the manual, and in my diagram. When you solder a connection, your solder joint should include *both* of the contacts in each pair, as shown in Figure 5-132.

Remember that the PICAXE must have 5 volts DC, and remember that your voltage regular will deliver this voltage reliably only if you give it extra voltage on its input side. If you provide it with 9 volts, that will provide a good amount of headroom.

The 22K and 10K resistors are essential for using the chip; see the following warning note for an explanation. My schematic also includes an LED and a 330Ω resistor, but they are needed only for the test that we'll be making momentarily.

Pin 2 Pull-Down

Always include the 22K resistor and the 10K resistor in the configuration shown in Figure 5-131. These resistors apply correct voltage to the serial connection, and when you're using the PICAXE on its own, they pull down the voltage on pin 2.

If pin 2 is left unconnected (floating), it may pick up random voltages, which the chip can misinterpret as a new program or other instructions, with unpredictable and undesirable results.

The 22K and 10K resistors should be regarded as permanent items accompanying your PICAXE regardless of whether you have it attached to your computer.

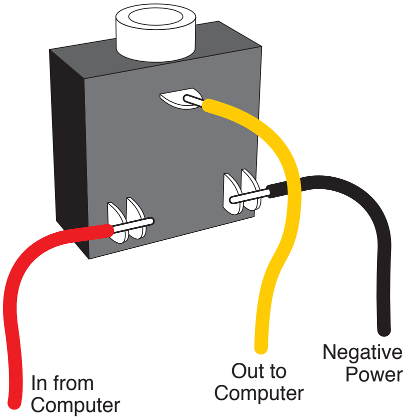

Figure 5-132. *Correct wiring of the socket is essential. When soldering wires to the lower terminals, make sure that you attach the wires to both of the terminals in each pair.*

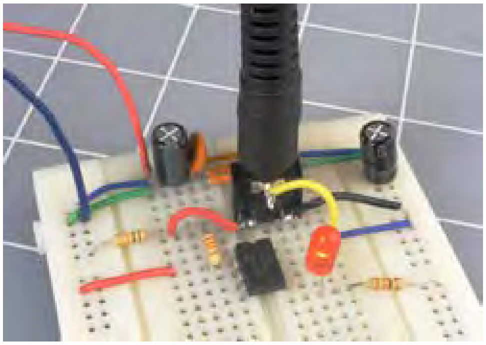

Figure 5-133. *The breadboard version of the test schematic, with the plug of the USB download cable inserted in the socket on the board. The PICAXE chip can now receive a downloaded program, and will immediately start to execute it.*

Verifying the Connection

Follow these steps carefully every time you want to program or reprogram your PICAXE chip:

1. Insert the USB plug of your PICAXE cable into the same USB port that you used before.
2. Start the Programming Editor (or AXEpad if you are using a Mac OS or Linux).
3. In the Programming Editor, select View→Options to verify that the editor is using the right COM port and is expecting the 08M PICAXE chip.
4. Plug the stereo plug on the free end of the USB cable into the stereo socket that is now wired into your breadboard. See Figures 5-133 and 5-134.
5. Check your wiring, and then connect your power supply to the breadboard.
6. Click the button labeled "program" in the Program Editor window to tell the software to look for the PICAXE.

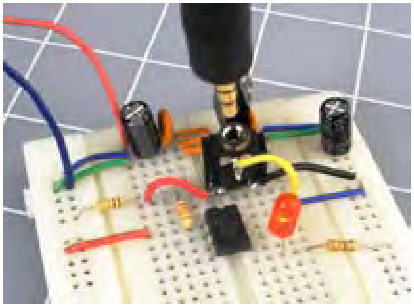

Figure 5-134. *After the program has been downloaded, the plug can be removed, and the program will continue to run, causing the LED to continue flashing.*

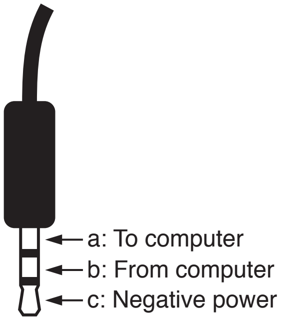
What If It Doesn't Work?

The first thing to do is pull out the plug of the USB cable from the PICAXE breadboard, leaving the other end of the cable attached to your computer. Set your multimeter to measure DC volts, and attach its probes to sections b and c of the plug. See Figure 5-135. Now click the "program" button again, and your meter should show 5 volts briefly coming out of your computer to the plug on the end of the cable.

If you detect the voltage, the software is installed and working properly. In that case, there's a problem on your breadboard, either in the chip or in the wiring around it.

If you cannot detect any voltage, the software probably wasn't installed properly, or is looking for the wrong serial port. Try uninstalling it and reinstalling it.



a: To computer
b: From computer
c: Negative power

Figure 5-135. *The stereo plug on the end of the USB download cable can be used for fault tracing. A multimeter set to measure DC volts can be attached to sections b and c of the plug to establish whether the Programming Editor is sending data through the serial connection.*

Your First Program

Finally you're ready to create your first program. Type the following code into the Programming Editor window:

```
main:
    high 1
    pause 1000
    low 1
    pause 1000
    goto main
```

Be sure to include the colon after the word "main" on the first line. See Figure 5-136 for a screenshot. The indents are created by pressing the Tab key. Their only purpose is to make program listings more legible. The software ignores them.

```
main:
        high 1
        pause 1000
        low 1
        pause 1000
        goto main
```

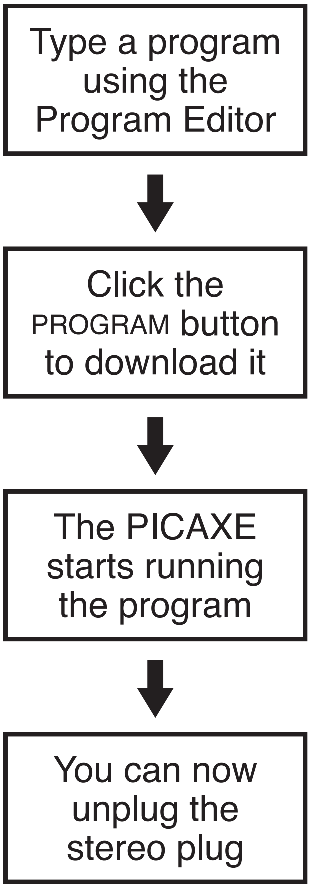
Figure 5-136. *This screenshot shows the first test program as it should be displayed by the Programming Editor (on a Windows computer).*

Click the Program button in the Programming Editor to download this program into the chip. As soon as the download is complete, the chip should start flashing the LED, lighting it for 1 second and then switching it off for 1 second. Figure 5-137 shows the steps that you should have followed to program the chip.

Now for the interesting part: disconnect the USB cable from the breadboard. The chip should continue flashing.

Disconnect the power supply from the breadboard and wait a minute or two for the capacitors to lose their charge. Reconnect the power, and the chip will start flashing again.

The program that you downloaded to the chip will remain in the memory inside the chip and will begin running every time power is applied to the chip.



Type a program using the Program Editor
Click the PROGRAM button to download it
The PICAXE starts running the program
You can now unplug the stereo plug

Figure 5-137. *Four steps to create and run a program on the PICAXE controller chip.*

Decoding the Code

The program doesn't use the usual pin numbers on the chip. It uses what I will call "logic pin numbers." Figure 5-138 shows how they are numbered. Figure 5-139 shows their multiple functions. I have put Logic Pin 0 in parentheses because its main purpose is to send data to the computer through the USB cable. It can do double duty as a digital output, but you have to disconnect it from the USB cable first. It's easy to forget to do this. It's a hassle that I prefer to avoid.

Let's take a look at the little program that you typed in. The first line identifies a section of the program. This program only has one section, and we're calling it "main." Any word with a colon after it is the name of a section of a program:

```
main:
```

The second line tells the chip to send a high output from Logic Pin 1:

```
high 1
```

The third line of the program tells the chip to wait for 1,000 milliseconds. This of course is the same as one second:

```
pause 1000
```

The fourth line tells the chip to change Logic Pin 1 back to its low state:

```
low 1
```

The fifth line tells the chip to wait for another 1,000 milliseconds:

```
pause 1000
```

The last line tells the chip to go back to the beginning of the "main" section:

```
goto main
```

Editing

What if you want to change the program? No problem! Use the Programming Editor to change one of the lines in the program. Substitute 100 instead of 1000 milliseconds, for instance. (The `pause` command can be followed by any number up to 65535.) In your program, don't use a thousands comma in any of the numbers that you specify.

Plug the USB cable into the breadboard again, hit the Program button on the screen, and the new version of the program will be automatically downloaded to the chip, overwriting the old version.

What if you want to save the program for future use? Just go to the File menu in the Programming Editor and save the program onto your computer's hard drive. Because the PICAXE uses a variant of the BASIC computer language, it adds a *.bas* filename extension.

Simulation

If you make a simple typing error, the Programming Editor will find it and stop you from downloading your program. It will leave you to figure out how to fix the line that contains the error.

Even if all the statements in your program are correctly typed, it's a good idea to run a simulation of what they'll do, before you download them. This is easily done: click the "simulate" button on the menu bar of the Programming Editor. A new window will open, displaying a diagrammatic view of the PICAXE chip and showing you the states of its pins. (Note that if you use very short `pause` commands, the simulation won't run fast enough to display the time accurately.) A simulation screenshot is shown in Figure 5-140.

The >> button at the bottom-right corner of the simulation window will open up a list of all the variables in your program. So far, it doesn't have any variables, but it soon will. All the zeros on the righthand side are binary numbers, which you can ignore for now.

You'll need to check the second part of the PICAXE documentation, which contains all the programming statements and their correct syntax. At the time of writing, this is stored at http://www.rev-ed.co.uk/docs/picaxe_manual2.pdf.

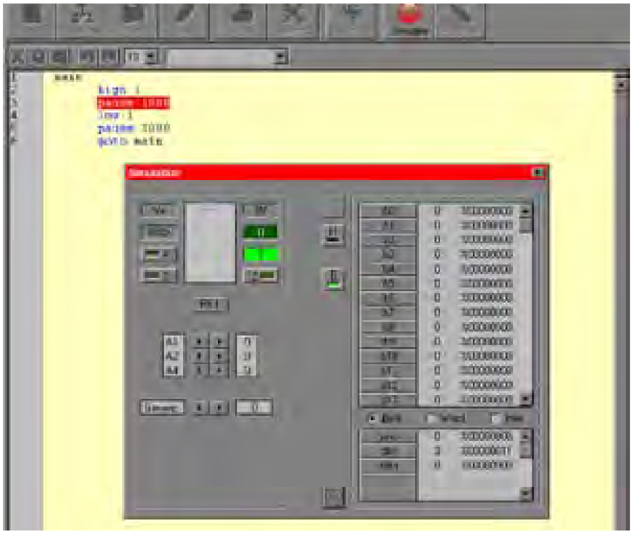

Figure 5-140. *This screenshot shows the simulation window that can be opened in the Program Editor to test program code before it is downloaded to the chip. The values of variables are shown in the section on the right. The pin states are shown on the left.*

Loops

Here's another thing I'd like you to try. Rewrite your program code as shown here and download it onto the PICAXE:

```
main:
    for b0 = 1 to 5
        high 1
        pause 200
        low 1
        pause 200
    next
    wait 2
    goto main
```

Note that `b0` is letter b followed by a zero, not letter b followed by letter O. The extra indents once again are added to make the listing easier to understand. The four lines beginning "high 1" and ending "pause 200" will be executed repeatedly. It's helpful to see them as a block.

Watch the light and see what happens. It should flash five times quickly, then wait for two seconds, and then repeat. You just added a *loop* to your program. You can use a loop if you want something to happen more than once.

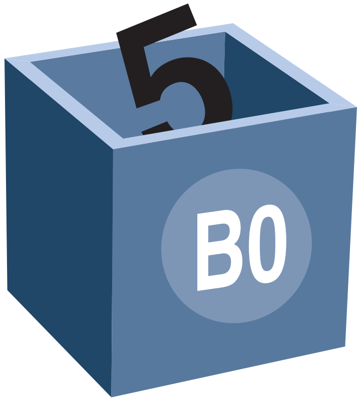

Figure 5-141. *To understand how a program works, visualize a variable as being like a "memory box" with its name on the outside and a number stored on the inside.*

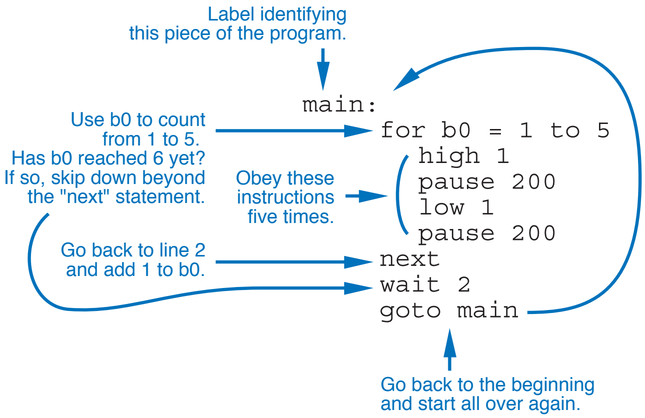
b0 is known as a *variable*. Think of it as being like a little "memory box" with its name, b0, on a label on the outside. Figure 5-141 illustrates this concept. This particular memory box can contain any number from 0 through 255. The loop begins by telling the computer to put number 1 in the box, then process the remaining statements, until the word "next" sends the processor back to the first line, at which point it adds 1 to the contents of b0. If the value of b0 is 5 or less, the loop repeats. If the value is 6, the loop has run five times, so it's over, and the PICAXE skips down to the "wait 2" statement after "next." See Figure 5-142 for an annotated version of the program listing.

"Wait" is a PICAXE command that is measured in whole seconds, so "wait 2" waits for 2 seconds. Then "goto main" begins the procedure all over again.

If your flashing-light demo worked out as planned, it's time to take the next step and make the chip do something more useful.



Label identifying
this piece of the program.
Use b0 to count
from 1 to 5.
Has b0 reached 6 yet?
If so, skip down beyond
the "next" statement.
Obey these
instructions
five times.
Go back to line 2
and add 1 to b0.
Go back to the beginning
and start all over again.

```
main:
for b0 = 1 to 5
   high 1
   pause 200
   low 1
   pause 200
next
wait 2
goto main
```

Figure 5-142. *The blue annotations explain what the program, on the right, is telling the PICAXE to do.*

FUNDAMENTALS

Basic PICAXE parameters

Here are some of the most useful parameters of the PICAXE:

- The PICAXE requires 5 volts DC, regulated.
- The inputs and outputs of the PICAXE are compatible with 5-volt logic chips. You can attach them directly.
- Each PICAXE pin can sink or source up to 20mA. The whole chip can deliver up to 90mA. This means that you can run LEDs directly from the pins, or a piezo noisemaker (which draws very little current), or a transistor.
- You can use a chip such as the ULN2001A Darlington array (mentioned in the previous experiment) to amplify the output from the PICAXE and drive something such as a relay or a motor.
- The chip executes each line of your program in about 0.1 milliseconds.
- The 08M chip has enough flash memory for about 80 lines of program code. Other PICAXE chips have more memory.
- The PICAXE provides 14 variables named b0 through b13. The "b" stands for "byte," as each variable occupies a single byte. Each can hold a value ranging from 0 through 255.
- No negative or fractional values are allowed in variables.
- You also have 7 double-byte variables, named w0 through w6. The "w" stands for "word." Each can hold a value ranging from 0 through 65535.
- The "b" variables share the same memory space as the "w" variables. Thus:
  - b0 and b1 use the same bytes as w0.
  - b2 and b3 use the same bytes as w1.
  - b3 and b4 use the same bytes as w2.
  - b5 and b6 use the same bytes as w3.
  - b7 and b8 use the same bytes as w4.
  - b9 and b10 use the same bytes as w5.
  - b11 and b12 use the same bytes as w6.
  - b13 and b14 use the same bytes as w7.

  Therefore, if you use w0 as a variable, do not use b0 or b1. If you use b6 as a variable, do not use w3, and so on.
- Variable values are stored in RAM, and disappear when the power is switched off.
- The program is stored in nonvolatile memory, and remains intact when the power is off.
- The manufacturer's specification claims that the nonvolatile memory is rewritable up to about 100,000 times.
- If you want to attach a switch or pushbutton to a pin and use it as an input, you should add a 10K pull-down resistor between the pin and the negative side of the power supply to hold the pin in a low state when the switch is open. Figure 5-143 shows how pull-down resistors should be used in conjunction with a SPST switch or a pushbutton.
- On the 08M chip, if you apply a varying resistance between Logic Pins 1, 2, or 4, and the negative side of the power supply, the chip can measure it and "decide" what to do. This is the "Analog-Digital Conversion" feature—which leads to our next experiment.

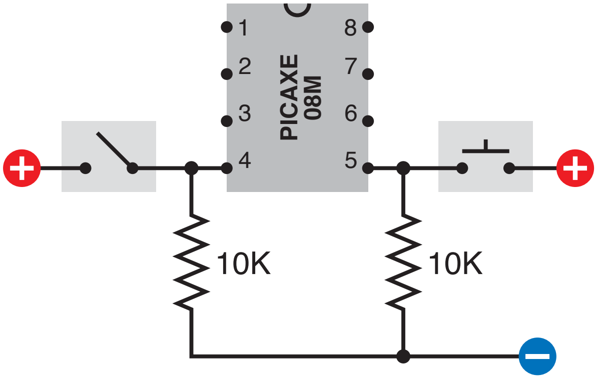


Figure 5-143. *The PICAXE can respond to the state of a switch or button attached to any of its input-capable pins. A 10K resistor must be used to pull down the state of the pin when the contact of the switch or button is open. Otherwise, you may get unpredictable results.*

Experiment 35: Checking the Real World

Often we want a microcontroller to measure something and respond in an appropriate way. For instance, it can measure a low temperature and sound an alarm, as I suggested in the example that I gave earlier.

The PICAXE has three analog-to-digital converters (ADCs) built in, accessible via logic pins 1, 2, and 4, as shown in Figure 5-139. The best way to use them is by applying a potential somewhere between 0 and 5 volts. In this experiment, I'll show you how to calibrate the response of the chip.

You will need:

- Trimmer potentiometer, 2K. Quantity: 1.
- PICAXE 08M chip and associated USB cable and socket. Quantity: 1 of each.

Procedure

Take the same trimmer potentiometer that you used in Experiment 32 and wire its center terminal to Logic Pin 2 of the PICAXE (which is hardware pin 5). The other two terminals of the 2K trimmer go to positive and to negative, respectively. So depending how you set the trimmer, the pin of the PICAXE is directly connected to positive (at one end of the scale), or directly connected to negative (at the other end of the scale), or somewhere in between. See Figure 5-144 for the revised schematic, and Figure 5-145 for a photograph of the breadboarded circuit.

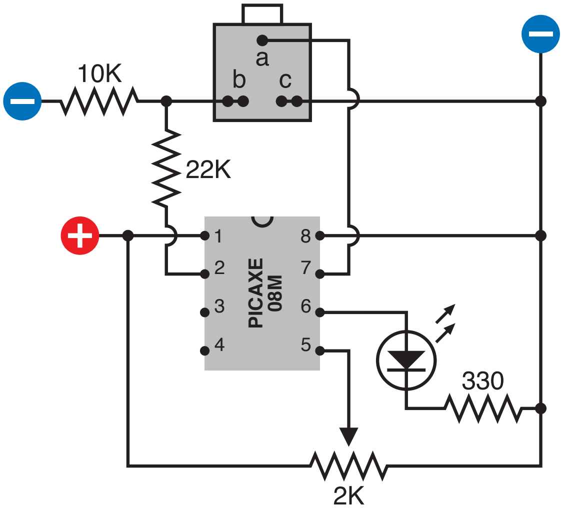

Figure 5-144. *This schematic, drawn in a layout suitable for breadboarding, shows how a 2K potentiometer can be used to apply a varying voltage to one of the pins of the PICAXE that is capable of converting an analog signal to a digital value.*

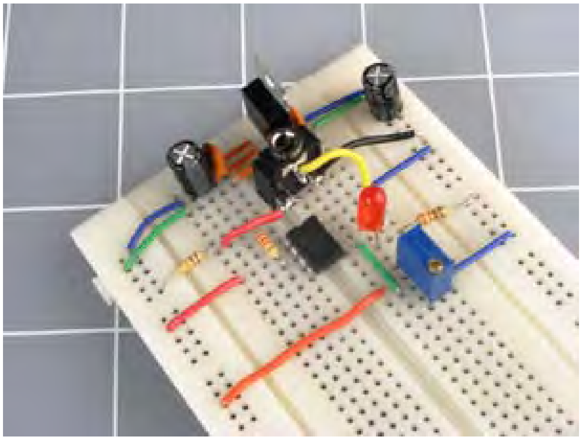

Figure 5-145. *The trimmer potentiometer added to the previously breadboarded circuit.*

Now we need a program to tell the chip what to do. Using the Programming Editor, start a new document. The code should look like this:

```
main:
    readadc 2,b0
    debug b0
    goto main
```

The command "readadc 2,b0" means "read the analog input on Logic Pin 2, convert from analog to digital, and store the result in b0."

The command "debug b0" tells the chip to go into program debugging mode, in which it uses its USB cable to tell the Programming Editor the values of all the variables while the program is running. The variables are displayed in a debugging window.

Download the program, and as the program starts to execute, the debugging window should open. Start adjusting the trimmer while looking at the value of b0, and you'll see b0 change its value.

You can make a table and draw a graph showing the relationship between the resistance between Logic Pin 2 and ground, and the value of b0. Just pull the trimmer off the breadboard, measure its resistance with a meter, then increase its resistance by, say, 200Ω, put it back into the breadboard, and look at the value of b0 again.

This is laborious, but calibrating equipment is always laborious—and in any case, I decided to do it for you. The graph is shown in Figure 5-146. You can also see the raw data numbers in the following table. I was pleased to find that the PICAXE gives a very precise, linear response to the input voltage. In other words, the graph is a straight line.

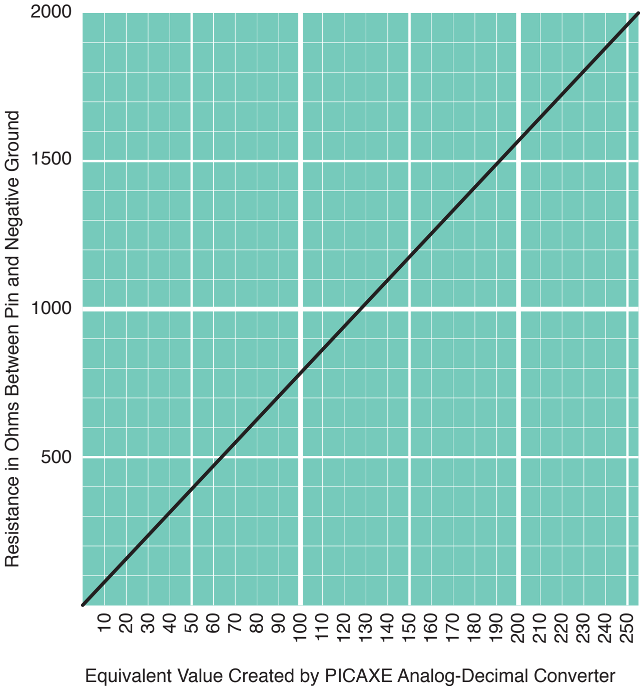

Figure 5-146. *When an ADC input pin is hooked up to a 2K potentiometer, which is connected across the same voltage that powers the chip, you should find that the resistance between the input pin and the negative side of the power supply generates the series of digital values shown on the graph. Note that the potentiometer must have a 2K value, and the power supply is assumed to be precisely 5 volts.*

This table shows measurements made with PICAXE 08M controller.

Resistance (in ohms) between the ADC pin and the negative supply	Equivalent digital value
2000	255
1900	243
1800	230
1700	218
1600	205
1500	192
1400	179
1300	166
1200	154
1100	141
1000	128
900	115
800	102
700	90
600	77
500	64
400	51
300	38
200	26
100	13
0	0

Now we can modify the program to make it do something with the information that it's taking in:

```
main:
    readadc 2,b0
    let w1 = 5 * b0
    high 1
    pause w1
    low 1
    pause w1
    goto main
```

Notice what's happening here. First we get a value in b0, and then on the next line, we do some arithmetic with it. The asterisk means "multiply." So the statement says, "Take whatever value is in b0, multiply by 5, and transfer it to another variable, w1." We have to use a w variable, because when we multiply the value of b0 by 5, we may get a number that is bigger than 255—too big to fit into a byte variable.

Finally, we take variable w1 and use it with a "pause" statement instead of a fixed number value. We're saying to the PICAXE, "pause for whatever number of microseconds you get by checking the value of w1."

So the software checks a variable resistance, turns it into a number, and applies that number to adjust the flashing speed of the LED.

Think back to the need of the cart powered by stepper motors. It was supposed to check two photoresistors, and adjust the speed of each motor accordingly. Well, this PICAXE program is a step in that direction. It can measure voltage on a pin and change the output frequency on another pin. If you had two PICAXE chips, you could wire each of them to a photoresistor and a motor. Then you could adjust the behavior of your cart by editing the second line in the program, where it converts the value of b0 to the value of w1 which will be used in the "pause" command to determine the number of pulses per second. Instead of multiplying by 5 you could multiply by 7 or whatever number gives you the result you need. This leads to an important conclusion: *a big advantage of a programmable chip is that you can make adjustments in software*.

Because the PICAXE 08M actually has more than one ADC input, and has three pins that can be used for output, you might wonder whether you could use just the one chip to control both motors in response to inputs from two sensors. The problem is that the three output pins on the 08M also function as the three ADC input pins. You'd do better to buy one of the more advanced PICAXE chips, such as the 18M, which has more pins to choose from. It uses the same basic set of programming instructions, and doesn't cost much more money.

Also, you should read the PICAXE documentation and look up the "pwmout" command, which is short for "pulse-width modulation output," but you can think of as meaning "power motor output." This is specifically intended to run stepper motors. It establishes an output frequency of pulses that will continue while the chip obeys other instructions in its program.

FUNDAMENTALS

Extra features

A complete guide to the 08M would fill a book of its own, and of course such books already exist (just search the books section of Amazon.com for keyword "picaxe"). But I'll finish my introduction to the controller by listing some of its extra capabilities, leaving you to look them up and explore them. Then I'm going to suggest one last experiment.

Interrupts

The PICAXE 08M allows you to set one "interrupt." This feature tells the chip to make a mental note that if a particular event occurs—such as a switch applying voltage to one pin—it should stop doing whatever else it was doing, and respond to the interruption.

Infrared

One pin on the PICAXE 08M can be used to receive infrared signals from a TV-style remote that you can buy from the same suppliers that sell the PICAXE itself. With an infrared sensor attached to the chip, you can issue commands remotely. If you want to build a remote-controlled robot, the chip is specifically designed with this in mind.

Servo motors

Every PICAXE chip has at least one pin that can send a stream of pulses to control a typical servo motor. On the 08M chip, it's Logic Pin 2. The width of each pulse tells the motor how far to rotate from its center position before stopping. A 555 timer can send this stream, but the PICAXE makes it easier. You can search online for more information about servo motors, which are especially useful for applications such as steering model vehicles, adjusting the flaps on model airplanes, and actuating robots.

Music

The PICAXE has an onboard tone generator that can be programmed with a "tune" command to play tunes that you write using a simple code.

Alphanumeric input/output

The "kbin" programming command is available in the PICAXE models 20X2, 28X1 and 28X2, and 40X1 and 40X2. You can plug a standard computer keyboard into the chip, and it will read the keypresses. You can also attach alphanumeric displays, but these procedures are nontrivial. For instance, when you're trying to figure out which key someone has pressed on a keyboard, your program has to contain a list of the special hexadecimal codes that the keyboard creates.

Pseudorandom number generation

All PICAXE models can generate pseudorandom numbers using a built-in algorithm. If you initialize the number generator by asking the user to press a button, and you measure the arbitrary time that this takes, you can seed the pseudorandom number generator with the result, and the pseudorandom number generator will have a less repeatable sequence.

Visit *http://www.rev-ed.co.uk/docs/picaxe_manual1.pdf* to learn more.

Experiment 36: The Lock, Revisited

The combination lock that I described in Experiment 20 is especially appropriate for a microcontroller, because it requires a series of operations that resemble a computer program. I'm going to show how this project can be redesigned using a PICAXE 08M, and then leave it to you to consider how some of the other projects in this book could be converted.

You will need:

- The same type of keypad and relay recommended in Experiment 20.
- A transistor or Darlington array to amplify the output from the PICAXE so that it can drive the relay.

Getting the User Input

Any of the input pins on the PICAXE can sense a switch closing. The trouble is that we only have three pins capable of doing this, and even the most advanced PICAXE chip has fewer than 10 such pins. So how can we attach a 10-key keypad to the 08M?

I have a suggestion: attach various resistors to the keypad, so that each key applies a different voltage to one of the ADC pins. Then use the ADC feature to convert the voltage to a number, and use a table of possible numbers to figure out which key is being pressed. This may not be the most elegant solution, but it works!

The keypad can be wired as shown in Figure 5-147. The asterisk key is still being used to supply power, as in the original experiment, while the pound key resets the relay at the end of your computing session, as before.

Current flows through a series of resistors, beginning with one that has a value of 500Ω. Because this is not a standard value, you will either have to make it by combining other resistors in series, or by presetting a trimmer potentiometer. After that, each button is separated from the next button by a 100Ω resistor. Finally, at the end of the chain, a 600Ω resistor separates the last button from the negative side of the power supply. Again, this is not a standard value, and you may have to use a trimmer.

Add up all the resistances and you have 2K, which is the range that the PICAXE wants us to use. When you press a button, you tap into the chain of resistances. Button 9 puts 600Ω between the PICAXE ADC pin and ground. Button 6 is 700Ω, button 3 is 800Ω, and so on. (You may prefer to lay out the buttons so that the resistance progresses in a more logical fashion. That's up to you. I chose to lay them out in the way that would be easiest to visualize on a keypad.)

Now look back at the ADC values that I supplied in the table on page 308. These are the values that you should get when you press various keypad buttons—but you cannot count on them being absolutely precise, because they may vary if your resistor values are not quite accurate, or if your power supply isn't exactly 5 volts. It's not safe to say, for example, that the PICAXE will deliver an ADC conversion value of precisely 77 when the resistance is 600Ω. It's safer to say that the value will be between 71 and 83. If we specify a range as shown in the following table, we have a much better chance of interpreting each button correctly.

Button number		Range
9	600	71–83
6	700	84–96
3	800	97–108
0	900	109–121
8	1000	122–134
5	1100	135–147
2	1200	148–160
7	1300	161–172
4	1400	173–185
1	1500	191–198

Suppose you attach the common pin of your keypad to ADC Logic Pin 2 of the PICAXE. You can now use the Program Editor to write a program that looks like this:

```
getkey:
    readadc 2,b0
    let b1 = 9
    if b0 < 84 then finish
    let b1 = 6
    if b0 < 97 then finish
    let b1 = 3
    if b0 < 109 then finish
    let b1 = 0
    if b0 < 122 then finish
    let b1 = 8
    if b0 < 135 then finish
    let b1 = 5
    if b0 < 148 then finish
    let b1 = 2
    if b0 < 161 then finish
    let b1 = 7
    if b0 < 173 then finish
    let b1 = 4
    if b0 < 186 then finish
    let b1 = 2

finish:
    return
```

What does the word "return" mean at the end? I'll get to that in a second. I want to explain the rest of the routine first.

b0 receives the value supplied by the analog-digital converter when it looks at the keypad. After storing the number in b0, the routine has to figure out which keypad key it matches. The key identity (0 through 9) will be stored in another variable, b1.

The program starts by assigning value 9 to b1. Then it checks to see whether b0 < 84. This means "if b0 is less than 84." If it is, then the routine tells the PICAXE to "finish," which means "jump to the finish: label." But if b0 is *not* less than 84, by default the PICAXE continues on to the next line, which makes a second attempt at guessing which key has been pressed. It assigns number 6 to b1. Now there's another if-then test—and so on. This process of reassigning values to b1 stops only when it gets to the point where b0 is greater than a number in the table.

If you're familiar with other dialects of BASIC, this may seem a bit laborious to you. You may wonder why we can't use a statement such as this:

```
    if b0 > 70 and b0 < 84 then b1 = 9
```

The answer is that PICAXE BASIC isn't sufficiently sophisticated to allow this. An if-then statement has to result in a jump to another section of the program. That's the only permitted outcome.

If you don't have any prior programming experience, the routine may still seem laborious to you, and perhaps a bit puzzling, too. This is understandable, because you're getting a crash course in software design without any formal preparation. Still, the PICAXE Programming Editor can be a big help, because it has its simulation feature. Before you can use this, though, you have to precede the routine that I just supplied with a control routine that you must type above it. The screenshot in Figure 5-148 shows you how it should look.

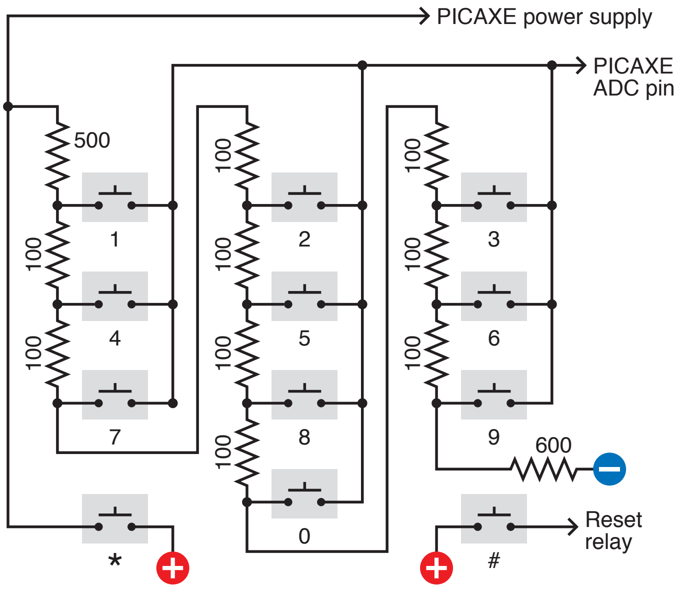

Figure 5-147. *A quick and simple way of attaching a keypad to provide numeric input to the PICAXE uses a chain of resistors totalling 2,000Ω. When a button is pressed, it connects the ADC input pin to a point in the chain. The resistance detected by the input pin can then be converted by the program in the chip to determine which key has been pressed.*

I have chosen an arbitrary combination of 7-4-1 for our combination lock. Using these numbers, the main section of the program looks like this:

```
main:
    low 1
    gosub getkey
    if b1<>7 then main
    gosub getkey
    if b1<>4 then main
    gosub getkey
    if b1<>1 then main
    high 1
    end
```

I should explain that the <> pair of symbols mean "is not equal to." So the fourth line of the program means, "if b1 is not equal to 7."

The value of b1 is supposed to be 7 if the user is putting in the correct combination. So if it's not 7, the user has entered the wrong value, and the if-then statement sends the PICAXE back to the beginning. In fact anytime the user inputs a number that is not in the correct 7-4-1 sequence, the program sends the PICAXE back to the beginning. This is the way the pure-hardware version of this experiment was set up.

But what is this word "gosub"? It means "go to a subroutine." A subroutine is any sequence of program statements that ends with the instruction to "return." So "gosub getkey" tells the PICAXE to mark its current place in the program while it skips to the `getkey:` section of code, which it obeys, until it finds the word "return," which returns it to the place from where it came.

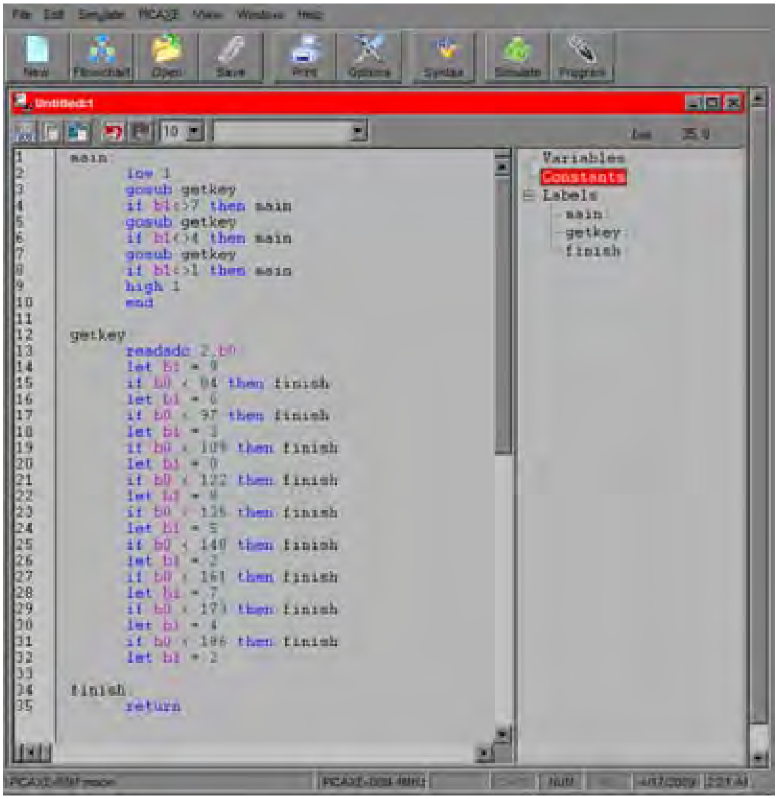
The PICAXE continues in this fashion until it reaches the word "end." I had to insert the word "end" because otherwise the PICAXE will continue executing the program and will fall into the subroutine. "End" stops it from doing so. Figure 5-148 shows a screenshot of the complete listing.

So—is that all? Yes, that's it. If you enter the code into the Programming Editor exactly as I have supplied it, you should be able to run it in simulation mode, and in the simulation window, click the right-arrow beside Logical Pin A2 to increase its value in steps. Each time you pass one of the values in the `getkey:` subroutine, you should see the value for variable b1 change in the display.

This is really all you need to perform the functions of the combination lock. When the PICAXE runs this program, it waits for the correct combination. If it receives the combination, it sends the output from logical pin 1 high; otherwise, logical pin 1 stays low.

The only additional item you need is a transistor or CMOS gate between logical pin 1 and the relay that unlocks the computer, because the PICAXE cannot deliver enough current to operate the relay by itself.

Putting this procedure into a controller chip not only simplifies the circuit, but offers another advantage: you can change the combination simply by rewriting the program and downloading the new version into the chip.



```
main:
        low 1
        gosub getkey
        if b1<>7 then main
        gosub getkey
        if b1<>4 then main
        gosub getkey
        if b1<>1 then main
        high 1
        end

getkey:
        readadc 2,b0
        let b1 = 9
        if b0 < 84 then finish
        let b1 = 6
        if b0 < 97 then finish
        let b1 = 3
        if b0 < 109 then finish
        let b1 = 0
        if b0 < 122 then finish
        let b1 = 8
        if b0 < 135 then finish
        let b1 = 5
        if b0 < 140 then finish
        let b1 = 2
        if b0 < 161 then finish
        let b1 = 7
        if b0 < 171 then finish
        let b1 = 4
        if b0 < 186 then finish
        let b1 = 2

finish:
        return
```

Figure 5-148. *This screenshot shows the complete listing of a program to read a sequence of three keypresses in conjunction with a combination lock. If the sequence is correct, the PICAXE sends a high output from one of its pins. If the sequence is incorrect, the program loops back to the beginning.*

FUNDAMENTALS

Limitations of MCUs

The PICAXE does have some disadvantages. Its voltage requirements alone restrict you from using it with the kind of freedom of a 555 timer.

Also, although I can get an instant result by plugging a 555 timer into a breadboard and adding a couple of resistors and a couple of capacitors, the PICAXE requires me to add a download socket, hook it up to my computer, write a program in the Programming Editor, and download the program.

Some people don't like writing software, or they have difficulty thinking in the relentlessly left-brain way that computer programming requires. They may prefer the hands-on process of assembling hardware.

Other people may have the opposite preference. This of course is a matter of taste, but one thing we know beyond all doubt is that computer programs often contain errors that may not reveal themselves until weeks or months later. The PICAXE, for instance, doesn't protect you if a number is assigned to a variable that exceeds the limit for that type of variable. Suppose b1=200 and b2=60 and your program tells the PICAXE:

```
let b3 = b1 + b2
```

The result should be 260, but byte-size variables can only count up to 255. What happens? You will find that b3 acquires a value of 4, without any warning or explanation. This is known as an "overflow error," which can be very difficult to predict, because it happens at runtime, when external factors are in control. The code looks perfectly good; the Programming Editor doesn't find any syntax errors; the simulation behaves properly. But in the real world, days or even months later, an unexpected set of circumstances results in an input that causes the overflow, and because the code is residing inside the chip at this point, you may have a hard time figuring out what on earth went wrong.

Software has its problems. Hardware has its advantages.

FUNDAMENTALS

Unexplored territory

If you've taken the time to complete most of the projects in this book with your own hands, you have gained a very rapid introduction to the most fundamental areas of electronics.

What have you missed along the way? Here are some topics that remain wide open for you to explore. Naturally you should search online if they interest you.

The informal, learning-by-discovery approach that I have used in this book tends to be light on theory. I've avoided most of the math that you'd be expected to learn in a more rigorous course on the subject. If you have mathematical aptitude, you can use it to gain a much deeper insight into the way in which circuits work.

I didn't deal much with computer architecture, either. We didn't go very far into binary code, and you didn't build a half-adder, which is a great way to learn how computers function on the most fundamental level. Perhaps you should think about assembling one.

I avoided going deeply into the fascinating and mysterious properties of alternating current. Here again, some math is involved, but just the behavior of current at high frequencies is an interesting topic in itself.

For reasons already stated, I avoided surface-mount components—but you can still go into this area yourself for a relatively small investment, if you like the idea of creating fascinatingly tiny devices. This may be the future of hobby electronics, so if you stick with it, you'll probably end up in the world of surface-mount.

Vacuum tubes were not mentioned, because at this point, they are mainly of historical interest. But there's something very special and beautiful about tubes, especially if you can enclose them in fancy cabinetwork. In the hands of a skilled craftsperson, tube amplifiers and radios become art objects.

I didn't show you how to etch your own printed circuit boards. This is a task that appeals to only certain people, and the preparation for it requires you to make very neat drawings or use computer software for that purpose. If you happen to have those resources, you might want to do your own etching. It could be a first step toward mass-producing your own devices.

I didn't cover static electricity at all. High-voltage sparks don't have any practical applications, and they entail some safety issues—but they are stunningly impressive, and you can easily obtain the necessary information to build the equipment. Maybe you should try.

Other Controllers

If you want something more powerful, a BASIC Stamp is the logical next step after a PICAXE. the BASIC Stamp is so called because it originally looked like a postage stamp. The BASIC Stamp has a larger vocabulary of commands and a bigger range of add-on devices (including displays with graphical capability, and a little keyboard that is specifically designed for use with the controller). The BASIC Stamp is shown in Figure 5-149.

On the downside, you'll find that everything associated with the BASIC Stamp is a bit more expensive than in the PICAXE world, and the download procedure isn't quite as simple.

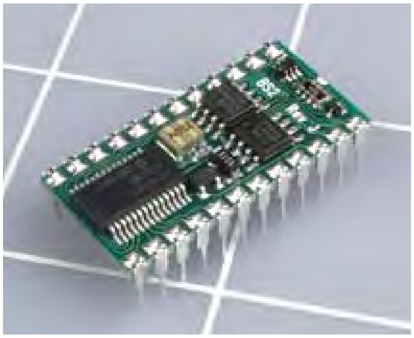


Figure 5-149. *The BASIC Stamp controller consists of surface-mounted components on a platform that has pins spaced at 1/10-inch intervals, for insertion in a breadboard or perforated board. This component uses a version of BASIC that is similar to the programming language of the PICAXE, but has many more extensions. The BASIC Stamp is available for use with a wide range of peripheral devices, including many alphanumeric dot-matrix displays.*

One of the more recent developments in the world of MCUs is the Arduino, which is both sophisticated and powerful. It does require programming in the C language. This language is a little more difficult to understand, and has only the vaguest similarity to the syntax that is used in the PICAXE and BASIC Stamp. On the other hand, because C dominates the larger world of computing, learning it might not be such a bad idea—and the Arduino offers some truly amazing capabilities. Because it is so popular, there are also many software tools, documentation, user forums, and many enthusatic hobbyists to help you. Two other Make: Books titles that I mentioned previously, *Getting Started with Arduino* and *Making Things Talk*, provide a great introduction.

In Closing

I believe that the purpose of an introductory book is to give you a taste of a wide range of possibilities, leaving you to decide for yourself what you want to explore next. Electronics is ideal for those of us who like to do things ourselves, because almost any application—from robotics, to radio-controlled aircraft, to telecommunications, to computing hardware—allows opportunities that we can explore at home, with limited resources.

As you delve deeper into the areas of electronics that interest you most, I trust you'll have a satisfying learning experience. But most of all, I hope you have lots of fun along the way.

Every text I've seen on the subject of electrostatics seems to begin with a history of the subject. A. D. Moore, one writer whose works I particularly enjoy, said that if cavemen had cats that rubbed up against them then they must certainly have been aware of the presence of static electricity. There are theories now going around the scientific community that claim lightning triggered the formation of the first chains of DNA. I'll take that one step further and guess that lightning began the evolutionary process that created our species.

Static electricity is one of the most fascinating and possibly most overlooked fields of modern electronics. We all take static for granted. Before I began experimenting with static electricity it would have been very difficult to convince me that it was easy to get 3500 volts from an old plastic bottle or 10,000 volts and more from a rubber band! Even now as I watch one of these tiny generators in action it is difficult to imagine that it is producing these voltages.

As you learn about electrostatics you will find many strange and wonderful experiments to perform. For example, it is possible to mysteriously levitate objects, blow a candle flame to one side with an invisible wind, and to light neon bulbs without wires.

There are motors that can be built to run on static electricity! Well-made electrostatic motors are so sensitive that they have been powered by the earth's natural electrical charge alone! Connect your motor to an antenna, and off it goes!

In addition to the many curiosities static electricity makes possible, there is also the potential for serious research with many astounding possibilities.

Consider the work of Professor John G. Trump, formerly of the Massachusetts Institute of Technology. Professor Trump points out that electrostatic forces are the most powerful forces known in nature – stronger by far than gravity or magnetism. Professor Trump demonstrates the practical application of electrostatic generators with the following illustration:

Consider two conductive plates, 100 square inches in area, facing each other and separated by an insulator. If the plates are each charged oppositely to 300 volts per centimeter the force of attraction between them will be one 2,000th of a pound. Increase this charge to 30,000 volts per centimeter and the attraction escalates to half a pound. Now increase this voltage to the order of three million volts per centimeter and the force of attraction jumps to 5,700 pounds! As Trump has said "Force of this order has more than a passing interest for power engineers." Trump and his colleagues had been pursuing the creation of electrostatic generators they hoped would one day rival modern electromagnetic generators.

Just how much electrostatic energy is theoretically possible? Consider an aluminum cube only one centimeter square. Imagine that all the electrons in that cube were removed and kept one meter away. The cube has only positive charges, and the electrons one meter away only negative charges. Since positive and negative charges attract, what would be the force of attraction generated between them? The answer turns out to be an astounding thirty-two million million million million pounds! Professor A.D. Moore, an expert in electrostatics, points out that this force would be equal to the weight of a steel cube 76 miles high!

Of course, as much fun and as inspiring as it is to ponder the theoretical world of electrostatics, back in the real world we find that electrons don't leave home so easily. The most useful electrostatic inventions to date make use of the 'little' forces of electrostatics. But keep that cube in mind and let everyone wonder why you have that curious smirk on your face whenever you run your generator.

What voltages are possible for the experimenter? The four easily assembled generators shown in the following text will give you an idea. Each one intentionally operates on a slightly different principal of gathering an electrostatic charge. If you build them, or just simply become familiar with them, you will develop a understanding of the most popular ways of generating static electricity.

I am confident that if you become acquainted with these machines you will have no difficulty at all in constructing many others of your own design. The reason that I am so confident is that I designed and constructed all of these machines to teach myself about electrostatics! Each machine represents the best of my thoughts at the time I constructed it.

You will soon find that it is easily possible to construct a static generator capable of producing 50 to 100 thousand volts! If you are a craftsman, 200 thousand volts and more can be obtained by optimizing the designs of the higher power generators such as the Van De Graaff shown later in the text.

Electrostatic generators are also remarkably inexpensive. With a little foraging through the surplus bins, no generator in this text cost me more than $30 to build! I know of no other way to approach these voltages for such a low cost.

A Little History of the First Practical Generators

The first electrostatic generators produced their voltage with friction. Towards the end of the 17th century Otto von Guericke, an amateur physicist from Magdeburg, developed the first practical electrical machine – an electrostatic generator. What follows are his own instructions for building one:

"Secure one of the glass globes which are called phials, about the size of a youngster's head; fill it with sulfur, ground in a mortar and melted by the application of flame. After it freezes, break the phial, take out the sulfur globe and keep it in a dry place, not a moist one. Perforate it with a hole so that it can spin upon an iron axle. Thus the globe is prepared.

"To demonstrate the power developed by this globe, place it with its axis on two supports in the machine – a hand's breadth above the baseboard – and spread under it various sorts of fragments such as bits of leaves, gold dust, silver filings, snips of paper, hairs, shavings, etc. Apply a dry hand to the globe so that it is stroked or grazed two or three times or more. Now it attracts the fragments and, as it turns on its axis, carries them around with it.

"When a feather is in contact with the globe, and afterwards in the air, it puffs itself out and displays a sort of vivacity ... and if someone places a lighted candle on the table and brings the feather to within a hand's breadth of the flame, the feather regularly darts back suddenly to the globe and, as it were, seeks sanctuary there."

Otto Von Guericke goes on to describe experiments by which he produced both light and sound from his amazing globe!

The instructions for von Guericke's globe are simple enough for any experimenter today to follow. The only note that I would add is that in casting my own globe I found that large quantities of sulfur would become much smaller pools when melted, and that if the globe were not filled on the first pouring it would not appear nearly as attractive when finished. So, remember to begin with a large amount of sulfur.

THE ELECTROPHORUS

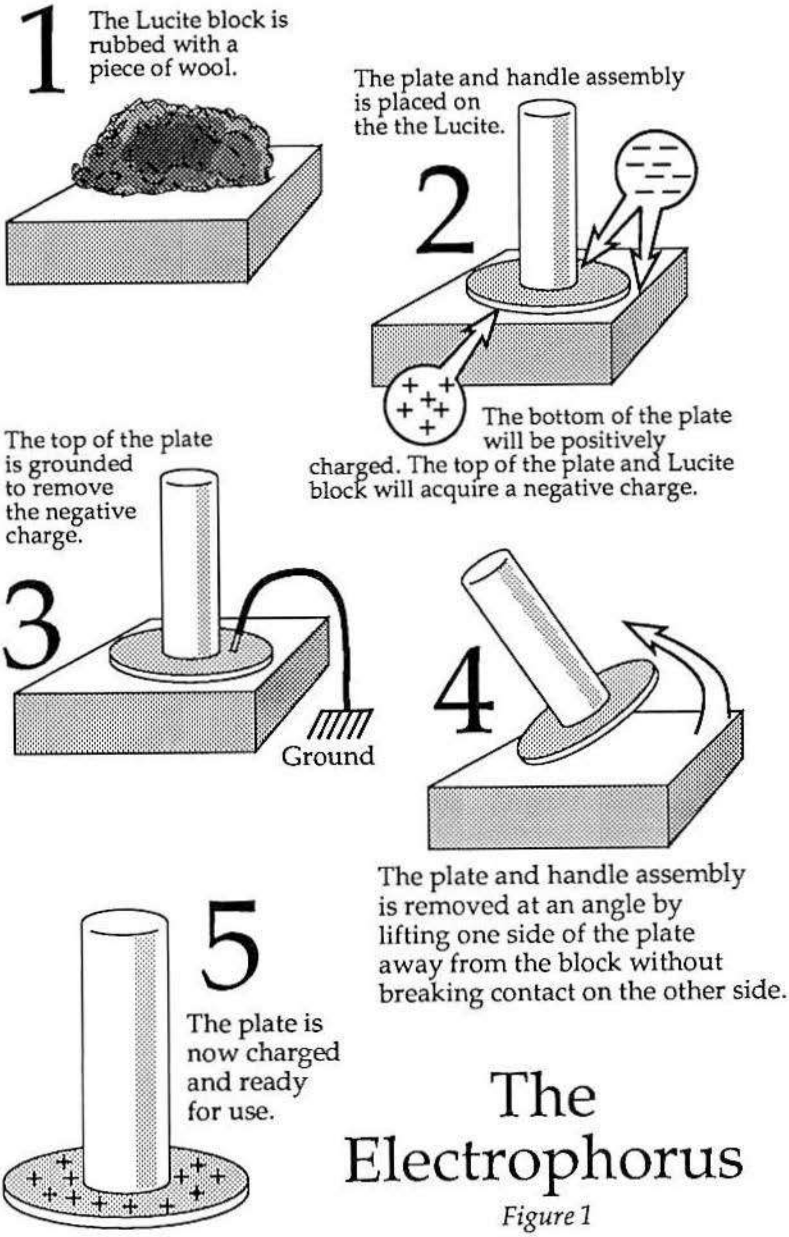
Many generations passed and many ingenious machines were developed without great change using materials and processes similar to von Guericke's globe. The most important historically was Alessandro Volta's *electro perpetuo* known now as the electrophorus. With it we can dramatically demonstrate that electrostatic charges are much like magnetic forces in that like charges repel one another while opposite charges attract.

An electrophorus is very easily assembled. It consists simply of a rectangular block of insulating material such Lucite or, better yet, polyethylene and a metal disk which is attached to an insulating handle (Figure 1).

When the Lucite is rubbed with a woolen cloth, electrons are removed from the cloth and held on the Lucite. This happens because the cloth will hold its electrons less tightly than the Lucite. An insulating material, in this case Lucite, by its nature, will not allow the electrons to move around freely. The charges are therefore 'static' or held in place by the insulating material. The Lucite will now have a negative charge, and the wool will pick up a positive charge, respectively.

Next, the metal disk with the handle is set on top of the Lucite. The negative charges on the Lucite are attracted to positive charges on the metal disk, so, the positive charges in the metal disk move to the side of the metal plate facing the Lucite. The negative charges are similarly repelled to the back of the metal disk. Now, your hand or, better yet, a ground wire are touched briefly to the top (handle side) of the metal disk and then removed. In this way the negative charge is transferred to your hand (or ground) leaving only a positive charge. The metal plate will now have a positive charge, and the plastic negative.

If you have achieved a large enough charge, the Lucite can be picked up by the metal disk!



The Lucite block is rubbed with a piece of wool.

The plate and handle assembly is placed on the the Lucite.

The bottom of the plate will be positively charged. The top of the plate and Lucite block will acquire a negative charge.

The top of the plate is grounded to remove the negative charge.

The plate and handle assembly is removed at an angle by lifting one side of the plate away from the block without breaking contact on the other side.

The plate is now charged and ready for use.

The Electrophorus

Figure 1

Slowly remove the metal plate by the handle, drawing it away from the Lucite at an angle. The metal plate now holds the charge you seek. Having charged your electrophorus, you can perform the experiments with Von Guericke's globe mentioned above including attracting hair, styrofoam and other small objects.

Because the charged surface of the electrophorus is flat, a startling demonstration can be performed wherein the electrophorus disk is actually floated above the Lucite by electrostatic forces. Performing this trick takes some practice. Make a second metal plate and handle. Remember that if the plate is to float above the other it must be very light weight. (Figure 2)

Now, we have the challenge of charging both the disk and the Lucite with a like charge so that they will repel each other. Charge your first disk with a positive charge as described above, and then bring it close to, but not touching, the second disk. This will charge the second disk by attracting a negative charge to the front of the disk. Next, ground the handle side of the second disk to bleed off the positive charge. The second disk is now negatively charged. The Lucite is also negatively charged, so, provided everything has been accomplished and the weight is not too great, the second disk will now float above the Lucite block!

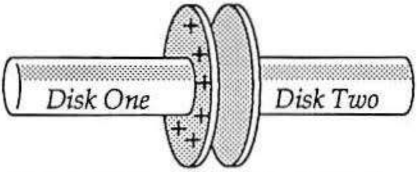
Electrophoruses act a great deal like capacitors discussed later on and can be used for many surprising experiments including charging a Leyden jar and flickering a neon bulb in a darkened room!

Special Notes on Friction Generators

Before we move on to the more powerful friction generators, there are a number of things you should be aware of that will help you in both troubleshooting and designing generators.

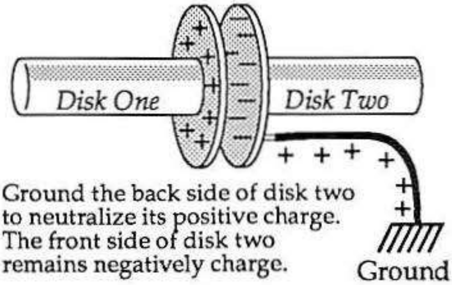
My first bit of advice is to avoid humidity. It makes air more conductive. Moisture in the air can have a devastating effect on the charges stored by electrostatic devices.

I was given a first rate example of this shortly after building my first two generators. Both machines, only days old in their construction, were whirling away in my shop. I was doing "careful scientific study" – in other words, I was zapping everything in sight to see what would happen. Suddenly, and most mysteriously, both generators



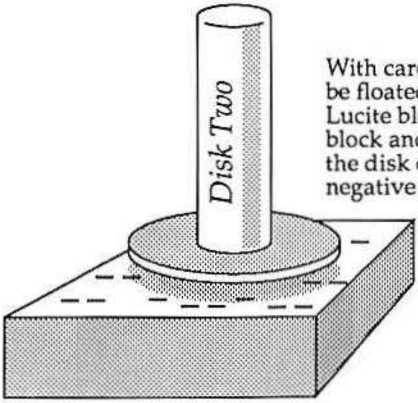
Disk One
Disk Two

Charge disk one on the Lucite block.
Then bring it close to a second disk.



Disk One
Disk Two
Ground

Ground the back side of disk two to neutralize its positive charge. The front side of disk two remains negatively charge.



With care disk two can be floated above the Lucite block. Both the block and bottom of the disk carry repelling negative charges.

Floating the Electrophorus

Figure 2

stopped producing a charge. I couldn't imagine why both, each being very different in construction, might fail at exactly the same time. Then the culprit made itself known! Just outside the door the automatic lawn sprinklers had come on and extremely humid air was coming through my door!

Another good example of this problem is demonstrated by walking across a padded carpet. When the relative humidity is 20% or less, charges of up to 35,000 volts can be obtained by shuffling one's feet along the carpet. However, raise the humidity to 60% or more, and the maximum charge will plummet to a mere 1,500 volts! If you live in a humid region, you may not be able to get the same performance from a generator that someone living in the desert might. Hopefully, humidity will only be a seasonal problem for you. Dry winter days are best.

There are fascinating static generators which are more or less immune to humidity. These rely on generating a charge by induction rather than by friction. These machines will also be discussed in detail later on.

Be careful in selecting paint for your generator. I have found that many spray paints contain ingredients that will conduct static electricity. For the most part I have had few problems with this, although in a darkened room I have seen the telltale blue corona glow of escaping electrons coming from painted plastic surfaces on a generator. To correct the problem I simply coated the nearby metal surfaces that were losing their charges to the paint with high resistance "corona dope" sold in T.V. and better electronic stores.

Avoid using wood to build generators. Although we think of wood as an insulator, in reality it becomes an excellent conductor of very high voltages. In the machines that follow, you'll see polyvinyl chloride (pvc) pipe used extensively. If you can get acrylic or phenolic tubing, use it. It offers much better dielectric strength.

Dust can bleed away a charge. Dust on a high potential terminal can reduce your generator's efficiency by a whopping 40%. Because your high potential terminal carries a charge, dust will be attracted to it in much the same way that dust accumulates on the front of a T.V. screen. I have actually seen a tiny particle of dust prevent an eighth inch spark from arcing. Keeping your terminal clean is important.

On the other hand, the attraction of dust to your generator can be quite entertaining. One way that I enjoy cleaning my generator is to ground myself and then pass my hand over the high potential terminal. The dust which has been sitting there has acquired a high voltage charge and jumps to your hand which it sees as ground. The effectiveness of this method for really getting your generator clean is doubtful since after a few seconds the dust in your hand looses its charge and heads back for the generator, but it's lots of fun.

Once during a rare Southern California thunderstorm I observed a particularly confused particle of dust. Apparently the storm had charged the air, and my generator had charged a large particle of fluff. The fluff couldn't decide where it wanted to be and would repeatedly fly around my bench only to return to the generator and then again off into the air. It was an astounding sight.

SUPER FRICTION GENERATOR – ROTOSTATIC

Now that you understand the basics of how a charge is picked up by friction, doesn't it seem that it would be possible to design a mechanical means to make and store a charge automatically and continuously? One solution to the problem is what I call a "rotostatic" generator, so named for an old magazine article that called a similar device a "rotostat." I said earlier that it was possible to get 3500 volts from an old plastic bottle, and I wasn't kidding. All you have to do is build the "rotostat".

These generators are extremely simple to build and may be hand cranked or operated by a small electric motor. They consist simply of a plastic drum – an old plastic jar works great – and a rubbing block – wool, nylon, asbestos, leather. When the bottle is rotated against the rubbing block a charge is developed on the plastic and on the block.

We need to attach some metallic brushes to the side of the plastic drum opposite the block to pick up the charges as they are generated. The brushes are attached to a metal sphere where the charges can be stored. A complete schematic of a rotostatic generator is shown in figure 3.

There is an infinite variety of possible configurations for such a generator, but keep in mind in designing yours that for static voltages even wood is a good conductor. It is most important to remember to keep your high potential components well insulated from ground.

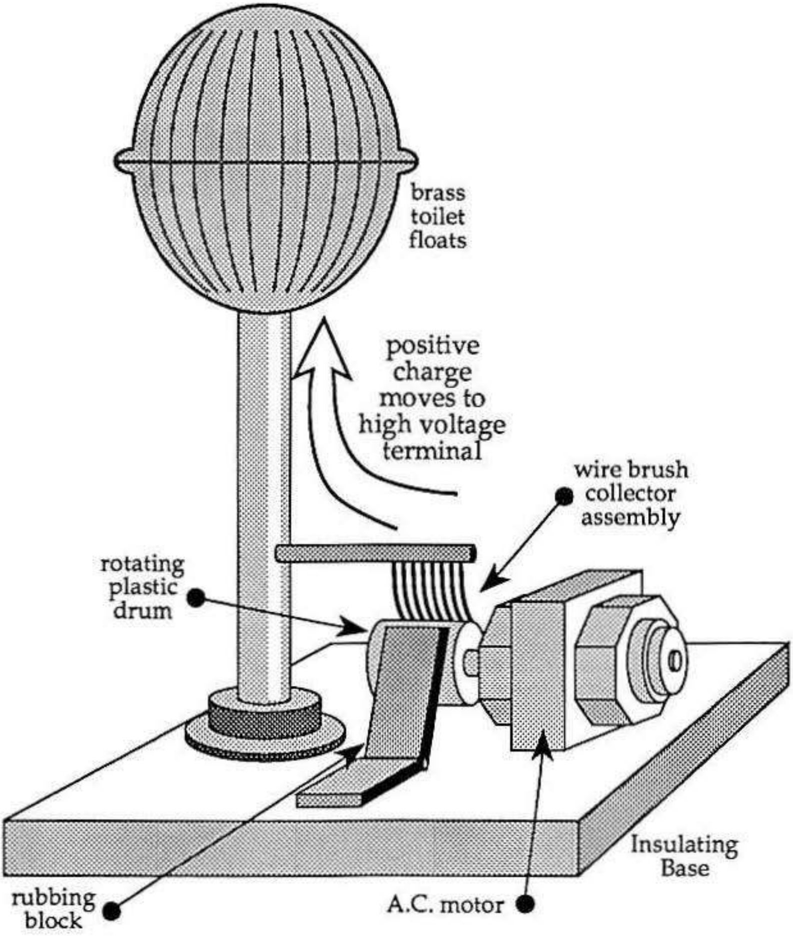
Figure 3

If your generator is well made it will generate enough power to light a neon bulb (Ne2 type), levitate styrofoam, and arc a spark perhaps as long as 1/16 to 1/8 inch – all of this while still being perfectly safe to touch. When touched, your generator will give your finger only a very light "pop" much like a very small static discharge from a doorknob. As an interesting side note, if you can feel a static charge at all, it will be at least 3,500 volts!

Though static machines deliver these high voltages, their rapid, low current discharges make them unusually safe. Even generators producing 100,000 volts or more rarely present a danger, though I for one would not intentionally take a shock from one. A later chapter on capacitors (energy storage devices) will give you an equation for finding out when a charge has become dangerous.

Building a Film Case Rotostatic Generator

In my rotostatic generator design I have attempted to maximize the output and storage capacity of this type of machine. I am sure that there are still many improvements that can be made. This device works extremely well, is reliable, and very easy to construct. A schematic and a photograph are shown in figure 4.



brass toilet floats

Insulating Base
rubbing block
A.C. motor

Rotostatic Generator

Figure 4

I used a surplus AC tape recorder motor to drive the unit. I like to use tape recorder motors in many projects because they are quiet and often have threaded axles that are very easy to mount components onto. In this case, I wanted to be able to switch plastic drums easily so I could experiment with a wide variety of materials. If you are unable to find such a motor, something similar can be used. A breakdown of

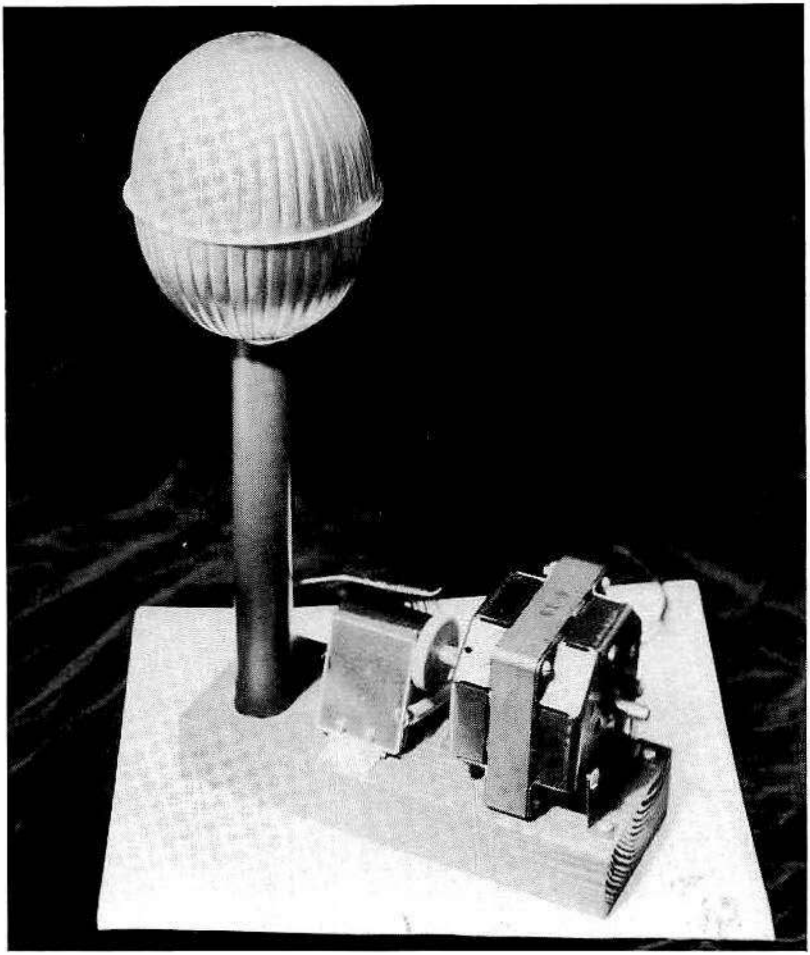

Fig. 5 – The complete Rotostatic Generator uses only a small plastic drum and a few common parts, and yet will light a hand-held 90 volt neon lamp!

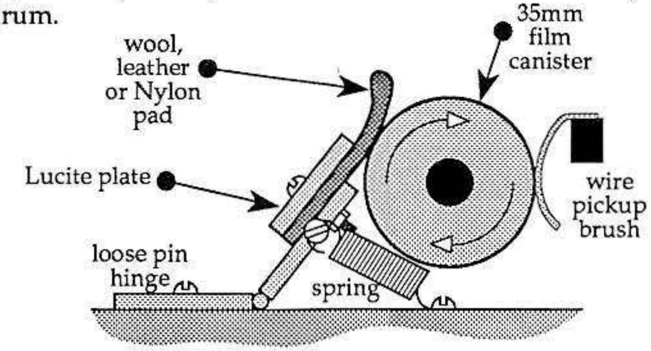
AC and DC motors and their suggested hookups are shown in detail in the next chapter.

Assembly is straightforward and simple. The motor is mounted securely with wood screws to the base – in this case a section of 2x4. Make sure this connection is secure since in experimenting with different drums you will undoubtedly have some which will wobble due to imbalances in the drum or in the mounting. Also, remember to select a motor with plenty of power. Tiny D.C. toy motors can work, but they have little torque and can stall, and that can be frustrating.

The drum can be mounted to the motor in a variety of ways. If the motor axle is hollow as the tape recorder axles are, you can simply use a screw to secure the bottle cap directly to the motor axle. If the axle is solid, you will probably want to extend the axle all the way through the drum.



Wiper Assembly
for Roto Static Generator

Figure 6

To mate the motor axle to the axle running through your drum, glue progressively larger pieces of plastic tubing to the smaller axle until the tubing size matches that of the larger axle, then slip the tubing over both axles. Tubing used as fuel line on model airplanes, aquarium tubing, compressor hose, and the insulation stripped from wire can be used to make excellent adapters. Heat shrink tubing can also be used, however, after it has been shrunk it tends to become somewhat brittle.

As long as the pieces of tubing fit tightly over one another, any glue can be used to hold them together. I like cyanoacrylate (Super Glue) because it seems to hold rubber tubing nearly as well as it does skin. If you have used "Super Glue" for any length of time will know what I mean by this.

This method of connecting a motor to an axle also has the beneficial effect of acting as a "universal" joint. That is, your motor can actually power your axle from a variety of angles since the tubing will flex without difficulty. This is useful when using a variety of motors to drive a variety of unusual drums.

The drum must be very well centered on the motor axle, but fortunately, this is surprisingly easy to do. Most plastic pill bottles, film cases etc. already have a little nub right on the center of the lid. I assume this is some natural artifact of the process by which they are formed. Just hunt around a bit and use a bottle with this built-in center mark, and you'll have no difficulty here.

Personally, I like to mount the lid from the bottle to the axle so that the bottle can be easily removed and replaced.

The rubbing block shown in figure 6 turned out to be a very handy design. By looping a piece of wool against the Lucite as shown, the block makes excellent contact with the drum. A variety of rubbing materials can be tried by simply slipping them in between the block and the drum. I think that leather or nylon probably provided the best results when used with the film case. To make these experiments easier, use "loose pin" hinges for mounting the rubbing block.

Rather than use steel brushes to collect the charge from the drum, I came up with what I call "riders." These are formed by wrapping a short length of wire around the copper wire conductor coming from the globe. These wires should be loose enough to dangle down onto the drum and "ride" along its surface. Riders have many advantages. They are very tolerant of wobble in the drum. You may be able to change drum types and sizes without adjusting them in any way. You can improve the efficiency of "riders" by coating unusued surfaces with corona dope.

The PVC tube and collecting ball are easily mounted by drilling a tight hole in the 2x4 to accommodate the PVC tubing, by applying a little Silicone glue to the base, and by tapping it into place with a hammer. A large copper wire is run through the tubing as shown and is connected to the collecting ball with a brass screw. The ball, itself, is then mounted with a bead of Silicone glue.

Testing and Operation

Turn on the static generator's motor and allow it to run for 20 to 30 seconds. It takes some time to build up a charge. Next, hold one lead of a Ne2 neon bulb, available at electronics stores for about 49 cents, and bring the other lead near the brass bulb. When the free lead is nearly touching the bulb, the lamp should flicker or flash. Though the shock from this tiny generator can barely be felt, keep in mind that it takes nearly 90 volts to light the bulb!

Next spread some small, dry, pieces of styrofoam on the top of the ball. By bringing your hand close to the styrofoam you can actually cause them to move mysteriously toward your hands.

Touching this generator is perfectly safe. Under good conditions you should feel and hear a light static "pop" when you touch the fully charged top terminal. If you have trouble feeling the "pop" with your fingers try using your nose. I don't know why, but bringing your nose near the ball brings on a very subtle and strange electric sensation.

With this generator you can do many of the experiments mentioned later including charging up capacitors and energizing spark gaps. So experiment and enjoy.

REMEMBER!

If you are using yourself as ground, as described in the above experiments, you might find that generator performance seems to decrease after several experiments have been performed. What has actually happened is that by repeatedly touching the ball, you have charged yourself up to the same degree of charge as that of the ball, giving the electricity no desire to jump to you! This is simply remedied. Just touch a cold water pipe or other ground from time to time while you experiment.

One minor problem that can pop up is motor speed. Your motor may run too fast. We'll discuss a motor speed control a little later on. Don't worry if the riders hop around a bit. This is usually OK and won't cause problems.

Although a plastic film canister appears in the photos, jars with semi-transparent finishes perform. PVC might also make an exellent drum. Experiment!

A Useful List of Materials for Friction Generators

What follows is a useful list of materials that have a predisposition for taking on a negative or positive charge. By choosing materials that are far apart on this list you can increase the efficiency of a generator.

This list is excerpted from *Nature's Electricity* TAB books No. 2769 and is called "The TriboElectric Series."

POSITIVE CHARGE

Air
Human hands
Asbestos
Glass
Mica
Human hair
Nylon
Wool
Fur
Lead
Silk

Polyurethane
Polyethylene
Polypropylene
Vinyl (PVC)
Silicon
Teflon

NEGATIVE CHARGE

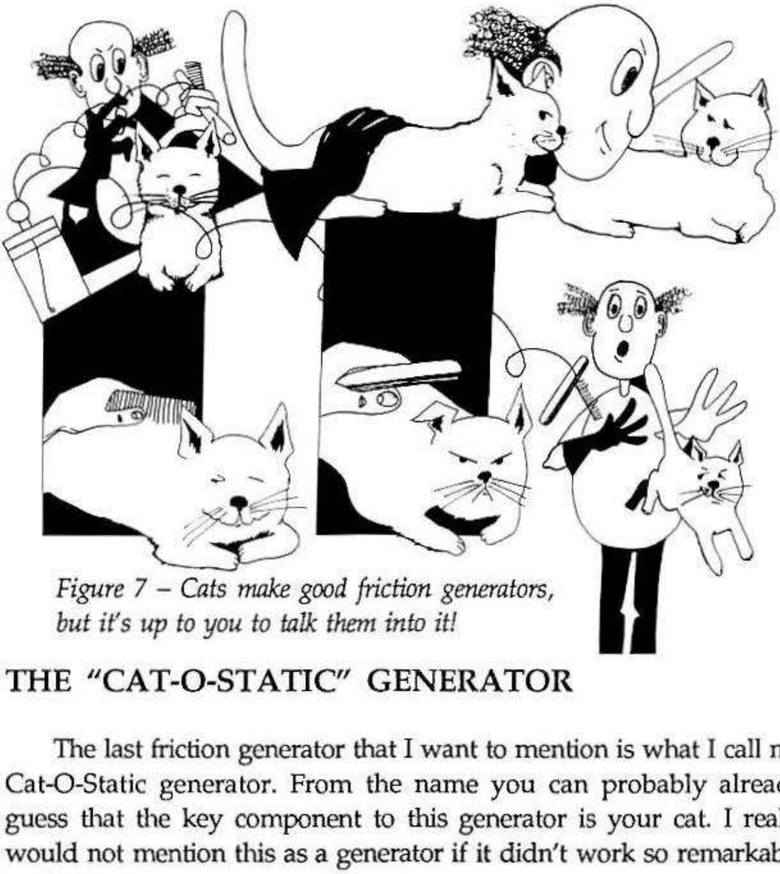

Figure 7 – Cats make good friction generators, but it's up to you to talk them into it!

THE "CAT-O-STATIC" GENERATOR

The last friction generator that I want to mention is what I call my Cat-O-Static generator. From the name you can probably already guess that the key component to this generator is your cat. I really would not mention this as a generator if it didn't work so remarkably well!

For the most part cats enjoy being electrostatic generators, the trick is to make them think they are being petted, and not used as a science experiment. (The cat commandments state somewhere: "Thou shalt allow thyself to be petted only when it suits your purposes and not those of another.")

First, you will need a rubbing material. The very best material I found for this purpose was the artificial leather used in cheap motorcycle gloves. It's actually a type of vinyl. You can secure a pair of these gloves for 5 or 10 dollars at any motorcycle shop. Some are called "man-made leather."

The next thing you will need is a metal flea comb and a length of PVC tubing. You will also need a Leyden jar to store the charge built up by your Cat-o-stat. Leyden jar construction is described in detail later on. The metal flea comb is held at the end of the PVC tubing by a slit cut in the tubing and some glue. A wire is attached from the flea comb to the top of the Leyden jar.

Put a glove on one hand and hold the PVC tubing with the other. Coax you cat into your lap, and tell him wonderful things about himself. This never fails to distract them. Pet him with the glove, and follow the glove with the metal comb to pick up the charge.

With my cat's fur and my particular gloves I am able to build up a charge so large that it will penetrate my vinyl gloves with a strong prickling! However, keep in mind that this type of generator will usually run off and hide before a large Leyden jar can be fully charged. Of course, if you have several cats, use them all to the charge the jar!

AC vs DC Motors and Controls

As we move on to the higher power generators, a little discussion is in order with regards to AC (alternating current) and DC (direct current) motors, and some good ways to control them.

In the generators I've built and discuss here, I have used both AC and DC motors. AC motors have advantages in that usually no external transformers or circuitry are required. They develop plenty of torque – so much so in fact, that you rarely have to worry about stalling the motor. Most AC motors have no brushes or other components to short or wear. They will generally run for years and years, often until the bearings themselves wear out! In general, I prefer using AC motors over DC motors whenever possible.

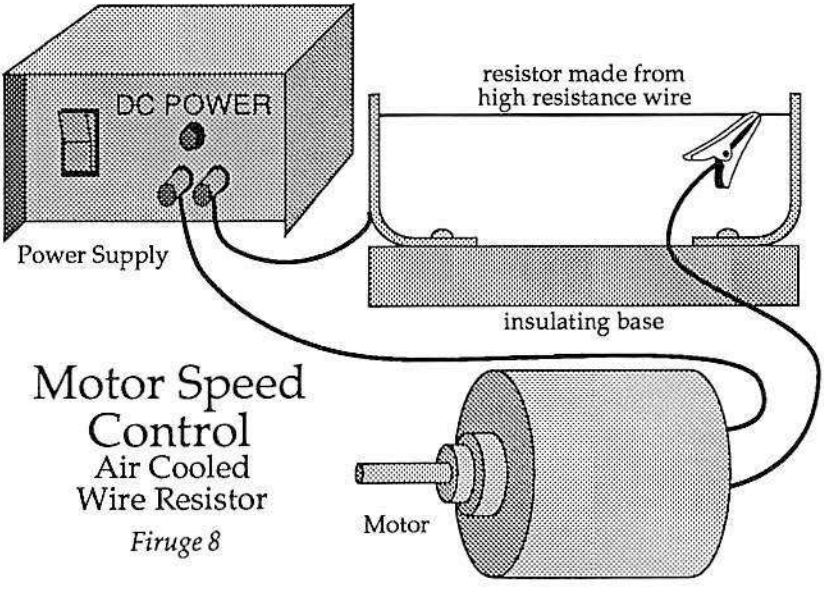
The major shortcoming of an AC motor is low rpm. The high performance Van-De-Graaff-type generators describe below work best at around 5,000 rpm. If the motor runs faster than this, electrons can literally be "blown" off of the carrying belt, and performance suffers. At lower rpm, leakage can impede the build up of high voltage. Since AC motors do not usually develop high rpm, DC motors should be considered for these high performance generators.

Unlike AC motors, DC motors are portable when battery powered and achieve high rpm easily. Keep in mind that a DC motor rated at

6500 rpm may not achieve that speed when driving your device. The rpm rating is usually the maximum no load speed of the motor.

Although not always necessary, you will probably find that you will want a motor with speed control as part of your DC static generator design. A number of dependable methods are shown in figures 8 through 12.

Figure 8 shows a piece of high resistance wire soldered or tied between two copper posts. One side of the wire is tied to a 12v (or similar) power supply. A wire coming from your motor is attached to an alligator clip which can be moved along the wire to increase or decrease the motor speed. This method works extremely well. However, be aware that the wire can become red hot when supplying current to the motor! Make sure to house it safely.



Motor Speed
Control
Air Cooled
Wire Resistor
Firuge 8

High resistance wire is easily obtained from a variety of sources. You can use the NiChrome wire that comprises the heating coils in an old toaster, hair dryer, or similar heating device. You can also purchase NiChrome wire from any well-stocked hardware store. Keep in mind that a fairly long piece may be required. Another variation that can be tried is to use a high wattage rheostat, or even the speed control handle from a "slot car" set.

Figure 9 shows the use of power resistors to slow a DC motor.

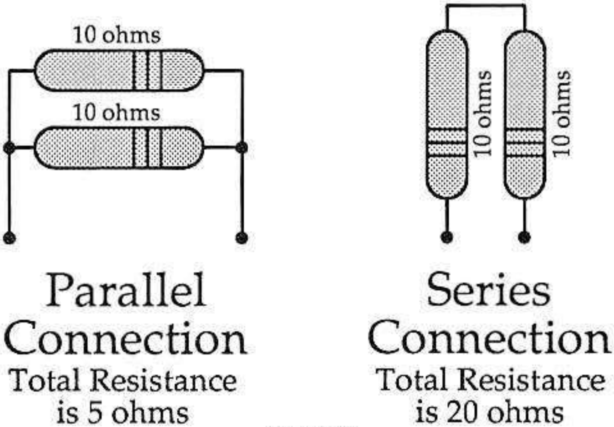


Figure 9

Power resistors are inexpensive, and if you buy a handful of different values you can connect them in parallel or series to get a wide variety of different values. Keep in mind that resistors have two ratings, the power handling capacity measured in Watts, and the resistance measured in Ohms.

An Ohm is a measure of the opposition to current flow. A resistor of 10 Ohms will oppose current flowing through it twice as much as a resistor of five Ohms.

Wattage is simply the amount of power your resistor can handle without being destroyed by overheating. In general, I'd say the higher the wattage rating the better. The Winter's Ring generator shown next required a 25 watt, 10 Ohm resistor, but had to be water cooled to increase its power handling capacity above the 25 watt air cooled rating.

Resistors oppose current flow and in doing so, convert electrical energy into heat. It's normal for them to become very warm. If your resistor gets too hot, its resistance can increase well above its stated value. A change in resistance can cause your motor to run at uneven speeds. You will either need to buy a resistor of a larger wattage, or use some means to cool it such as water (shown and discussed later). As a rule-of-thumb, don't use a resistor of less than 10 watts unless you have a very small or efficient motor.

Figure 10

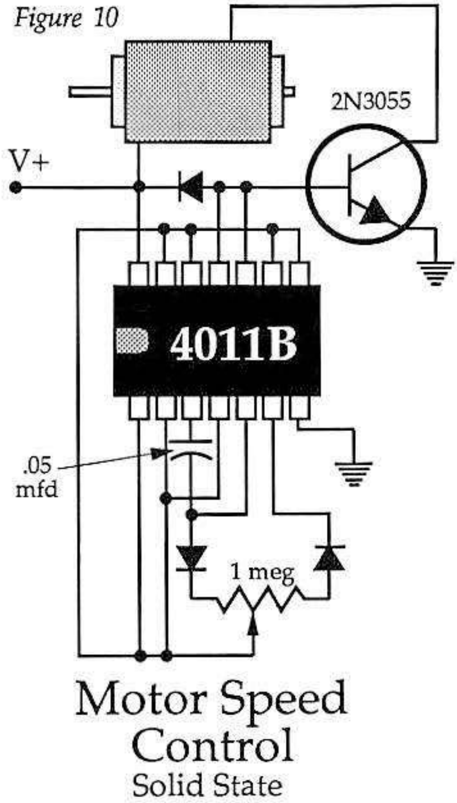

Figure 10 shows a very accurate and stable means of controlling a DC motor. An integrated circuit and power transistor are used to send a stream of pulses to the motor. As the pulse rate increases, the motor speed also increases. By simply turning the potentiometer, you can adjust motor speed at any time. For mid-sized DC motors a very large heat sink or water cooling is required for the transistor.

I have found that DC motors operating at high speeds can behave strangely. Slight variances in the motor's speed can set up an oscillation within the belt being driven. Because one side of the belt is being "pulled" and the other

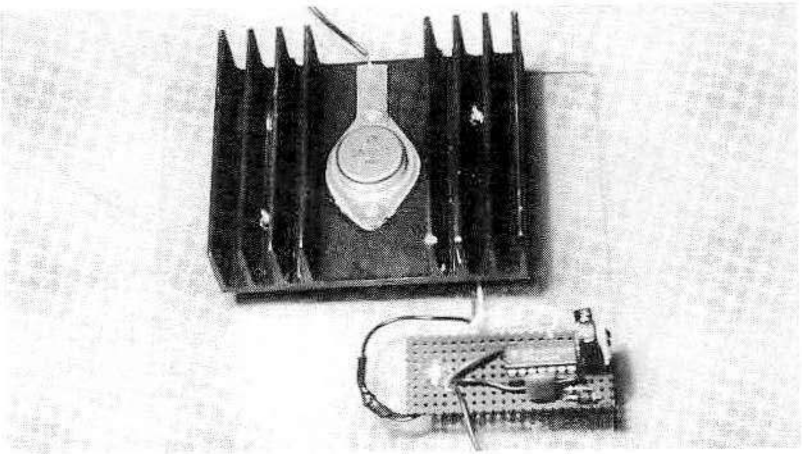

Figure 11 – Solid State Motor Control

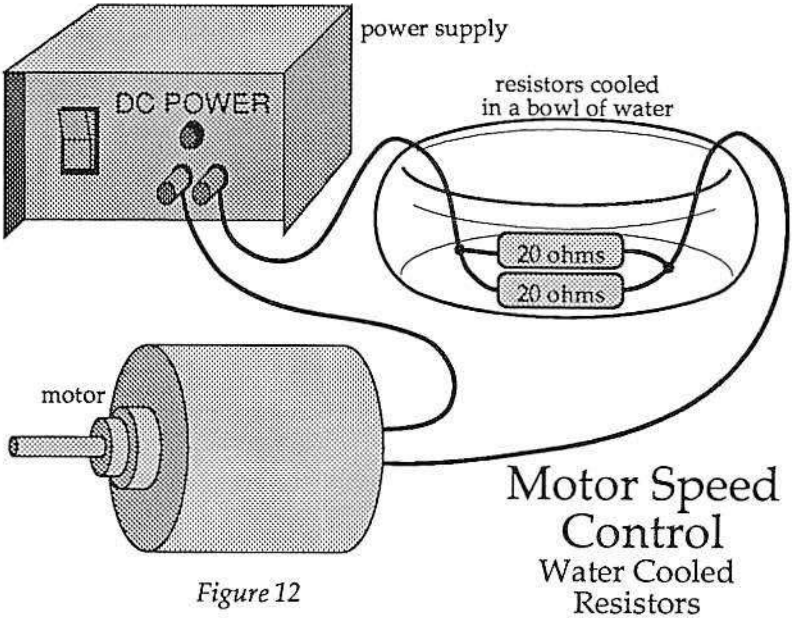
is being "pushed", uneven tensions react with the belt's flexibility to produce a "flying" belt that makes only intermittent contact with the rollers or pulleys. This can cause a belt to fly off, bend brushes, or just make a lot of noise. Also, if ball bearings are not used in the rollers, an oscillation can occur among the bushings of the upper roller, the axle, and the belt. All of these problems can be easily solved by using a versatile speed control.

Component Cooling

You may to have to improvise methods of keeping electrical components cool. If you are using a fairly large, high RPM, DC motor which will need sizeable amounts of electrical power, components in the speed control are going to get hot. It may seem a little unorthodox, but water makes a fantastic heat sink for electrical components! Power resistors and even power transistors can be run well beyond ordinary heat sink tolerances when submerged in water. (Figure 12)



power supply
DC POWER

in a bowl of water
20 ohms
20 ohms
motor
Motor Speed
Control
Water Cooled
Resistors

Figure 12

Distilled water is a very poor conductor of electricity and will not short out most components. Tap water is usually OK for resistors, but minerals and other gunk will cloud the water after a short time.

As long as the circuit is submerged in water, you know that the temperature of the water must be below 212 degrees Fahrenheit (100 Celsius) at normal atmospheric pressures. Above this temperature the water will boil away. Many electronic components work quite well up to 212 degrees. Just remember to add a little water now and then to compensate for evaporation.

AN EXTERNAL VAN DE GRAAFF USING "WINTER'S RING"

If you built the last generator described, you know that I wasn't exaggerating when I said you could get 3500 volts (or more) from an old film canister. Although interesting, this simple rotostatic generator won't keep you satisfied for long. There are higher voltages to conquer! So let's move on to the next type of generator and try for 10,000 volts (and possibly several times that amount) from a rubber band.

I call the following generator an "external" generator because all of the components of the generator have been mounted externally in such a way as to make construction and experimental modifications fast and easy. Since all of the workings are exposed, this generator is great for the experimenter who wants to quickly try different materials and configurations in developing his own generator design, or for someone who wants to whip together a simple generator to demonstrate.

The high voltage terminal of this generator consists of a metal ring, or toroid, of exceptional efficiency. I call it a "Winter's Ring" although such rings have been traditionally made of wood. They're rarely used anymore. As with other parts of this generator, the Winter's Ring may be quickly replaced by a more traditional spherical-shaped terminal or many others you might wish to try. Why not keep several on hand for demonstration?

Despite the fact that, as we've discussed, electrostatic principles have been well know for thousands of years, it was not until as recently as 1928 that a truly practical machine for generating high static voltages was perfected. Robert J. Van de Graaff, a young Rhodes scholar working at Princeton, designed his first machine to generate the high potential needed to power a particle accelerator to bombard atomic nuclei as part of his experiments in nuclear research.

Although it can be difficult, it is not impossible for the home experimenter to make his own atom smasher! A Van de Graaff generator such as described here is an integral part of such an apparatus. If you are interested in taking on a project of epic proportions, find a copy *"The Amateur Scientist"* by C. L. Stong which is now out of print and very difficult to find, but worth the effort. Or write for similar information from Information Unlimited, P. O. Box 716, Amherst NH 03031.

The Van de Graaff is so simple and obvious in design that it amazes me that is wasn't developed sooner. I have always thought that this is a good example of just how inventions don't have to be extremely complex to have a significant impact on society. How many other simple devices are there waiting to be designed and built? It could be you that dramatically changes the world!

The easiest way to understand the Van de Graaff is to refer to the schematic diagram in figure 13. A Van de Graaff generator consists of a belt, two pulleys, a motor, brushes, a high and a low potential terminals.

In newer machines the bottom pulley is plastic while older machines used an insulator covered by wool or similar rubbing material. The top pulley must be of a conductive material such as metal or even wood which is not a good insulator at high voltages.

When the machine is in operation, a small motor attached to the bottom pulley drives the belt that is lightly stretched between the pulleys. Friction occurs between the surfaces of the belt and the plastic wheel, putting an electrostatic charge on the belt. The charge is carried by the belt toward the upper terminal. A grounded wire brush makes contact with the lower portion of the belt and bleeds off some of the negative charge. The brush at the top of the belt accepts the positive charge remaining and distributes it on the high potential terminal. (Note: It is possible to make a Van de Graaff generator that develops a negative charge on the high potential terminal.)

As the belt moves, charge builds up on the high potential terminal. Theoretically, this charge could increase forever. However, leakage into the air from the upper terminal limits the maximum potential to

about 50 to 100 thousand volts typically.

A simple way to calculate the theoretical maximum for a "perfect" spherical top potential is to figure a voltage 70,000 times the smallest radius of the curvature of the high potential terminal. For example–most spheres are sold with reference to their diameter. For a 12 inch diameter sphere, we divide 12 by 2 to get the radius, or 6 inches. We multiply 6 by 70,000 to get a theoretical voltage of 420,000 volts.

Because your terminal will never be a perfect sphere, and because there will be leakage into the atmosphere, theoretical voltages won't be reached. You might find these ball-park calculations interesting, nonetheless.

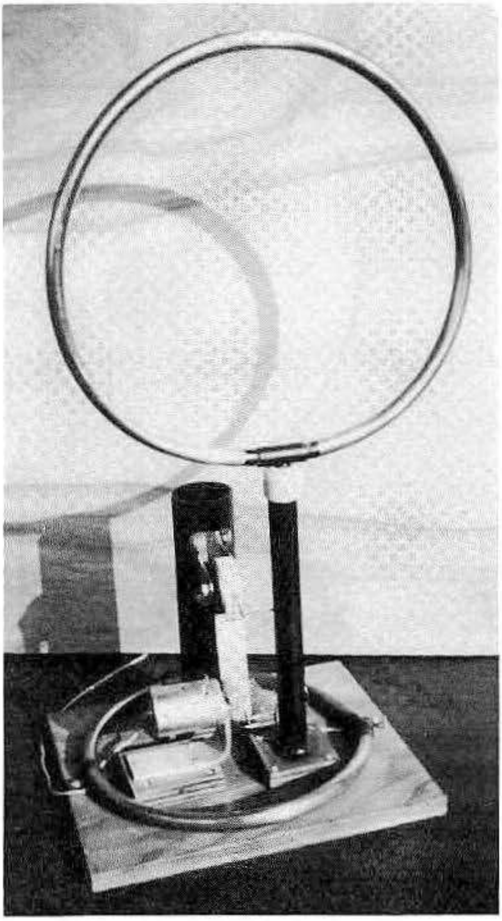

Figure 14 – External Van de Graaff Generator

A photograph of my external Van De Graaff and its schematic are shown in figures 14 and 15. I found this to be an extremely simple and inexpensive design. In operation it will produce a reliable voltage in the range of 10 to 30 thousand volts using an ordinary rubber band. It will produce a solid and exhilarating "pop" when it discharges to your hand. It can throw sparks to ground more than an inch in length. Neon bulbs such as a Ne2 will glow brightly and continuously when near the generator. A blue corona glow can be readily observed from the collecting brushes in a darkened room once your eyes have adjusted to the dark. Negative and positive corona can also be identified by their appearance using this device as discussed later.

The external Van De Graaff shown has some minor performance limitations due to the relatively high friction of the top wheel (no ball bearings) and excessive flexing of the rubber band. A rubber band should be used as a belt only for demonstration purposes. For more

serious experimenting, replace the belt with a less flexible belt such as made from a bicycle inner tube or, ideally, neoprene. Also, without ball bearings, the top wheel required occasional lubrication that frequently brought about the risk of oil contamination. Except for these minor problems, this generator has proven to be an excellent and reliable performer. It still remains the most easily modified and observed of the Van de Graaff designs I'll describe.

The construction of the external Van De Graaff is so simple and straightforward that little description is required outside of the drawing. A few tricks can simplify and improve construction.

An easy way to get your motor, roller and belt in alignment is to run your generator while holding the motor with your hand, experimenting until you find the right position for it. If your belt slips off, shift the motor slightly to change its attack or grip on the belt.

When connecting a belt between two rollers in any Van De Graaff type generator, it is natural to assume that pulleys should have flanges on their edges to provide a groove in which the belt will run preventing it from slipping off the driving wheel. Surprisingly enough, the belt will have a tendency to stay centered on the pulleys even when they are somewhat out of alignment! I assume this has something to do with the way the pressures change in the belt as it approaches the edge of a pulley. You may find that a small "hump" in the drive wheel can even be helpful at high rpm. Once aligned, you should have no problems at all with belts slipping off.

Use the largest diameter of copper tubing that you conveniently can for the top terminal. The problem is that when larger diameter copper tubing is bent into small diameter circles, undesireable ripples form. Larger gauge tubing must be bent into larger diameter circles forcing you to compromise between size and efficiency.

When soldering the two ends of the copper tube into the "T" connector, first clean them with extra fine steel wool, then coat (tin) them with a little solder before inserting them. This will give an exceptionally strong and smooth bond. You can use any ordinary propane torch for heating and soldering the tube.

If you use the same type of brushes as shown in the drawing, it might be tempting to shorten the copper wires leading to them from the PVC tubing or otherwise alter this mounting. Don't do it! It is the flexibility in these long copper wires that provides the "spring" needed to keep the brushes flat against the belt.

The plastic bottom pulley is simply one of the white plastic wheels used on cheap furniture casters. It is attached to the motor shaft by carefully drilling out the wheel's center hole to a size slightly smaller than the diameter of the motor axle. You then apply a few drops of super glue to the axle and press or tap the wheel into place.

If the hole in the wheel is larger than the diameter of the axle, glue progressively larger diameter pieces of rubber tubing to the motor axle until the wheel fits snugly in place.

One last note: Since your top terminal is copper which quickly tarnishes, you might want to apply a little Silicone cleaner/protectant such as that sold for cleaning chrome automotive parts. This will keep your top terminal bright and shiny at all times. It also seems to limit leakage and produce an interesting double "pop" when touched.

The Evils of Oil

The only major problem that I encountered in building and operating Van De Graaff generators regardless of design is oil contamination. Since a Van De Graaff generator relies on friction between the plastic wheel and rubber belt to produce a charge, you can imagine the devastating effect oil or any lubricant can have on belt performance. Even the oil from your fingers can reduce the charge carried by the belt. Handle your belts sparingly, and hold them only from the outside edges as you might a record album.

The worst lubricant is a petroleum-based oil such as used to lubricate motor axles and bearings. Angular momentum from the motor axle can actually pull a drop of oil all the way along the axle, along the side of a wheel, and out onto a belt. *Therefore,* ***Do not oil your motor or bearings excessively.***

If you want a graphic demonstration of this effect, place a drop of fast drying super glue on your motor's axle. Before it has a chance to dry, run your motor for several seconds. If your motor is like mine, you will have a little trail of super glue from the axle to the outside of the wheel where it will form a little blob.

Once your belt and wheels are contaminated, they can be very difficult to clean. The best way to clean the belt is not to clean it all, but to throw it in the trash and get another belt.

The conductive metal top roller can be cleaned with a residue-free cleaner like ammonia, followed by a light sanding with extra fine sand paper and then by another ammonia cleaning.

Cleaning the plastic wheel is the most difficult. The plastic wheel usually builds up a static charge of its own during the time the generator is run. This charge seems to act like a sponge for oil! The only way I have found to remove it is it by attaching a wire to ground and running the motor while dragging the wire along the outside of the wheel. After discharging the pulley in this way, ground a piece of metallic sand paper and again run the motor while sanding away some of the outside of the wheel. This is accompanied with or followed by ammonia cleanings. Other solvents may work, but watch out for those that may dissolve the plastic. I realize this procedure may sound extreme, but I have even tried soaking the plastic wheels in industrial degreasers not available to the general public and have had no luck at removing this oil in any other fashion. If you are careful in your use of oil you will never encounter this problem.

A Few Words On Brushes

In both of the Van De Graaff generator designs described in this book, I used a simple tuft of wire soldered to the end of a thicker solid copper wire spring which provides the force necessary to keep the brush riding firmly against the belt. By far the biggest problem you are likely to encounter will be in keeping the brush riding solidly on the belt. If your brushes are not well placed, or your belt has undue flexibility, the brushes may have to be readjusted frequently.

Many configurations, some very elaborate, have been tried in an attempt to perfect a fool-proof brush assembly. I haven't found one yet. You may want to try a hinge, a spring, a piece of metal screen, or even a conductive rubber or foam such as those use to package integrated circuits. In designing a brush assembly, keep in mind that, ideally, it should be comprised of many fine points like the ends of wires because the density of electrons in a fine point is higher and electron transfer is more likely. Nevertheless I have had very good luck with non-pointed objects such as conductive foams. Most texts, and my own experience has shown that a good old tuft of wire usually wins out, but, as mentioned, this is not a perfect solution to the problem. So, experiment. And have fun!

A Few Words On Belts

A good belt can be made from virtually any insulating material. Rayon, Dacron, rubber, paper, silk, plastic and even ordinary cloth have been used with success. Wear is probably the most important factor to consider in choosing a material. Rubber, for instance, rots in my home town due to the ozone contained in the smog here. Cloth will fray at high speed, although I have coated cloth with an extremely thin coating of Silicone rubber and have made good belts. Neoprene, joined with a diagonal splice is a long-time favorite.

In my opinion, the easiest all-around belt is made from an old bicycle inner tube, or even better, the rubber "liner" that covers the heads of spokes under the rim. One of these belts can be carefully spliced with inner tube cement from a tire patch kit. Even a little "Super Glue" will work if the splice is clamped.

In fabricating a belt also remember that the wider the belt, the faster a charge accumulates (within reason). And, you may also want to give a little thought to the noise generated by certain materials. At 5000 rpm a poorly made belt will make considerable noise.

One last belt option is to purchase a ready made belt from a scientific supply house such as Analytical Scientific, Post Box 675, Helotes, TX 78023. Such companies can often supply many different sizes and types of belts. I would suggest ordering the thickest, and strongest belt offered for a home-made generator. I find the price of commercial belts a bit too expensive for my bank account, but you might find their prices more acceptable depending on your project.

THE HIGH POWER "CLASSIC" VAN DE GRAAFF

Although these voltages are impressive, keep in mind that the classic Van De Graaff will easily produce 60 to 100 thousand volts or more and is only slightly more difficult to build.

The classic design for the Van De Graaff is shown in photograph 16. The one minor concession I made in my design was to use two stainless steel bowls for the high potential collector instead of the traditional sphere. I did this simply because I could not readily find a

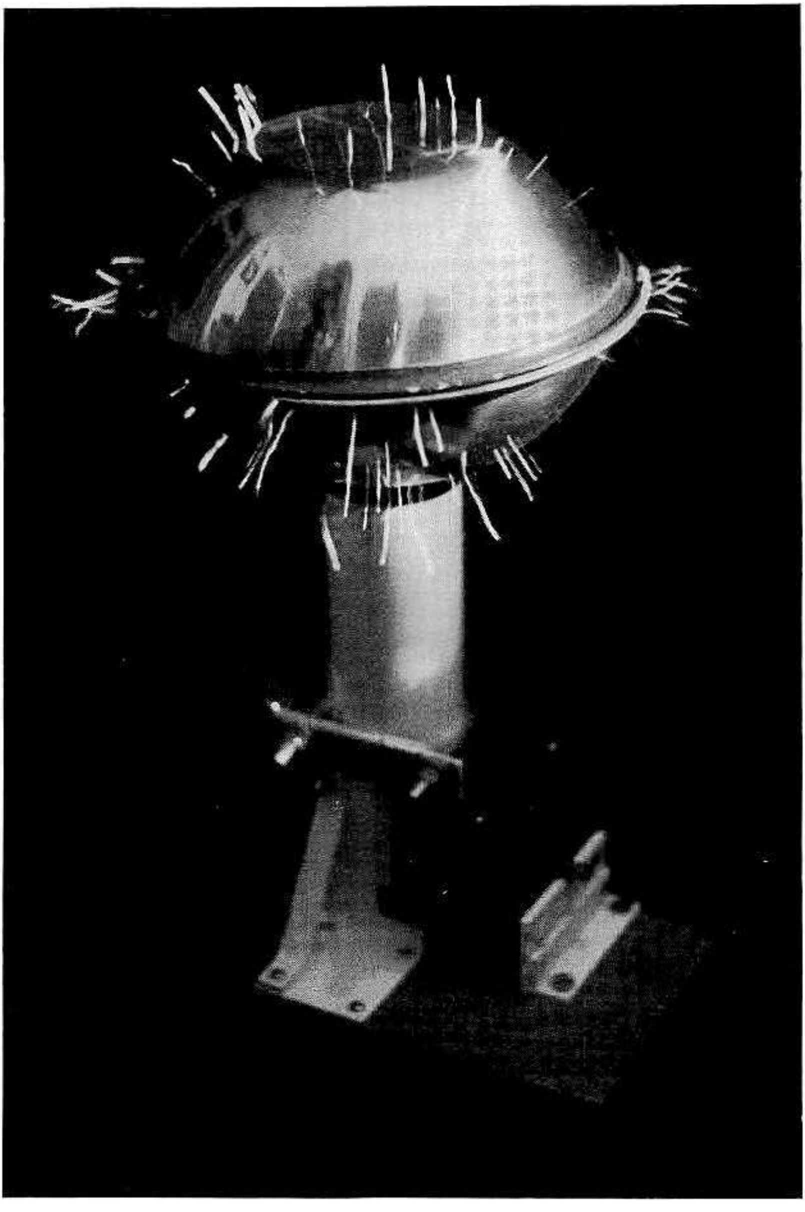

Figure 16 – Classic Van de Graaff Generator in Operation – This long-exposure photograph clearly shows the remarkable energy generated by this simple device.

support bracket

Figure 17

sphere of the proper dimensions. Besides, two bowls allow easy access to the top roller and brushes, and I wanted to test my hunch that almost as much power could be obtained from the bowls if the edges were heavily doped and insulated as could be obtained from a traditional spherical terminal.

All of the experiments to be described can be performed with this unit. It is an all-around solid machine and is fun to operate. If you plan to build only one generator from this book, and are wondering which generator to select, this machine is the best all-around performer. If carefully built, this design will exceed a voltage of 100,000 volts. It will arc thick, blue sparks well over four inches to an outstretched hand and deliver an invigorating, if not slightly uncomfortable, shock.

This generator is capable of charging up a person's body to a high voltage. It makes possible many experiments such as causing a person's hair to stand on end, or the rapid charging of large capacitors. The device will even produce an ominous "crackling" as your hand approaches the high potential terminal.

By standing on a large plastic insulator such as an overturned detergent bucket, a friend of mine was able to charge her body to such a high potential that her hands would "crackle" any time she pointed to a person nearby in the room. I think a physics or chemistry teacher would have little trouble keeping his/her students attention if the mere pointing of their hands produced this ominous cracking!

Though I am certainly not recommending the following approach, this generator was also inadvertently useful in training a dog in a single lesson not to jump on people. My dog, Merfi, had the bad habit of greeting people by jumping all over them. Nothing, it seemed, could discourage this behavior. One afternoon some friends and I were standing around a completed Van De Graaff and commenting on what an unusually large charge we had managed to bestow upon a person. Suddenly Merfi bounded into the shop. Despite our pleas, Merfi shot across the shop with his usual enthusiasm and leapt nose first into my highly charged friend, no doubt, intending to bestow upon him his traditional greeting.

We could do nothing but watch as a large blue spark jumped to Merfi's moist, waiting nose. Merfi stumbled back, temporarily lost control of his bladder, and then slunk out the door. A few moments later everyone was petting and reassuring Merfi, yet, to this day we have had virtually no problems with Merfi's traditional greetings. He still eyes the friend from whom he received the shock with suspicion. And with good reason!

I suppose it is needless to say that it is wise to keep any and all pets a safe distance from your experiments. As with the external Van De Graaff generator, very little description outside of the drawings is required for constructing the classic Van De Graaff design.

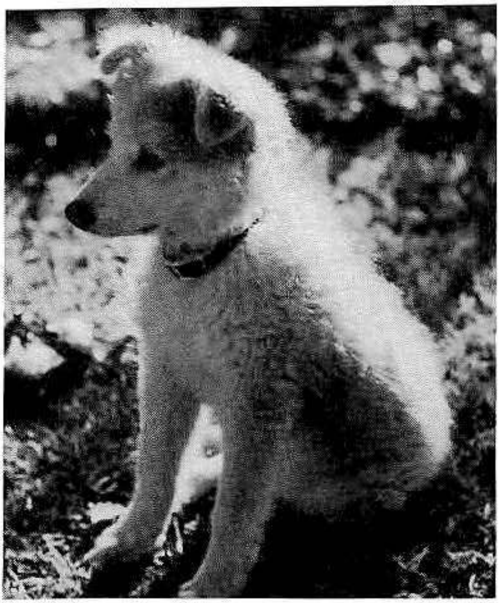

Figure 18 - "Merfi" – (An accidental electrostatic participant)

Things to keep in mind

The edges of the bowls are relatively sharp, even though the edges have been folded over. To prevent the charge from leaking through these sharp edges, they are coated with a special paint called "corona dope" which can be purchased in most T.V. and well-stocked electronic stores. It is available in both spray and brush-on forms. Corona dope has a high dielectric strength, and will prevent a charge from leaking off into the air. It can be used on any spots suspected of leakage on any of your high voltage projects. Keep in mind that the thicker the coating of corona dope, the better it will shield. I used around eight thick coats on my Van De Graaff and should have used more. Sparks fly right through it!

As with the last generator, the lower pulley is a white plastic wheel taken from an inexpensive furniture caster. It was mounted in the same way as was done in the external Van de Graaff.

The upper pulley is the front hub of a 10 speed bicycle wheel. I tried several different methods to reduce the friction of the hub bearings to make it turn more freely. I tried a variety of lighter oils and even

Generator
top assembly

Figure 19

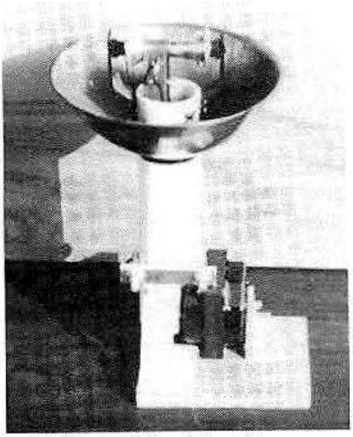

Figure 20 – Top Open

removed the rubber covers that protect the ball bearings from dirt contamination. I found that lighter oil works well, but because of the risk of oil contamination as discussed earlier, I ended up using grease. Removing the covers also helps, but when the generator is running and the roller is spinning, a sizable charge builds up on its surface, and every dust particle in the area is attracted to it! Although you may want to experiment, I have come to the conclusion that the hub should be left pretty much as it is when it comes off the bike.

The two top bowls can be hinged together from the inside with a wide strip of black tape, or can be bolted together by some nylon screws through the lip. Keep in mind that you want the surface of these bowls to remain as smooth as possible to prevent electrons from leaking off. Don't use metal hinges or any sharp objects in attaching them.

The main body tube is fabricated from three-inch diameter PVC drain pipe. (Remember that acrylic or phenolic pipe might be superior to

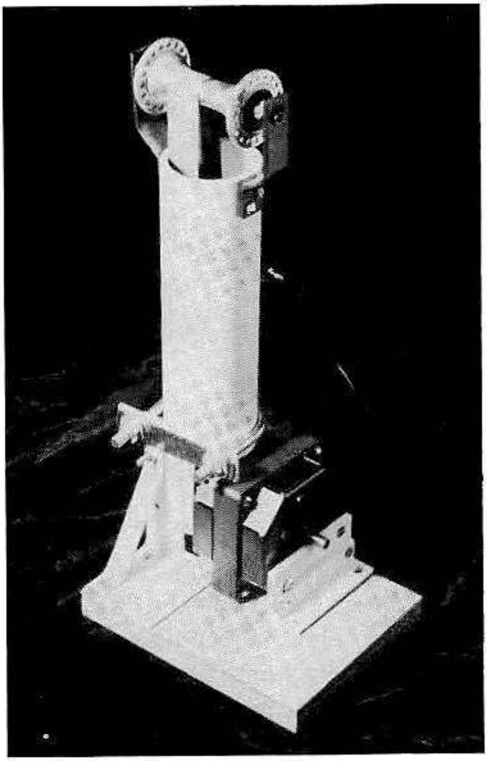

Figure 21 – Terminal Removed

Figure 22

plastic wheel that drives rubber band
AC motor

Classic Van de Graaff Generator
bottom assembly

PVC.) A slot is cut into the lower portion of the tube to allow the motor and plastic drive wheel to be inserted through wall. The PVC pipe is supported by a metal L-bracket and a U-bolt. Depending on the size of your motor, you may want to cut a notch into one side of the L-bracket to provide enough clearance for the motor to fully enter the bottom of the tube. Since this "L" bracket will support your whole generator, make sure it is sturdy and of a heavy gauge. You may even wish to add a metal brace as I did to increase rigidity.

When you have completed this generator, you will be able to perform any of the experiments that follow. This easy-to-build, high performance generator is a very exciting machine to own!

AN EXTREMELY HIGH POWER VAN DE GRAAFF

Before we move on to other types of static generators, I'd like to briefly describe one of the highest performance Van De Graaff generators I have ever seen. Shown in figure 24 is a design for an extremely high power Van De Graaff generator. I have not constructed this unit. I am providing details on this machine should you want to explore machines beyond the limits of my humble designs. This schematic will provide the essential design details.

At maximum efficiency this design could generate voltages exceeding 1,000,000 volts without using an auxiliary storage capacitor!

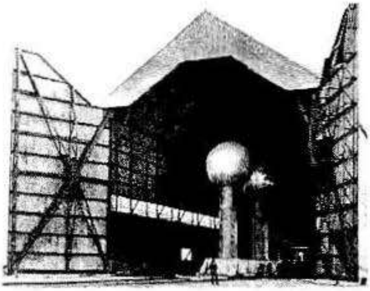

Figure 23 – Ten million volt Van de Graaff generators were built in the 1930's. One generator here is negatively charged, and the other is positive. Generators of this size are not recommended as a first project. (Perhaps not even as a second! ...but call me if you build one!)

Voltages of this order can be dangerous, possibly lethal. This is not a toy and should only be constructed by a serious and cautious experimenter. Because of its high output, I think this unit would make an outstanding laboratory power source for a homemade atom smasher.

The high power unit uses an external high voltage power supply to "spray" an initial charge on the rubber belt. Notice in the schematic that the ends of the spray wires are pointed. A rectified high voltage source between 5,000 to 10,000 volts is ideal. For low cost and ease of assembly you may want to try using an automotive coil as a transformer. For details see Lindsay Publications *"Build a 40,000 Volt Induction Coil."* (Written by an author who is generally a good sort.)

In this design, both top and bottom rollers are metal. The top roller itself is insulated from the high potential sphere. Charge is sprayed

onto the carrying belt as it passes through the corona discharge between the high voltage power supply and the lower roller which is grounded. A second set of points located just inside the upper high potential terminal picks up the charge and conducts it to the upper pulley. Once highly charged, current flows to the high potential terminal through the current regulating resistor. This configuration can also include a corona gap as shown near the inside surface of the high potential terminal.

An additional set of spray points, labeled "charging corona rod" on drawing, connect directly to the high potential terminal and are situated directly above the pulley.

According to *The Amateur Scientist*, *"The difference in potential between the upper pulley, made 'live' by the voltage drop across the current regulating resistor and corona gap, and the high-voltage terminal causes these points to 'spray a charge of opposite sign onto the downward run of the belt.' "*

The value of the current-regulating resistor can be computed roughly by Ohm's law. In small machines it is usually on the order of

40 megOhms.

Optimum belt speed for a high power unit is between 4,000 and 6,000 feet per minute. Most high power units use belts made from rubberized fabric.

If your design is to exceed 200,000 volts, charge distribution along the insulating column becomes important. Machines using belts more than four inches wide should be equipped with equipotential rings as shown spaced every two inches.

A large Van De Graaff generator intended to reach the million volt range is often sealed in a steel tank containing inert gases such as carbon dioxide and kept at many atmospheres of pressure. Keeping the gases at high pressure serves to increase their insulating properties and improves both the voltage and current output of the generator.

Owning a generator of this size would be incredible!

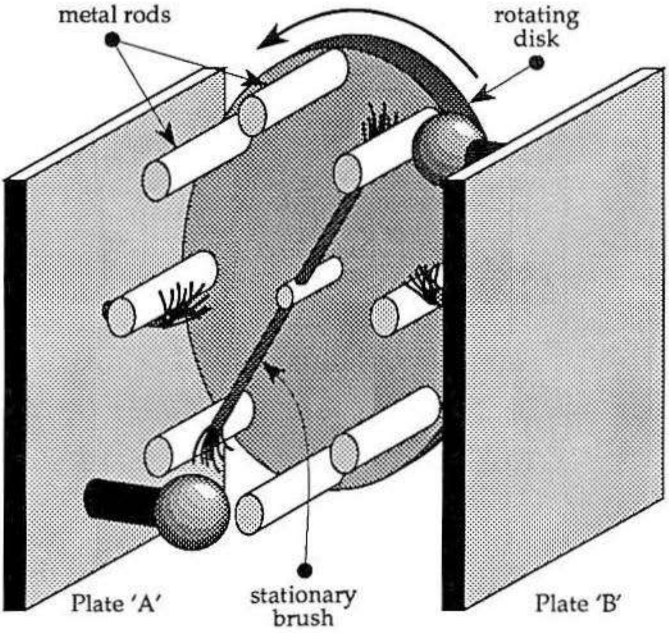
INDUCTIVE ELECTROSTATIC GENERATORS

Wouldn't it be wonderful to have a generator that could produce almost 90,000 volts while being virtually immune to changes in humidity? What if that same generator could be run extensively without concern for wear or maintenance? What if the same generator could be "daisy chained" to other generators to increase their output? What if it could be run as a motor, operating on electrostatic charges, just as a common D.C. generator can also by run as a motor? Well, what we would certainly have is a Dirod generator.

The Dirod generator is another invention of Mr. A. D. Moore. The Dirod gets its name from the main components of the generator: a high grade Plexiglas disk and a series of metal rods. "Dirod" is short for disk and rods. Its operation is most easily understood by observing a schematic representation of its workings.

Figure 26 shows a schematic of a basic Dirod generator. A number of metal rods are attached to an insulating disk (Lucite, glass, plastic, etc.) which is mounted on a bearing that allows it to rotate. In the center of the disk is an axle which is stationary, and attached to this axle is a wire with two brush ends as shown. As the disk rotates, each pair of metal rods is momentarily electrically connected to the stationary brushes as the rods pass by them.

Outside of the wheel we have two smooth metal plates each with



Induction Generator
schematic diagram

Figure 26

an electrode attached as shown and each having a pair of metal brushes as well. Positive and negative charges will form on these plates in the following manner. When the wheel begins its rotation, plate A and plate B will have similar amounts of negative and positive charges – similar, but of course, not exactly the same! Let's say that plate B has a slightly negative charge, and plate A has a slightly positive charge. Now, as a metal rod moves by the electrode from plate A, it is momentarily connected to the rod moving past the electrode from plate B, connected by the stationary brushes from the center axle as shown in figure 27a. At this point, since plate B has a slightly negative charge, the positive charges in the two bars rush into the bar closest to plate B (negative and positive charges attract), and the negative charges rush into the bar closest to plate A. This is comparable to one electrophorus charging the other without having them

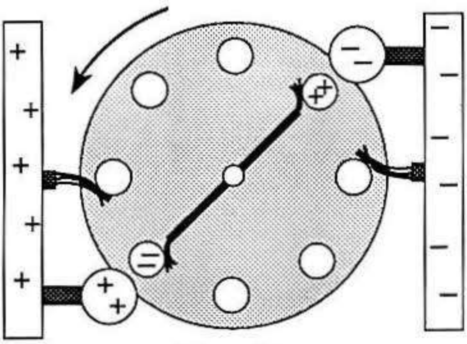


Figure 27a

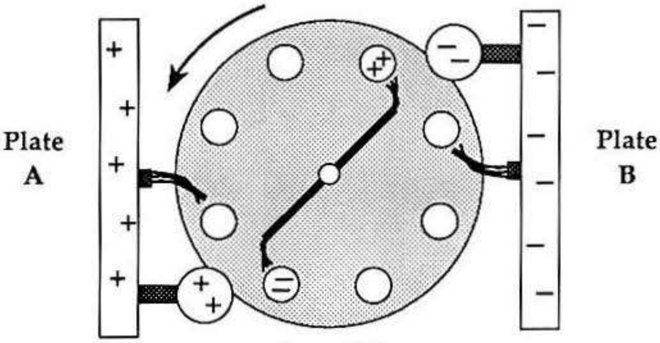

Plate
A
Plate
B

Figure 27b

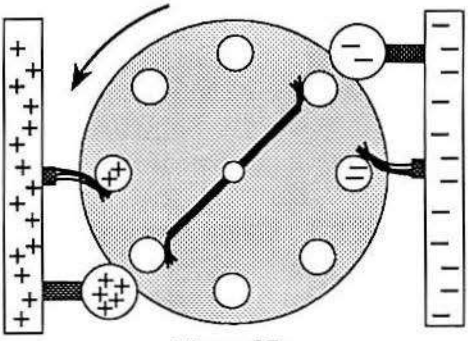

Figure 27c

Induction Generator Operation

actually touch.

As the disk continues to rotate, the two bars move past the brushes and break electrical contact. Now we have one bar with a mostly positive charge and one with a mostly negative charge. Figure 27b

As the bars continue to revolve around to the opposite plate, they briefly make a connection with the brushes from that opposite plate and bestow upon that plate their charge. Figure 27c. Now the plate has an even higher charge than it did originally. It charges the next rod passing by it even more forcefully. In this fashion the plates rapidly build up a larger and larger charge.

When you consider how fast these rods can be spun, and how fast these charges double, you realize how quickly this generator can produce high voltage!

To be a little more technical in describing the difference between our previous friction generators and an induction generator of this type, remember that friction generators charge by contact between two bodies and by the sharing of electrons from the resulting contact. Inductive generators make no demand on free electrons, but on the field they produce. This field causes electrons in the charging material to veer from their orbits. This displacement sets up or induces a charge in the formerly uncharged material. The series of figures 27a through 27c show not only how the machine moves but also how charges are built up during each step of the charging process described.

It is important to understand these simple principles of induction since they are critical to understanding and building the electrostatic motors that follow.

It is interesting to note that the Dirod generator is virtually the same as the world's first electric motor known as the "Franklin" motor for its inventor, Benjamin Franklin, and discussed later on.

Construction of the Dirod Generator

Construction of the Dirod generator is, again, straightforward and simple when viewing the drawings. Keep in mind that the metal rods can be mounted horizontally as shown or vertically, radiating out from the center. Vertical mounting is much trickier. However it is much less stressful on the Lucite disk allowing higher rotational speed to be achieved.

Also very important in achieving maximum voltages is a corona shield which is not shown in the drawing. A corona shield can be fabricated simply by placing a small sheet of Plexiglas between the metal spheres and the rotating rods. I would suggest that you first try your generator without a corona shield, and then with. If your design is optimum, your voltages will increase with the shield.

Because the brushes in this type of design can really take a beating I strongly suggest using a conductive foam such as the foam integrated circuits are packaged in or a conductive rubber brush. If forced to use a metal brush, use a metal that is very springy.

I built an induction generator by modifying the Franklin motor shown later on. By adding brushes and two stainless steel collectors to the Franklin motor, I had both an electrostatic motor and generator! Although I plan to build a much larger, more traditional Dirod machine, this small motor/generator still holds my fascination and continues to teach me the principles I will need to employ in devising the larger unit.

MEASURING VOLTAGES AND POLARITY

WARNING: As mentioned before, the electrostatic voltages produced by the generators in this text are generally safe for the experimenter even should he be accidentally shocked. The operation of the following devices is described for use with electrostatic devices. Should you choose to measure the voltage of other devices, more stringent safety precautions should be taken. Use extreme caution at all times.

Information in this chapter is useful not only in the field of electrostatics, but can also be valuable to those who work with Tesla coils, Oudin coils, induction coils, or other high voltage power generators. One of the most surprisingly difficult things to do with a high voltage is to accurately measure it. I was frustrated to find that text after text said simply that measurement of high voltages was impossible for the amateur. As a result of experimentation and having studied the writings of extraordinary experimenters such as Professor A.D. Moore, I can show you several methods of measuring high voltage that seem quite dependable and accurate. You can also use one of several means to determine the polarity of a high DC voltage – something which is rarely mentioned in any text.

Finding Polarity and Simple Voltage

There are several very simple means for determining the polarity of a high potential. The first, and by far the most sensitive is an FET based "electroscope." Figure 45 shows an electroscope of my own design. The device is simple to assemble and is shown in both schematic and component layout forms. The device works extremely well.

I highly recommend that you build one of these. It can show you the polarity of both very high voltages as well as low electrostatic voltages. In fact, this electroscope will respond to the static build up found in clothes taken from a dryer, or the charge that builds up on a hard rubber comb.

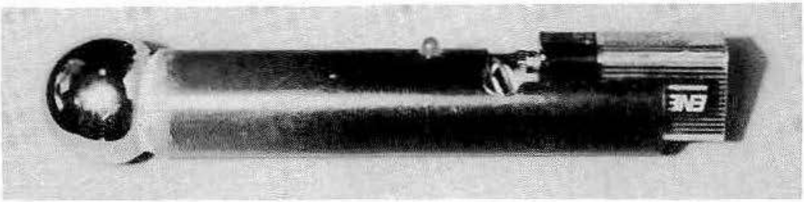

Figure 45 – The FET Electroscope

You may want to modify my design. You should consider replacing the 10 megohm resistor with one of a smaller or larger value. It controls the sensitivity of the circuit. The larger the resistor used, the more sensitive the device becomes, the smaller the resistor, the less

Figure 31

sensitive – within reason, of course. The resistor can also be removed all together for maximum sensitivity, but the device becomes unreliable because even stray radio emissions will be picked up.

When properly adjusted, the FET scope will light when placed in contact with a positive static charge. Keep in mind that the FET transistor, which is the heart of the circuit, could be damaged by an extremely high voltage, however, I have used my scope without difficulty to more than 30 thousand volts (30 Kv). This voltage was measured by placing the scope directly against the Van de Graaff with an appropriate spark gap.

A MECHANICAL ELECTROSCOPE

A mechanical version of the electroscope can be made quite easily from a glass jar, a little wire, and some aluminum foil. A mechanical electroscope is shown in figure 32.

When the top electrode on this scope is touched to a static voltage source, the aluminum leaves in the jar will separate. This happens because the foil in the jar takes on a uniform charge. Since like charges repel each other, the two leaves of foil are forced apart.

The demonstration of an electroscope can be quite impressive. Although it would be difficult, if not impossible, to calibrate, a

charge present

Mechanical Electroscope

Figure 32

mechanical electroscope of this type can also be used to measure voltage. Heavier leaves require greater voltages to separate them. Therefore, the distance the leaves move away from one another indicates a relative voltage.

The Neon Lamp Bank

Another less sensitive but much simpler way to measure low electrostatic voltages is with the use of a neon lamp bank. Figure 33 shows the assembly of such a bank. Ne2 neon lamps are wired in series along a Plexiglas panel as shown in the drawing. Since each lamp fires at about 70 volts, five bulbs wired in series will read a voltage of up to 350 volts. You can quickly see how larger or smaller banks can be easily built. The cost of these bulbs is quite low, so even fairly large banks can be built without great cost.

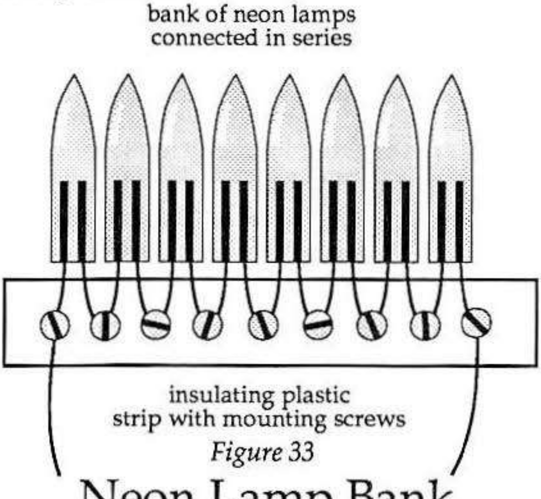

Figure 33

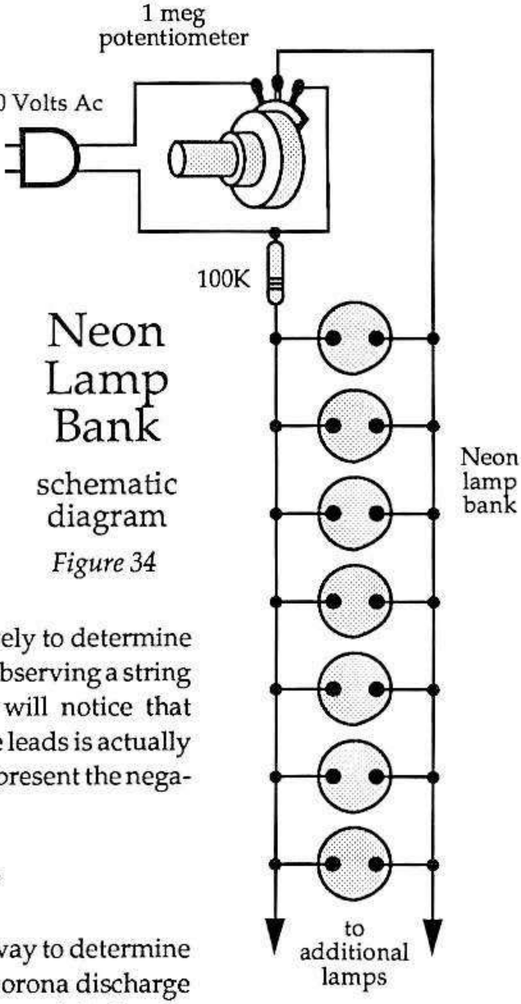
Neon Lamp Bank

When connected to a source of high voltage, it is quite easy to see which bulbs are lit. Sometimes, however, you may have to darken the room to get a more accurate reading. Neon lamps are not always easy to see.

You can increase visibility by leaving a small gap between the lamp bank and your high voltage source. Letting a spark periodically jump the gap will trigger the lamp bank. Attaching the bank directly to generator can draw enough current from the generator (load it down) such that it never reaches peak voltage. With a small Van de Graaff a steady stream of bright flashes will occur every two or three seconds.

Though this means of voltage measurement is crude, you could improve it somewhat by using bulbs with very close firing voltages.

The best way to find such bulbs is with the circuit such as shown in figure 34. Note that a volt-ohm meter can also be connected across the leads shown in order to gauge the exact voltage at which the bulbs will fire. By slowly bringing up the input voltage to a set of bulbs wired in parallel you can find which bulbs fire together and at what voltage.



Neon Lamp Bank
schematic diagram
Figure 34

A neon bank can also be used very effectively to determine polarity. After carefully observing a string of flickering bulbs you will notice that only one of the two inside leads is actually lighting. This lead will represent the negative electrode.

Corona and Polarity

Another interesting way to determine polarity is by observing corona discharge from your high voltage potential. Corona discharge is that strange very faint blue glow that surrounds portions of your high potential terminal. To observe it, you will need to be in a darkened room with your eyes fully adjusted to the dark and your generator running.

One might assume that positive corona and negative corona look the same, but this is not true! Positive corona is even and uniform in appearance while negative corona is bushy, often with streaks or streamers that move around.

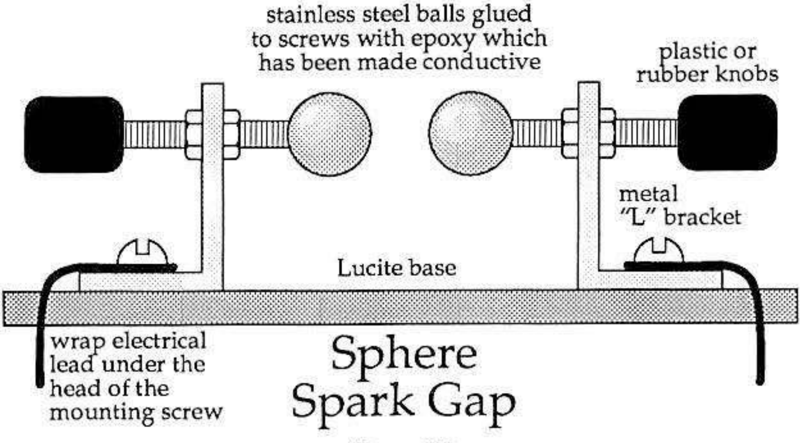
I first noticed this while using my external Van de Graaff, the same one described earlier. Not having had much experience with this generator, I immediately assumed that the light blue glow I was seeing in the darkness was due to arcing in the D.C. motor. It was too dark to see where the corona was coming from. Fearing the contacts in the motor would eventually be damaged, I tried every method I could think of to stop motor arcing, but the pesky blue glow went on unabated. Finally, I reached out in the darkness thinking I was going to touch the motor, but much to my surprise ended up touching the top of the generator! I had not expected to observe a corona discharge on this machine.

Another interesting fact is that negative corona can be heard! If you find that a hissing sound is coming from your generator, this will be generated by the negative corona discharges!

Using Spark Gaps To Determine Voltage

A spark gap is the best way I know of to accurately measure high voltage without having to resort to very expensive laboratory equipment.

Figure 35 shows the basic configuration of a "sphere gap" capable of accurately measuring up to 90,000 volts. A sphere gap consists simply of two hollow stainless steel spheres 1/2 inches in diameter which are attached to a length of threaded rod with epoxy glue that has



stainless steel balls glued to screws with epoxy which has been made conductive
plastic or rubber knobs
metal "L" bracket
Lucite base
wrap electrical lead under the head of the mounting screw
Sphere Spark Gap

Figure 35

been made conductive by some additive or has been coated with a little silver paint in order to make electrical contact between the sphere and the rod. The rod is threaded through a metal stand, and plastic handles are added to allow the spheres to be turned while the device is operating. The spheres must be at least 3 sphere diameters above the base to prevent distortion of the electrical field which can give inaccurate results.

Another type of gap you can build is a rod gap consisting of two aluminum rods 3/4 inch in diameter. The rods are lined up with each other just like the sphere gap. The ends of the rods are rounded by turning on a lathe. Precision is important. The ends of the finished rods must be as close to hemispherical in shape as possible and must be highly polished. A rod gap of this type will give fairly accurate measurements up to 60,000 volts.

Unfortunately, there are too many variables to give a simple equation for determining at what voltage a spark will bridge a given gap. The only practical solution is to either calibrate your gap by using devices that generate known voltages, or to use a set of measurements which have already been taken.

What follows is a chart of known values for the apparatus described. These charts are excerpts from *Electrostatics* by A.D. Moore.

kV	Rod gap	Sphere gap
5	0.056	
10	0.112	
15	0.170	
20	0.228	0.234
25	0.288	
30	0.355	0.370
35	0.430	
40	0.520	0.531
45	0.625	
50	0.750	0.710
55	0.903	
60	1.122	0.950
70		1.102
80		1.380
90		1.700

Note: Gaps listed are in inches.

One limitation of measuring high voltages with a sphere gap is that you will loose accuracy dramatically if the gap between the spheres becomes larger than the diameter of one sphere. Because of this, you might need a general way to calculate voltages for spheres of different sizes. Also, you may not be able to find a sphere of the exact size mentioned and will need to have a reference for adjusting your figures.

What follows is a listing of spark gaps for spheres of several different sizes. By using these numbers and plotting along a curve, you can remain fairly accurate in determining the characteristics of spheres whose sizes fall between those shown.

Gap Distances in Inches
for a variety of voltages and sphere sizes

	sphere sizes in cm				
kV	2.5	3	4	5	10
10	0.30	0.30	0.30	0.30	0.30
20	0.61	0.61	0.61	0.61	0.61

90			4.40	3.93	3.28
100				4.76	3.75

THE "NOON" ION HIGH VOLTAGE METER

OK, I have to admit that it is terribly arrogant for me to name one of my devices after myself, but what the heck. For the record, I won't complain if you affix your name to one of your inventions! I think that you will find this meter which has solved so many of my voltage measuring problems to be an extremely useful tool in experimenting with high voltage.

As we have discussed, the surfaces of a high potential terminal should be smooth and round, ideally spherical, in order to prevent electrons from flying off into space. If we intentionally direct these electrons onto a sharply pointed terminal, the density of electrons will increase to the point where they begin to jump out into the atmosphere that surrounds the terminal. As these electrons stream away, the pointed terminal moves in an opposite direction by virtue of Newton's second law of physics (ie. for every action there is an equal and opposite reaction.)

This reaction is extremely small. However, it is measurable, and can even drive a small motor (described later) or, as I have discovered, push the pointer on a standard panel meter! Since the strength of the reaction is directly related to the voltage accelerating the electrons, it is possible to construct a meter capable of measuring high voltage.

One difficulty with this meter is that, if constructed from off-the-shelf parts, no two meters will read exactly the same due to variations in the exact dimensions of the pointed terminal and the meter itself. It is necessary to use other methods to initially calibrate your meter such as comparing meter readings to voltages ascertained by the spark gap method.

When using your meter remember to keep it well clear of ground or any object that might attract the ions streaming off your high voltage generator. Anything that upsets the stream of electrons can affect the meter reading.

HIGH VOLTAGE AND SAFETY

Because storage devices can accumulate enough electrical charge to be lethal, we must discuss safety.

Most texts simply warn the experimenter to stay away from a high voltage discharge, and, of course, this is a good idea. No shock is completely safe, and people have been injured and even killed by remarkably small voltages.

Even low voltage can deliver high damaging current. A capacitor carrying just a few volts has been known to melt the end of a screwdriver that accidentally bridged its terminals!

If your experiences with electricity are anything like mine, no matter how careful you try to be, electricity will occasionally find some clever way to zap you when you aren't looking. Because of this, you should know how to determine when any source of high voltage you are experimenting with is safe.

The U.S. Atomic Energy Commission helps us by telling us that a discharge to the human body of 10 joules is known to be hazardous to life. A discharge of a mere 1/4 joules will deliver a heavy shock.

Use the following equation for figuring the charge in Joules:

$$\text{Joules} = \frac{1}{2}CV^2$$

where:

C = Capacitance in Farads
V = Voltage in Volts

What follows (again from A. D. Moore) is a short list of capacitors and the number of kilovolts needed to store up a dangerous 10 joule charge.

microfarads (uF)	kilovolts (kV)
0.002	100
0.20	10
20	1
80	.5
320	.25
2000	.1

From this you'll see that even small capacitors can store lethal amounts of electrical charge. Just because you may be dealing with less than 10 Joules does NOT mean you are safe! Again, remember that no shock is completely safe. If you are careful and use good judgement, you will have little to fear from electricity.

Most of the generators in this book will produce more than enough power to run any of the experiments outlined directly. High voltage static electricity is safe because there is so little current available. A Van de Graaff machine moving 50 square inches of belt per second generates only one microampere. Although the voltage (the pressure behind current) can be very high, there is very little current to be accelerated. Power is the product of voltage times current. One microampere would have to be accelerated by one million volts to be able to deliver one watt of power. With such low current levels, power levels are necessarily low and relatively safe.

If, however, small currents accelerated by high voltage are stored in a capacitor or bank of capacitors, it is possible to accumulate enough charge at high voltage that when it quickly discharges it can produce deadly levels of current. Some commercial high power static generators go as far as to present the warning "Do not attach capacitors." If you are experimenting with larger capacitors than those described, remember that it is no longer safe to verify static charges by touching terminals! Capacitors can store charges from *minutes to months* depending on the dielectric! Careless or thoughtless use can prove fatal!

Electrostatic generators are unusually safe. Most generators will produce no worse a shock than a good jolt resulting from shuffling across the carpet. However, in coupling your generators to energy storage capacitors you're moving into dangerously high voltages. Be very careful!

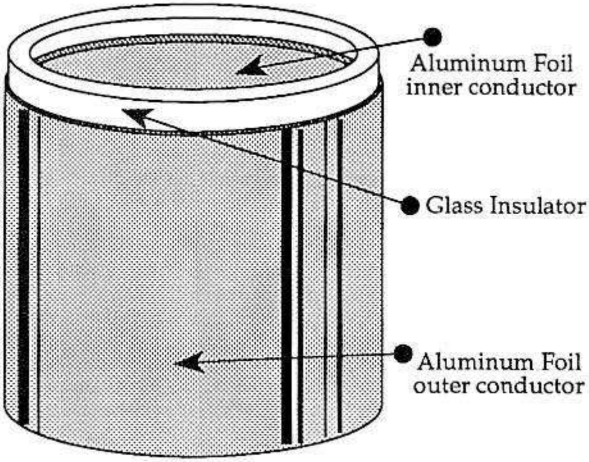
ENERGY STORAGE WITH THE LEYDEN JAR

A Leyden jar is simply a capacitor, that is, a device that stores electrical energy. Like all capacitors it consists of two conducting metal plates separated by an insulator. Figure 36

A brass knob such as those used on the handles of bathroom drawers is attached to an insulator, in this case, a flat piece of Lucite. You could also use cork, plastic, wax, or almost any insulator. The Lucite is cemented to the lid of a jar with a little Silicone glue. A large hole cut in the lid of the jar allows a wire to pass from the bottom of the knob to the bottom of the jar. The inside and outside of the jar are coated with a layer of aluminum foil. The foil should be worked with your fingers until it smoothly conforms to the sides of the jar. A wire is attached to the outside foil, and the entire outside is then wrapped with black tape.

To use the Leyden jar, the wire lead coming from the outside foil is attached to ground. A cold water pipe makes an excellent ground. The brass knob is connected to the output terminal of your generator.

Leyden jars can be assembled in any size, larger jars having larger capacitance. My personal favorite Leyden jar was made from a 5



Leyden Jar & Other Capacitors
showing the
conductor-insulator-conductor layers

Figure 36

gallon white plastic pail that had contained detergent. This huge capacitor has been charged by the "Classic Van de Graaff" generator. Under good conditions it yields a very heavy, thick, multi-colored, spark of more than 4 inches accompanied by a "crack" that could be heard for some distance.

A word of warning: I made the error of touching this capacitor when I had thought it fully discharged, and though it was partially discharged at the time, I received a remarkably painful shock. This capacitor should be treated with respect. You can never be too careful.

Leyden Jar Tool

One tool you should build for your Leyden jar is a discharge rod. After experimenting with your Leyden jar, you will always want to be sure that it is fully discharged before handling or storing it. This is a very good habit to get into to avoid getting zapped when you are in a forgetful mood.

Leyden Jar
cross section
Figure 37

Electricity often seems to find some way to get into the jar without telling you. I was once shocked by a Leyden jar that was standing a few feet from a generator. It was not until I observed the generator and Leyden jar in a completely darkened room that I noticed a blue glow around a length of wire which had been acting as an aerial above the Leyden jar and had partially charged it although it was not even directly connected to the generator!

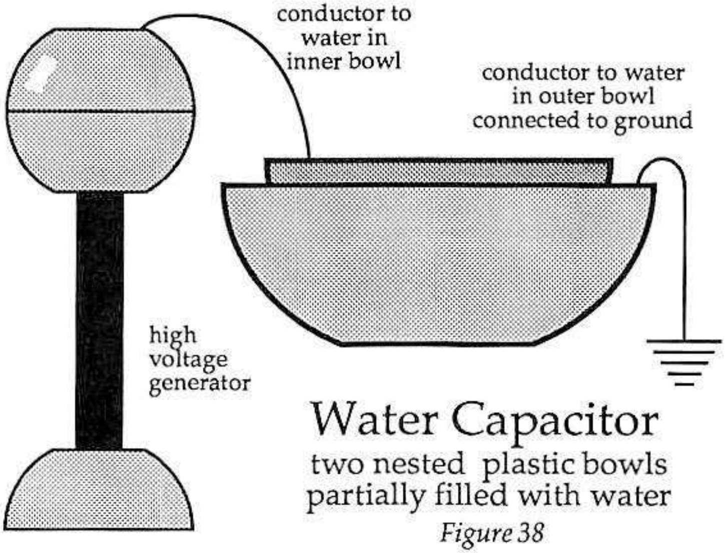
To make a discharge rod, simply take a length of heavy copper wire and bend it in a "U" shape. This "U" should cover the distance between the brass ball and the aluminum side of your Leyden jar. Attach an insulating handle to the center of the "U". Make sure this handle is long enough that a spark won't find its way along the handle to your hand. Holding it by the plastic handle, you can bridge the gap between the brass ball and side of the Leyden jar, and safely discharge it.

Discharging a large Leyden jar with this tool can be lots of fun since a large noisy spark can be safely produced. This provides a terrific demonstration for those who doubt the power of static electricity!

THE WATER CAPACITOR

Believe it or not, ordinary water and plastic bowls can be used to form an extraordinarily high dielectric, and make a good capacitor. Figure 38. A water capacitor is nothing more than two plastic bowls set inside one another each being partially filled with tap water. Any tap water will be somewhat conductive like the metal plates of the Leyden jar because of impurities. Dissolved salts in the water form positive and negative ions which move readily. The plastic wall of the inside bowl forms the dielectric while the water in each bowl forms the electrodes. A small capacitor of this type having 53 inches of useful surface area has a capacitance of approximately 100 pF.

This type of capacitor was supposed to have been a favorite of inventor, Nikola Tesla. Tesla, it is said, would wire together banks of



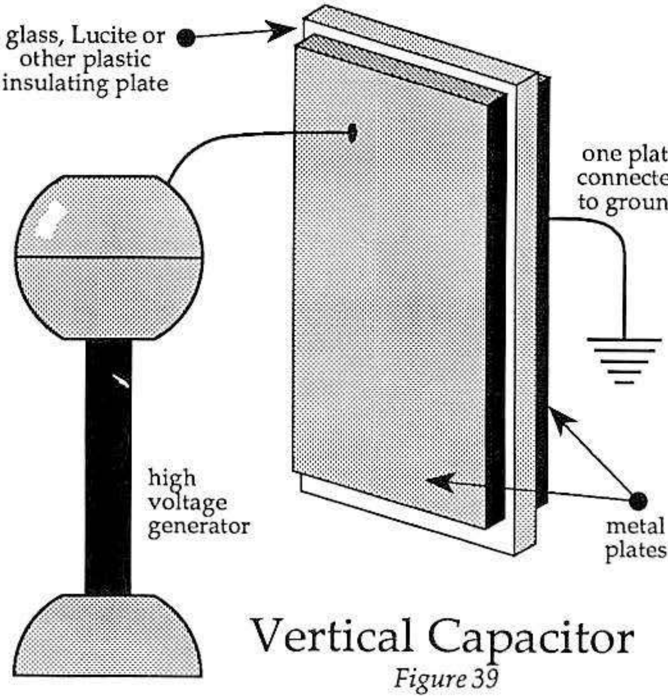
Water Capacitor
two nested plastic bowls
partially filled with water
Figure 38

insulated metal trays which were filled partially with water. By connecting these water capacitors in parallel, Tesla could reach very large storage potentials with a minimum of effort.

Plate Capacitors

As you have undoubtedly gathered, all that is required for a simple capacitor to hold a charge are two conductive plates with an insulator (dielectric) in between. There are an infinite number of configurations to be experimented with. Figure 39 shows what is probably the simplest useful capacitor possible.

The largest plate capacitor I attempted during the writing of this text was one made from aluminum foil and my sliding glass door. As soon as I became interested in electrostatics, and making high voltage capacitors, I started seeing the makings of capacitors everywhere. Every day I looked at my sliding glass door, and every day it looked less like a door and more like a capacitor. Finally I broke down and



glass, Lucite or other plastic insulating plate
one plate connected to ground
high voltage generator
metal plates

Vertical Capacitor
Figure 39

bought a large roll of aluminum foil and some tape. After a thorough cleaning, I transformed my door into a giant capacitor, by taping sheets of foil to each side of the glass. But alas! The results were disappointing. Temperature differences between the inside and outside of the glass caused condensation and all the problems that moisture brings, and the large sharp edges of the foil which I attempted to insulate bled off charge rapidly into the air. The foil did odd things such as crinkling and making sounds when charged, but failed to yield an interesting spark or hold a charge for any length of time at all.

I'm sure you'll come up with as many ideas as I do. Most recently, a television special showed the huge metal domes on buildings in Moscow square giving me visions of tremendous high potentials. As I watched, the buildings kept looking more and more like high potential tops of Van de Graaff generators and less and less like buildings. I think this high voltage stuff is affecting my mind! I think it's a good thing that I don't live in Moscow.

Calculating Capacitance

Once you begin designing and building capacitors, you will undoubtedly want to know what charges they are capable of storing. Capacitance is fairly easy to calculate, although homemade capacitors will be much less than perfect and probably perform more poorly than calculations might indicate. The following equations will give you a good idea of what can be expected from your designs.

Air is a good dielectric, and is accounted for in calculations. If we have two metal plates standing parallel to one another with air between, the equation for finding capacitance in picofarad is:

$$C = .08854 \frac{A}{S}$$

Where

A is the area of one side of one plate in square centimeters

S is the distance between plates in centimeters.

The same equation can also be revised for inches:

$$C = .2249 \frac{A}{S}$$

Note that these equations remain fairly accurate as long as the smallest dimension of the plate is ten or more times "S". In other words, the area of the plate should be much, much larger than the distance between them.

Different materials have different insulating capabilities which are reflected in their dielectric constant. Since you will want to use materials other than air as a dielectric, you will need to look up the dielectric constant from standard tables. You'll find that Plexiglas provides about four times the dielectric strength of air. A capacitor built from two conducting plates would have four times the capacitance of an air capacitor.

Another example: We might calculate from the equation above that a capacitor with a desired plate size has a capacitance of 100 pF using air as the dielectric. Using the chart below we see that if dry paper were substituted for air, the capacitance will be raised to 200 pF.

Shown below are some typical dielectrics relative to air borrowed from Attwood's book *Electric and Magnetic Fields:*

Dielectric Constant	Material
1	Air
25	Ethyl alcohol
2.5	Transformer oil
4.5 - 7	Various types of glass
6.8-8.4	Plate Glass
8.0	Window Glass
4.1-6.1	Pyrex
5.4-5.8	Bakelite

4	Wood

Capacitors can be connected in parallel or in series. Parallel connection increases total capacity. The total capacity is the sum of the individual capacities.

$$C_{Total} = C_1 + C_2 + C_3 + \ldots$$

For example, three capacitors having capacity of 10, 20 and 30 pF each would act as one capacitor having 60 pF when connected in parallel. The breakdown voltage of the combined capacitors is only as great as the lowest breakdown voltage of any single capacitor.

Calculating the capacitance of capacitors connected in series is more complicated, being the reciprocal of the sum of the reciprocals of the individual capacitances.

In series you would figure:

$$C_{Total} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \ldots}$$

For example, three capacitors have capacitance of of 2, 4 and 4 pF. When connected in series, the total capacitance would be 1 pF. Although capacitance has decreased, the maximum working voltage has increased. If each capacitor had a maximum working voltage of 10,000 volts, the series connection would have a maximum working limit of 30,000 volts.

Power Capacitors

You can build a very powerful capacitor by creating a stack of alternating sheets of dielectric material and metal plates. On a large sheet of dielectric place a metal plate, then another sheet of dielectric, another metal plate and so on. The plates must be absolutely clean and free of even the tiniest contaminant or the capacitor will not work. To complete the capacitor connect alternating metal plates to one lead and the remaining metal plates to another.

For your first attempt, build a power capacitor with 5 sheets of dielectric and 3 metal plates. Connect the top and bottom metal plate to one lead, and the middle metal plate to another lead.

Benjamin Franklin — The Turkey Killer

Benjamin Franklin, an incurable prankster, was an ardent experimenter with electrostatic machines. Amazing as it may seem, according to his biography, the major reason Ben Franklin tried his dangerous kite experiment was that he was tired of charging his Leyden jar by hand cranking his static electricity generator. He wanted to charge it with lightning which he was able to do without getting himself killed! (Note: this method of charging a Leyden jar is not recommended for those other than "founding fathers" and other experimenters who seem to have a supernatural gift for avoiding harm. In other words, don't you try it.)

Franklin's hand-cranked static machine was large enough when coupled to Leyden jars to produce a lethal voltage. In fact, Franklin often used his static machine to kill his Thanksgiving turkey. In his own words "*... to the amazement of many... A turkey is to be killed for our dinner by electrical shock, and roasted by the electric jack, before a fire kindled by the electric bottle...*"

Franklin's pranks were not without risk. Just a short time before his famous kite experiment Franklin accidentally took the full force of his turkey killing device. He wrote, "*Being about to kill a turkey by the shock from two large glass jars, containing as much electrified fire as forty common phials, I inadvertently took the whole through my own arms and body, by receiving the fire from the united top wires with one hand while the other held a chain connected with the outside of both jars. The company present (whose talking to me, and to one another, I suppose occasioned my inattention to what I was about) say that the flash was very great and the crack as loud as a pistol; yet, my senses being instantly gone, I neither saw the one nor heard the other; nor did I feel the stroke of my hand.... I then felt what I know not well how to describe: a universal blow throughout my body from head to foot, which seemed within as well as without; after which the first thing I took notice of was a violent quick shaking of my body, which gradually remitting, my sense gradually returned.... That part of my hand and fingers that held the chain was left white, as though the blood had been driven out, and remained so eight to ten minutes after, feeling like dead flesh; and I had a numbness in my arms and the back of my neck that continued till the next morning...*"

Franklin's account of his own mishap should certainly give thought to those who do not take the dangers of static electricity seriously!

ELECTROSTATIC EXPERIMENTS

The experiments here are divided into two categories. The first group describes electrostatic experiments that can be performed for an audience. In other words they're merely for entertainment.

The second section features experiments which possible useful applications of electrostatics which are not often discussed. Many of these "useful" experiments could be or are being developed into very real, marketable industries and should be particularly interesting to the serious experimenter.

Hair Raising Experiences

Using electrostatic voltages to make a person's hair stand on end is a classic experiment every audience should see. It can be done in a number of ways. Find a subject with hair that is light and clean. With some experience you will be able to recognize the best subjects immediately. Next, convince the subject that the ominous apparatus that they have just seen throwing four inch sparks will not harm them.

You may want to explain why the experiment is perfectly safe by describing the "skin effect" of high voltages. This effect refers to the strange fact that voltages of this order travel only on the outside or "skin" of the object they pass over and will not travel through the inside of a body where they could do any harm. For alternating currents this is a true skin effect, but for direct currents there is a similar effect that occurs probably because of the repulsion of like charges rather than due to a true skin effect.

The subject should stand within reach of the generator and should be well insulated from any ground. This is accomplished by having the subject stand on a large insulator such as an overturned plastic bucket, or, as a joke, a stack of college text books since they are usually very dry. Instruct the subject to place one hand on the high potential terminal, and then turn the generator on. Remember to remind a nervous subject not to remove his hand from the terminal until the experiment is completed since removing his hand could provide a

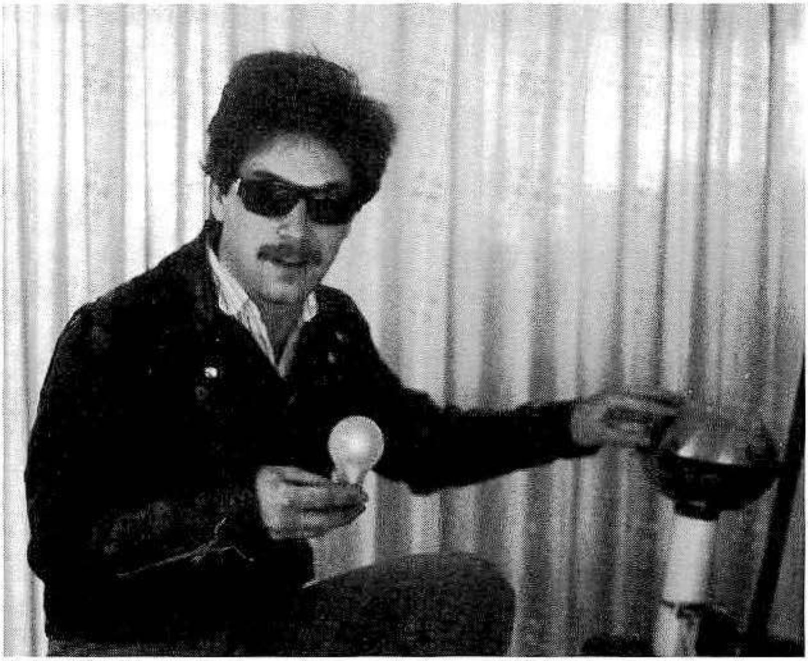

Figure 40 – The author's hair is usually flat and combed somewhat back. After a few minutes connected to a running Van de Graaff generator, and he's ready for a punk-rock concert!

shock. Depending on the output of your generator you may need to allow it to run for several minutes before your subjects hair will begin to rise. Having your subject shake his head occasionally with speed up the process.

During this whole procedure the subject will not feel the electricity passing over him other than perhaps a light tickling as his hairs stand on end. What is happening is that the subject's hair and whole body is taking on a charge from the generator. Since all of the hairs have the same charge whether it be positive or negative, and because like charges repel each other, every hair is repelled from every other hair and any nearby parts of the body. Warnings: **1) Don't use capacitors. 2) Hairspray is flammable. 3) Voltages over 500,000 are unsafe.**

Strangely enough, your generator will actually have a higher potential with someone is touching it than when it is operated alone since it can now use the person's body as a high potential collector. The success of this experiment depends largely on the subject's hair. Some women with short frizzy hair will have their hair stand out nearly straight from their head!

After the experiment is complete, have your subject remain standing on the insulator. This will allow the charge accumulated in their body to bleed off and will reduce the possibility of a large spark occurring when they eventually touch something that is grounded.

There are a few simpler although perhaps less dramatic ways to perform the same experiment. One is to make a wig out of fuzzy yarn and to place it over the generator's high potential terminal. You can place it on the spherical terminal of a Van de Graaff generator to simulate a person's head. Some Mr. Wizard impersonators even like to put a pair of plastic sun glasses under the wig to give the generator a little character. After the generator has run for a time, the hairs of the wig will stand on end.

A very quick way to demonstrate this effect is to simply take a few hairs from an old hair brush and place them on the generator's surface. They will immediately stand on end, and will often fly off the generator all together! Many different light weight materials can be used for these type of experiments. Bits of styrofoam work extraordinarily well.

The Magic Wand

As discussed, smooth, round objects tend to hold their charges while sharp pointed objects will allow electrons to fly off in a stream sometimes referred to as an "electric wind." The effects of this wind can easily be seen. Connect a short length of wire to your high potential terminal and hold the free end of the wire with a handle made of an insulating materials such as plastic. Point the end of the wire toward a lighted candle, and observe the flame. The flame will bend mysteriously away from the invisible "electric wind." In a well darkened room with ones eyes well adjusted the "wind" may actually be visible.

Another interesting experiment is to use the wand to chase a soap bubble. Because there are two forces acting on the bubble, the outcome of the experiment may be unpredictable. One force is the charge of the generator itself which draws the bubble toward the wand. The other force is the electric wind from the wand that pushes the bubble away. How the bubble will act is anyone's guess! It depends on which force is dominant.

A little later on we'll use this surprisingly powerful wind to create a small pinwheel motor.

Levitation

There are a number of ways that you can levitate lightweight materials using your generator. The easiest ways to demonstrate this is to simply spread very small shavings of styrofoam along the top of your generator. When the power is on, the pieces will take on the same charge as the surface of your generator and be repelled by it since like charges repel one another. The bits of styrofoam will levitate off into the air after the generator has been on a few seconds.

An entertaining experiment can be done by placing a number of tiny styrofoam balls in a short section of clear glass or plastic tubing about 2 1/2 inches in diameter and a few inches in length setting on your high potential terminal. Cover the top of the tubing with a metal plate, and connect it to ground. When your generator is turned on, the balls become charged and levitate to the top of the plastic tube. When they touch the metal plate at the top of the tube they lose their charge to ground and fall back to the generator again. The balls will oscillate between the ends of the tube until the generator is shut off. You should coat these balls with a conductive paint for a more complete charge transfer.

If you enjoy reproducing electrostatic experiments as they were originally done, you might want to try making your own old-fashioned pith balls instead of using styrofoam. Pith balls were used for these experiment before modern products like styrofoam were available. Pith balls are made by removing, shaping, and drying the insides of certain plants such as dandelions. Details can be found in old physics textbooks before 1900. I'll stick with good old styrofoam.

Place larger bits of styrofoam on your generator, and turn your generator on while touching the bits with your hand. The styrofoam will assume that you are ground and that your generator is a high voltage source. One side of the styrofoam will be charged one way, and the other side of the styrofoam the other. After removing your hand, a number of things can happen. The styrofoam may flip over and be stuck to your generator like a magnet. The styrofoam may stick to your hand like a magnet. Or you may find the styrofoam floating on end as the hair did in the last experiment.

An interesting trick can be performed by passing your hand over the styrofoam remaining on your generator terminal. As you do so, the electrical charges in the foam and in your hand will cause the styrofoam to jump about.

I have meant for some time to place a metal plate on a table underneath a table cloth and to energize that plate from a hidden electrostatic machine. I could then sit at the table and "mysteriously" move light weight objects such as bits of hair, sawdust, styrofoam or other similar materials around the table simply by passing my hands over them. I think this would make a very convincing illusion of mental telekinesis. Try it.

Lighting Without Wires

If you or your friends doubt the power of your generator, have on hand a supply of Ne2 neon bulbs which are available for less than a dollar at any electronics store. Remind those onlooking that it takes at least 70 volts to light a neon bulb. Hold one lead of the neon bulb in your hand and move the bulb toward your generator. Within inches, or even feet, the bulb will flicker or light. I have seen some experimenters hold the bulb in their mouth while reaching toward a generator with their hand. Seeing a 70 volt bulb light in a persons mouth with no wires attached is an impressive demonstration.

You may want to try large florescent bulbs as well. When my generator has been running I have seen flickers in the florescent lights in the ceiling of my home. These bulbs are many feet above the top of my generator yet respond well in a darkened room.

Perpetual Motion

Anything that people assume can't be done interests me. Many of the greatest inventions of all time would never have come into being if their inventors hadn't at one point been told that it couldn't be done. Currently, perpetual motion qualifies as such.

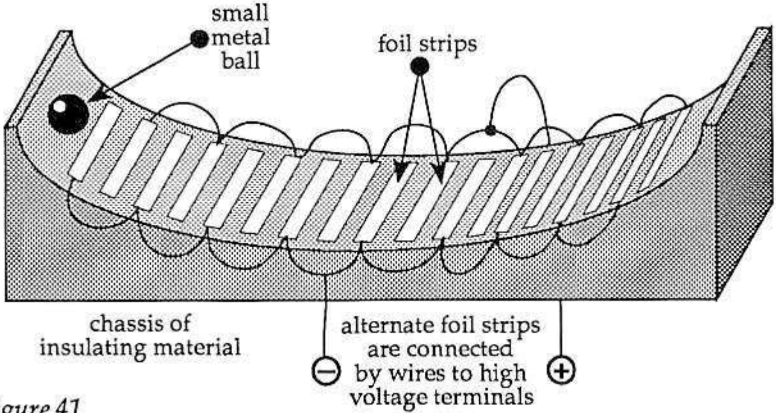

Figure 41

"Perpetual Motion"

The following device doesn't really qualify as perpetual motion, but it appears to be! Figure Pl shows the device. The idea is simple. A few light-weight conductive balls are released onto a U-shaped track on which the balls rock back and forth. It is normal to assume that the balls will slowly lose their energy and come to a stop in the center of the track. Instead, because of the electrodes in the track,the balls continue back and forth indefinitely and even pick up some speed along the way.

What has happened is that you have constructed simple electrostatic motor. As the balls pass over the foil strips they pick up the charge from that strip. Having the same charge as the strip, they are repelled by that strip and are simultaneously attracted to the next strip which has a dissimilar charge. Inertia will cause the balls to roll over the dissimilarly charged strip and on to the next. The electrostatic forces replace the energy lost in rolling friction. In this manner the balls will remain in motion for as long as power is supplied.

If you wish to really complete the illusion given by this device you will naturally want to hide the foil strips from view. To do this you could either use a conductive material other than foil that blends into the background, or, if your generator is powerful enough, you could probably bury the foil strips under the ramp material and still transfer a sufficient charge.

Trick Gun

We know that like charges repel one another. This has been demonstrated with the 'hair' experiments and others. What would happen if we introduced a charge into a liquid, and then shot that liquid out in a stream? We can find out with the use of a squirt gun. Purchase an inexpensive water gun that stores its water in the handle. Drill a small hole into the handle and twist a brass sheet metal screw into the hole. You may want to put a little Silicone glue around the top of the screw to make sure that this point will not leak when the gun is later filled with water. The brass screw provides electrical contact between your hand and the water.

Fill the gun with water, and pump out a few squirts. The water will come out in its customary straight stream probably covering the length of the room. Then stand on an insulator and charge yourself up as described earlier. When you squeeze the trigger, a stream of scattered droplets will be ejected only a few feet. What has happened is that all water droplets have a similar charge so each droplet is repelled by every other droplet. Other than being just an interesting way to get an unsuspecting friend wet, this mechanism can be applied anywhere that a liquid must be atomized.

I've wondered about making an electrostatic chamber on the carburetor of my car to see if better atomization of the fuel would result in better combustion. But first I need to check into the dangers of a spark occurring! I don't really want to blow myself up!

An Ion Motor

There are several different electrostatic motors that can be run by your generator, the simplest being an ion motor. You can make one by simply bending a length of light weight wire into a "Z". At the center of the "Z" shape, place a conductive bearing. Nothing fancy is required. In fact, just looping the center of the Z around an axle may work. Make sure however, that the Z will rotate very easily. A simple schematic of the ion motor can be seen in figure 42.

When power is applied to ion motor electrons stream off the pointed ends of the wire creating an electric wind. The force of the wind pushes the wire in the opposite direction. Again, for every action

Ion Motor
pointed wires attached with silver paint

Plastic Toy Airplane Propellor
Figure 42

there is an equal and opposite reaction. If your rotor is well balanced and the bearing friction is very low, your motor can and will achieve speeds of several thousands revolutions per minute! Of course, the torque generated by this motor will be very, very small. Nevertheless, it is fascinating to watch a motor propelled by a stream of electrons!

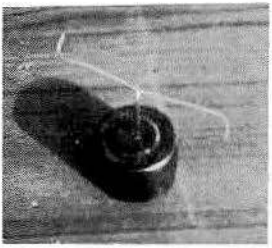

Figure 43 –Simple Ion Motor

Although the thrust of this motor is very small, I am certainly not the type of experimenter to let this hard-earned stream of electrons get away without doing some useful work along the way. I have attached one of my pinwheel motors to a tiny plastic airplane propeller as shown to blow a little air cool air my way. I think this is probably one of the few fans that I know of that must be connected to 100,000 volts or so to operate!

Another thought that I had for this fan was to drive it with a negative charge. Negative ions are thought to have many health benefits, and to cut down on pollutants in the air. Negative ions apparently attach themselves to specks of airborne dust and cause them to fall from the air. There are a number of negative ion generators being marketed for this purpose. I thought that a spinning propeller of this sort would be an absolutely outstanding way of both distributing and producing negative electrons in a room environment.

Ion motors also have serious applications in space travel. The Soviets have used ion motors to propel some of their long range probes. The problem with these motors is that the thrust is very small. However, ion motors offer at least two enormous advantages. First, they can be powered by a nuclear or solar electrical source which can provide power far longer than conventional chemical rockets. Second, an ion motor can provide higher velocity thrust than current chemical rockets because the nozzle velocity of a rocket is limited by the internal pressures that can be safely generated inside the rocket motor. An efficient ion motor can accelerate ions to speeds approaching the speed of light! Although the thrust is small, over time the space craft could itself approach the speed of light, at least, in theory.

A few tips for getting the best operation out of your ion motor—Make sure that your rotor is well balanced especially if you want your motor to be self-starting. Your rotor should spin easily for several seconds when tapped lightly by your finger. The more freely your rotor can spin, the faster it will revolve. The bearing used in a radiometer would make an excellent ion motor bearing.

Run your generator/motor in an area free of objects that might provide sources of ground. My first ion motor was well built and carefully balanced, yet it refused to spin. When I reached down to give it a tap to get it started, it refused to move. In fact it felt as though it were being held in place by a magnet. It was then that I realized that one of the arms of the rotor must have been attracted to an object with an opposite charge. That object turned out to be me! When I moved a short distance away, the ion motor sprang to life and immediately whirled up to several hundred RPM.

For this motor, voltage is more important than current. The motor will run and do useful work on currents under a microampere. Electrostatic motors have been run with currents of less than .001

microamperes, and have even from the earth's electrical charge itself.

Another interesting use that I have found for an ion motor is that of a primitive high voltage meter. The higher the voltage, the greater the thrust from the motor. This may be used to move a pointer such as in a panel meter or may be used simply to a relative indication of voltage.

I like to place a small ion motor on top of my Van de Graaff generator when I am charging capacitors. When the capacitors are charging, the motor will not move since the charge is being bled off from the generator to the capacitors. When the capacitors are fully charged, they stop drawing current from the generator. The terminal voltage rises, and the motor begins to spin. This is a very useful application of the ion motor since it is usually impossible to tell when a capacitor is fully charged any other way.

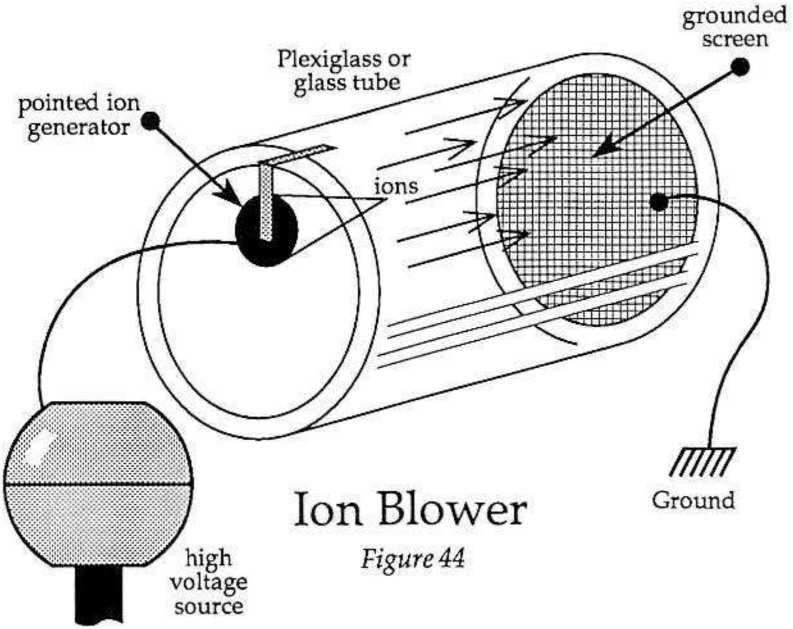
I am told that ion motors have been used in scientific toys such as those that can influence a balsa airplane in flight. Gustave LeBon's electrified rocket was a small aluminum foil rocket that could actually fly on electrostatic forces (Patent No. 2,018,585). I have not seen these devices, but they sound like something worth investigating.

Experimenting with "micro" sources of power can bring out the engineer in everyone.

An Ion Blower

The last experiment uses a stream of ions to propel a small rotor. Since in essence what we really have is a little jet engine, why not put our blower into a tube and see if we can pull a little air along with it. Figure 44 shows one possible configuration.

One end of a small, clear tube such of glass, Plexiglas, or other insulating material is fitted with a sharp metal point. A metal screen covers the other end. Electrons reach a high density at the metal point, break free into the air, and stream through the tube to the screen at the far end. As they move rapidly through the tube, they pull some of the air inside the tube with them. Obviously, a blower of this type has very low efficiency probably in the neighborhood of 1% under ideal conditions, Nevertheless, a puff of smoke at the intake side of the tube will easily be drawn through.



Ion Blower

Figure 44

Clearing The Air

Before moving on, here's another interesting smoke experiment you can try. Get a clear plastic or glass jar having no metal parts. Drive a pointed nail through the center of the lid. Blow a little smoke into the jar, and seal the jar with the lid. Next, connect the head of the nail to the output terminal of one of your high voltage generators.

As charge is applied to the smoke, it will begin to swirl. Soon the smoke will seem to disappear, although in reality it has been redistributed along the sides of the jar.

Variations of this effect are used in industry to place very fine films on surfaces. Similar electrostatic methods are being used to make sandpaper. When the tiny metallic abrasive particle are distributed along the surface of the sand paper they are given a charge that causes them to stand on end creating sandpaper with a better abrasive action.

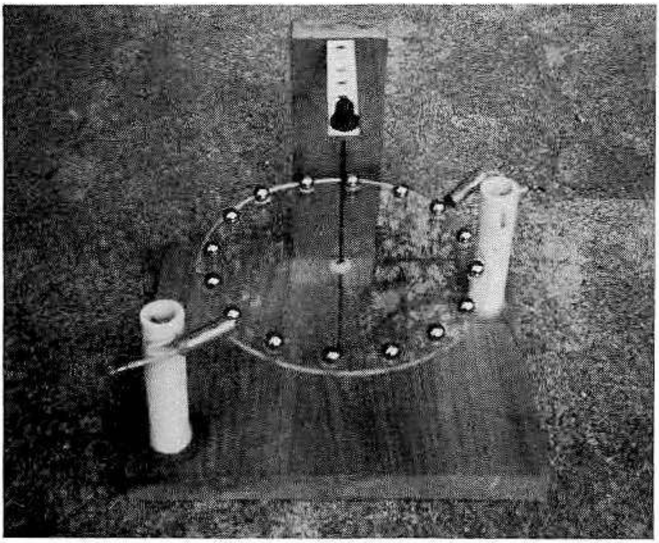


Figure 45 - Franklin Motor – Using large sling-shot balls and a simple Lucite disk, this little motor quickly speeds to over 600 rpm on less than 1 microampere of current!

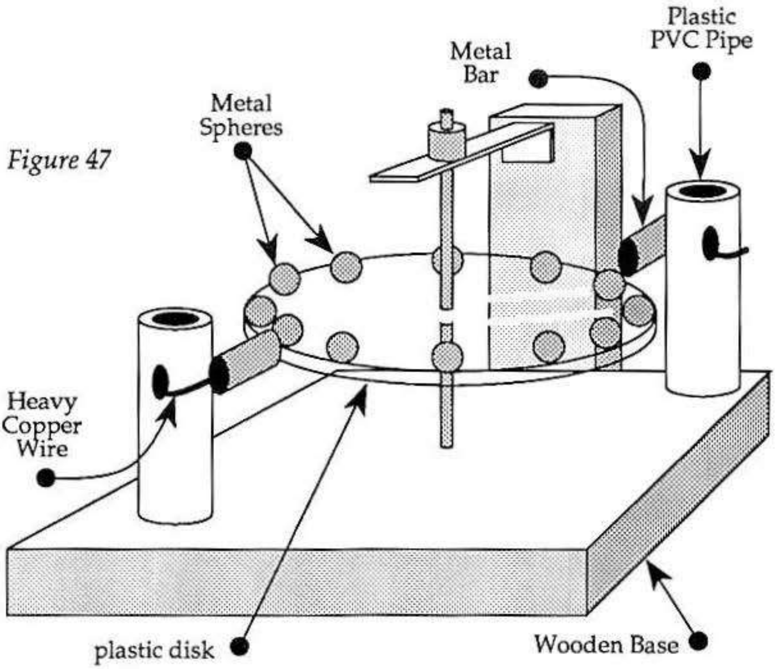
Figure 46

Franklin Motor

Front View

Figure 47



Franklin Motor

THE FRANKLIN ELECTROSTATIC MOTOR

The Franklin motor, named after its inventor Benjamin Franklin, is often said to be the first electric motor ever made. Its construction is simple, and, in fact, it is very similar in operation to the Dirod generator described earlier which can be run as a motor although inefficiently. Figure 47 shows the basic Franklin motor.

A series of lightweight spheres is glued in place along the outside of an insulating disk of Plexiglas, glass, etc. As these spheres rotate, they pass through the corona emanating from a highly charged high potential terminal at each side of the disk. One terminal is charged negatively and the other positively. As a sphere passes a terminal, it picks up a charge that will be attracted to other terminal causing the whole assembly to turn until the high voltage is removed.

One modification that you might like to experiment with is to make the Franklin motor self-starting. This can be accomplished by adding points on the high potential sources to create an electric wind that gives the spheres just enough of a nudge to start the rotor revolving.

Corona Motor
schematic diagram
Figure 48

Poggendorff's Corona Motor

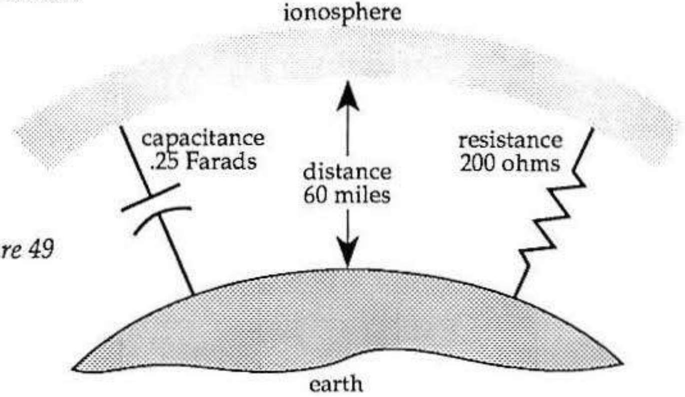
Franklin's motor works by charging a series of spheres as they pass by alternating high potentials. It is also possible to alternately charge an insulating surface as it passes near high potential terminals. Plexiglas, glass, and probably other materials will work. A drawing of Poggendorff's motor is shown in figure 48.

Here is how it works. Notice that there are two sets of brushes or combs with sharply pointed ends mounted at an angle. One brush sprays a negative charge onto the disk and the other a positive charge. As the disk continues to revolve, the charges on its surface find themselves attracted to the entire oppositely charged comb – not just the tiny spray points. It is important that the brushes be mounted at an angle, so that charges on the disk may be attracted to the comb of opposite polarity before they are replaced with an opposite charge as the disk rotates under the points of the comb. Understanding how a motor like this works is simple. Getting one balanced well enough to be self-starting and smoothly running takes quite a bit of patience. It is nonetheless an exciting and interesting project.

Atmospheric Electricity

The earth itself is a huge electrostatic generator. In the air at any time there are some 200 volts of electricity encircling you all of the time. The reason that we aren't being zapped all the time is simply that we are all at roughly the same potential. That is we all have the same level of charge, so, the electricity has no reason to move from one point to another.

Figure 49



Earth's Atmosphere
electrical parameters

Between the earth and the electrically conductive ionosphere, both of which store electrical charge, exists an electrical potential. The same sort of buildup exists between clouds and the earth. When the potential builds to a level great enough, the air ionizes, loses its insulating capacity and becomes an excellent conductor. The result is a huge arc of static electricity we call lightning. As current flows between the cloud and the earth, the potential is reduced until the arc can no longer be sustained, and the lightning bolt is extinguished. It fascinates me to think that I live on one of two highly charged electrodes.

As an electrostatic generator the earth is fairly impressive. Between two and six thousand thunderstorms are in progress at any one time. Worldwide, a hundred bolts of lightning strike the earth every second. It is estimated that this gives the earth a high voltage potential of approximately 360,000 volts between ground and ionosphere with an average lightning bolt conducting 1800 amperes. The density of the electric field decreases as altitude increases. Near the earth's surface, however, the field is estimated to be approximately 100 volts per yard of height.

I say that the earth is fairly impressive because for all its size it is limited to these voltages by the fact that the atmosphere is relatively conductive having a resistance of approximately 200 Ohms. This is a relatively low resistance which quickly bleeds away charges.

Although it can take a significant amount of time depending on weather conditions, any conductive material insulated from ground can acquire charge from the surrounding air, and become charged to a high potential. Although the charge accumulated is usually negative in polarity, thunderstorms and other atmospheric conditions may create a positive potential with respect to ground. Radio antennas and flag poles insulated from ground have been known to throw hefty sparks and even start fires.

Plugging In To The Earth's Charge

If you're as curious as I am, you're asking yourself, "Can I tap into this charge?" The answer is yes! The first order of business is to measure and verify that a charge is present. If you are a skeptic like me, you've "gotta see that needle move" before you are going to believe there is something there!

The best antenna for capturing atmospheric charge is a metal structure, insulated from ground, pointing straight up into the air. The simplest, and probably easiest way to accomplish this is to simply attach a length of very light, bare, copper wire to a large helium balloon. This can be dangerous! Remember to avoid power lines and airports if you plan to launch such an energy-gathering balloon!

Having your bare copper wire come in contact with a high-tension power line is not a pleasant way to die! Thunderstorms are extremely dangerous. (Ben Franklin was lucky to have survived his experiment.)

The bottom of the wire should be attached to a high quality insulator well above ground. Attach one lead of a extremely sensitive meter to ground. Occasionally attach the other lead to the vertical metal conductor. Be careful! Do not take for granted that the potential will be harmless! If left unchecked it could easily reach a level that will bite you. You may find that it can take an hour or more to build up a significant charge, however.

At one time I tried using a kite flown with bare copper wire but had mixed results. I experienced significant difficulty with the wire kinking as I let it out and reeled it in, in response to changing winds.

Another time I hooked a diode into the line and got surprising voltages, but I had been fooled. The diode and coil in the meter had made a primitive crystal radio. I was extracting power from the atmosphere that had been placed there by radio broadcasting stations. Although this is not static electricity, it is nonetheless interesting because it is a demonstration of wireless transmission of power that Tesla was trying to perfect.

An antenna of this type has been used quite adequately to run a corona motor from the natural potential that exists between the earth and its atmosphere! A motor of this type must be extremely well built having great sensitivity and very low friction bearings. I have seen such a motor run, but I have not run one of my motors from this charge.

Because of weather, it can take a long time to build the potential up to a level capable of doing useful work such as moving a sensitive meter or a small corona motor. Several methods have been devised to speed up the charging process. Early experiments devised by Lord Kelvin used an insulated metal tank filled with water suspended above the ground constructed in such a way so as to allow a steady stream of water droplets to reach the ground. Appropriately, he called the setup a "water dropper." He reasoned that the surface of each water drop would be an extension of the surface of the water in the tank at the moment it dropped away. As it did, the drop would carry charges away with it. This continues until equilibrium was reached between the tank and the air.

Using this same idea, charging time can also be reduced by spraying a fine mist of water along a bare copper wire a hundred feet or more in length which is insulated from and suspended above ground. The falling water droplets can help to charge this wire to a measurable level in less than a minute's time.

Another method of speeding up the charging process is to increase the number of ions in the vicinity of the wire itself. A flame applied to the wire will increase the number of ions in the area of the flame and can bring a wire up to the same potential as the air around it in a matter of seconds. To accomplish this easily, wrap the wire with a flammable substance such as string or paper soaked in lead nitrate, and ignite it. It is also possible to get good results by simply waving a torch lightly across the wire.

In Conclusion

I hope that you will enjoy experimenting with electrostatics as much as I have! I find few subjects more fascinating than high voltage and its generation. As a technically minded person, you will undoubtedly see many improvements that can be made in my designs. I know that this is true because at times it seemed I might never complete this text because there was always one more improvement to make and one more experiment to try. No doubt, you will conceive of dozens of new ways to apply the basic principles of electrostatics. Like all experimentation, every change, every test, every improvement will suggest many more questions to be answered and new improvements to be made. You'll probably devise many new inventions!

Electrostatics is also a subject that everyone is absolutely fascinated by – even those who can't change flashlight batteries,. When I was experimenting with different friction generator materials, I purchased quite a number of little swatches of material from a local fabric store. The young ladies working in the store demanded to know what the fabric was for, and, were so fascinated by the idea of generating a spark that I emerged from the store piled high with swatches of material which they insisted be tried on the generator.

My own mother, who despises anything technical, shocked me to no end by demanding that I explain to her the workings of the atom immediately after seeing the classic Van De Graaff in operation. I do not think anyone can watch a powerful Van De Graaff generator at work and not be curious about the forces at work. (And you and I will always want control of those forces!)

So dig in, get to work! Mysteries await!

ADDENDUM

Electroplating High Potential Terminals

As you have certainly realized by now, a tremendous amount of your generator's efficiency rests in the quality of your high potential terminal and in your ability to effectively store the charges produced. I think you will be very happy with the performance of any of the classic generators and storage devices described earlier. However, for those of you seeking to go beyond these boundaries of performance, I'd like to let you in on new area of experimentation: electroplating.

Electroplating is simply a process wherein metal salts such as copper sulfate or nickel ammonium sulfate dissolved in an acidic aqueous solution can be deposited as elemental metal on conductor by applying an electrical current. This means simply that any conductive object can be covered through the process of electrodeposition with a layer of metal!

Since electrostatic charges can be distributed quite nicely on even very thin conductive surfaces, this is a perfect system for making a flawless Leyden jar or a huge high potential terminal. I am currently working on creating very large, near-perfect high potential terminals by plating large plastic globes sold in many lighting stores for under $15.00!

Anything can be plated – plastic, glass, pvc, etc. The only trick is in making their surface conductive initially so that a current can be applied.

The basic procedure for producing a perfect Leyden jar is as follows.

Begin by making the glass jar extremely clean. No fingerprints, water, or oil of any kind can remain. Use masking tape to cover the top 20% of the jar to prevent plating in this area and to preserve a well-proportioned jar. Paint the exposed glass with a resin such as white shellac thinned with denatured alcohol, if necessary. I've even used a spray lacquer.

From here there are several routes that you can take. The easiest method is to take a finely powered metal such as iron or aluminum (something around 400 mesh) and sprinkle it on the sticky, wet shellac. Since these finely powdered metals will float in the air much like talcum powder, I usually put the metal powder and jar in a box and shake the two around around. Remember! These metals SHOULD NOT BE INHALED! Wear a safety mask, and if working with heavy metals, wearing protective clothing is a good idea. The metal powder should create a beautiful, even, light coating over the painted surface of the jar. Allow the paint to fully dry, and repeat the procedure on the inside of the jar. This is a little trickier, but not impossible.

At this point you can actually stop, and use the jar quite successfully. The tiny sandpaper edges of this powder metal coating will bleed off a stored charge when the jar is not in use. This makes a good natural safety feature.

The only drawback to the powdered-metal approach is that if you choose to copper plate it, the copper plating will be just as bumpy as the powdered metal surface itself. As a result, this method will always allow some leakage.

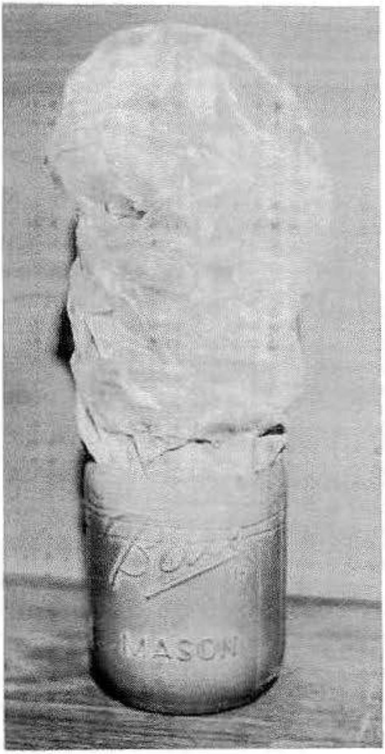
Another simple method of making the jar conductive is to cover the shellac with powdered graphite. This can be rubbed smoothly onto the surface when the shellac is partially dry and will provide a smoother surface which in turn will produce smoother plating. On the other hand, graphite surfaces often require considerably longer plating times and the process is less reliable.

Although both of the above methods work well and have merits, the very best way to make the jar or any non-conductor conductive is to allow the shellac to dry completely, then paint or dip it in a solution of

1/2	ounce	silver nitrate
4	ounces	distilled water
6	ounces	alcohol

While this is still wet, suspend the jar inside a larger jar or other acid-proof non-metallic vessel, and place a few lumps of potassium sulfite or iron pyrite in the bottom of the larger jar. Cover this with a solution made up of one part sulfuric acid and eight parts distilled water, and close the lid. You now have a jar covered with silver nitrate solution hanging above the potassium sulfite-acid solution in a sealed vessel. This will produce hydrogen sulfide fumes that will convert the nitrate to a sulfide which is a conductive coating for you jar. Within a

A glass jar for the Leyden jar capacitor is selected and thoroughly cleaned.



The jar is masked off and coated with conductive graphite.

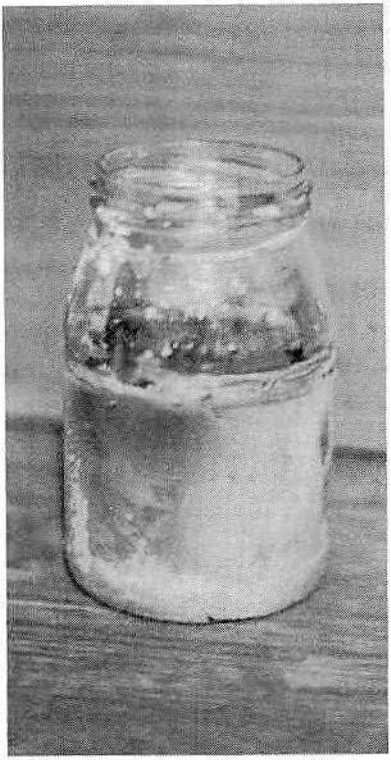
few minutes the chemical reaction will stop, and your jar will be ready to be plated.

Now that the outside of the jar has been made conductive, it can easily be plated with copper. In an appropriate acid-proof vessel, make a solution of

25	ounces copper sulfate
6	ounces sulfuric acid
1	gallon distilled water

Use warm water when mixing to dissolve the copper sulfate more quickly. Do not allow this solution to touch your skin or clothes.

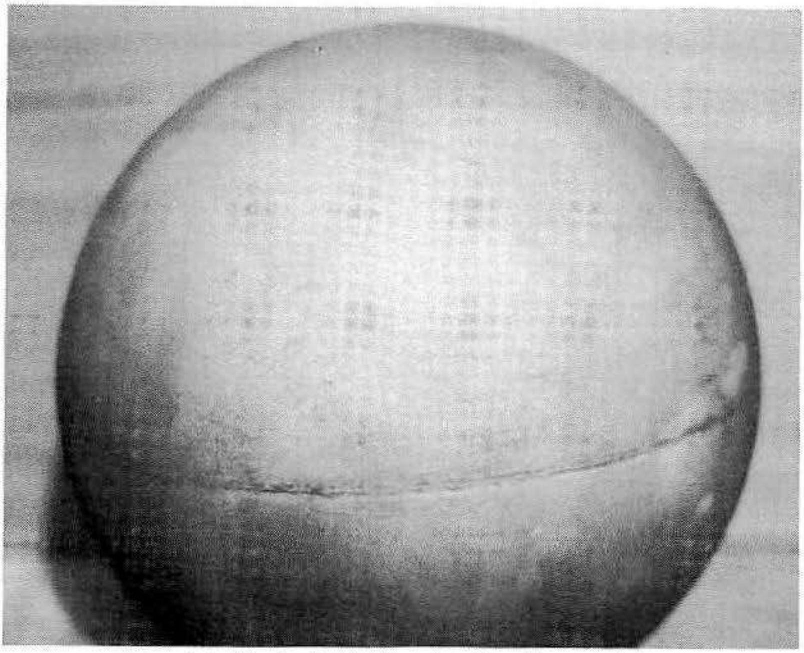
After a few hours, the deposit of copper is easily seen.



The plated jar is ready to be cleaned up and put into use.

Attach a wire from the negative lead of a 2 to 5 volt battery or transformer to the conductive part of your jar. A rubber band works well for this. Immerse the portion of your jar to be plated in the copper sulfate solution. Finally, attach a wire from the positive lead of your power source to a copper electrode having a large surface area such as a thin copper sheet. Set this electrode in your solution.

All that you have to do now is watch the jar as the plating takes place. Be sure you keep the solution warm, or the plating will proceed very slowly. I like a thick copper coat and usually allow my plating to take place overnight. However in a fairly short period of time you should see a reddish copper coating forming on the outside of your jar! Simply repeat this process for the inside of your jar.



A twelve inch plastic sphere has been coated with graphite and is ready to be plated.

Very large spheres and other shapes can also be plated by scaling up this process. I have seen many inexpensive large glass and plastic globes since I began experimenting with this process that would lend themselves to this technique. For more information, refer to books on electroplating and electroforming that can give you advanced details on plating superior finishes.

As you can see, simple electroplating can make possible a vast number of new shapes and designs for high voltage terminals!

Preface

By inventing the wireless transmitter or radio in 1897, the Italian physicist Tomaso Guglielmo Marconi added a new dimension to the world of communications. This enabled the transmission of the human voice through space without wires. For this epoch-making invention, this illustrious scientist was honored with the Nobel Prize for Physics in 1909. Even today, students of wireless or radio technology remember this distinguished physicist with reverence. A new era began in Radio Communications.

The classical Marconi radio used a modulation technique known today as "Amplitude Modulation" or just AM. This led to the development of Frequency Modulation (FM), amplitude shift keying (ASK), phase shift keying (PSK), etc. Today, these technologies are extensively used in various wireless communication systems. These modulation techniques form an integral part of academic curricula today.

This book presents a comprehensive overview of the various modulation techniques mentioned above. Numerous illustrations are used to bring students up-to-date in key concepts and underlying principles of various analog and digital modulation techniques. In particular, the following topics will be presented in this book:

- Amplitude Modulation (AM)
- Frequency Modulation (FM)
- Bandwidth occupancy in AM and FM
- Amplitude shift keying (ASK)
- Frequency shift keying (FSK)
- Phase shift keying (PSK)
- N-ary coding and M-ary modulation
- Bandwidth occupancy in ASK, FSK, and PSK

This text has been primarily designed for electrical engineering students in the area of telecommunications. However, engineers and designers working in the area of wireless communications would also find this text useful. It is assumed that the student is familiar with the general theory of telecommunications.

In closing, I would like to say a few words about how this book was conceived. It came out of my long industrial and academic career. During my teaching tenure at the University of North Dakota, I developed a number of graduate-level elective courses in the area of telecommunications that combine theory and practice. This book is a collection of my courseware and research activities in wireless communications.

I am grateful to UND and the School for the Blind, North Dakota, for affording me this opportunity. This book would never have seen the light of day had UND and the State of North Dakota not provided me with the technology to do so. My heartfelt salute goes out to the dedicated developers of these technologies, who have enabled me and others visually impaired to work comfortably.

I would like to thank my beloved wife, Yasmin, an English Literature buff and a writer herself, for being by my side throughout the writing of this book and for patiently proofreading it. My darling son, Shams, an electrical engineer himself, provided technical support in formulation and experimentation when I needed it. For this, he deserves my heartfelt thanks.

Finally, thanks are also to my doctoral student Md. Maruf Ahamed who found time in his busy schedule to assist me with the simulations, illustrations, and the verification of equations.

In spite of all this support, there may still be some errors in this book. I hope that my readers forgive me for them. I shall be amply rewarded if they still find this book useful.

Chapter 1
Introduction to Modulation

Topics

- Background
- Modulation by Analog Signal
- AM and FM Bandwidth at a Glance
- Modulation by Digital Signal
- ASK, FSK and PSK Bandwidth at a Glance

1.1 Background

Modulation is a technique that changes the characteristics of the carrier frequency in accordance with the input signal. Figure 1.1 shows the conceptual block diagram of a modern wireless communication system, where the modulation block is shown in the inset of the dotted block. As shown in the figure, modulation is performed at the transmit side and demodulation is performed at the receive side. This is the final stage of any radio communication system. The preceding two stages have been discussed elaborately in my previous book in this series [1, 2].

The output signal of the modulator, referred to as the modulated signal, is fed into the antenna for propagation. Antenna is a reciprocal device that transmits and receives the modulated carrier frequency. The size of the antenna depends on the wavelength (λ) of the sinusoidal wave where

$\lambda = c/f$ m
c = Velocity of light = 3×10^8 m/s
f = Frequency of the sinusoidal wave, also known as "carrier frequency."

Therefore, a carrier frequency much higher than the input signal is required to keep the size of the antenna at an acceptable limit. For these reasons, a high-frequency carrier signal is used in the modulation process. In this process, the

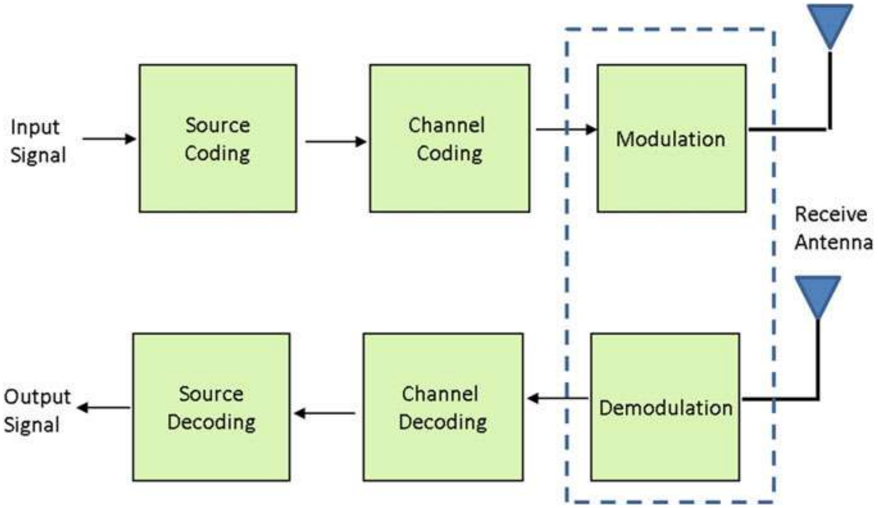

Fig. 1.1 Block diagram of a modern full-duplex communication system. The modulation stage is shown as a *dotted* block

low-frequency input signal changes the characteristics of the high-frequency carrier in a certain manner, depending on the modulation technique. Furthermore, as the size and speed of digital data networks continue to expand, bandwidth efficiency becomes increasingly important. This is especially true for broadband communication, where the digital signal processing is done keeping in mind the available bandwidth resources.

Hence, modulation is a very important step in the transmission of information. The information can be either analog or digital, where the carrier is a high-frequency sinusoidal waveform. As stated earlier, the input signal (analog or digital) changes the characteristics of the carrier waveform. Therefore, there are two basic modulation schemes as listed below:

- Modulation by analog signals and
- Modulation by digital signals.

This book presents a comprehensive overview of these modulation techniques in use today. Numerous illustrations are used to bring students up-to-date in key concepts and underlying principles of various analog and digital modulation techniques. For a head start, brief descriptions of each of these modulation techniques are presented below.

1.2 Modulation by Analog Signals

1.2.1 AM, FM, and PM

For analog signals, there are three well-known modulation techniques as listed below:

- Amplitude Modulation (AM),
- Frequency Modulation (FM),
- Phase Modulation (PM).

By inventing the wireless transmitter or radio in 1897, the Italian physicist Tomaso Guglielmo Marconi added a new dimension to the world of communications [3, 4]. This enabled the transmission of the human voice through space without wires. For this epoch-making invention, this illustrious scientist was honored with the Nobel Prize for Physics in 1909. Even today, students of wireless or radio technology remember this distinguished physicist with reverence. A new era began in Radio Communications. The classical Marconi radio used a modulation technique known today as "Amplitude Modulation" or just AM. In AM, the amplitude of the carrier changes in accordance with the input analog signal, while the frequency of the carrier remains the same. This is shown in Fig. 1.2 where

- *m*(*t*) is the input modulating audio signal,
- *C*(*t*) is the carrier frequency, and
- *S*(*t*) is the AM-modulated carrier frequency.

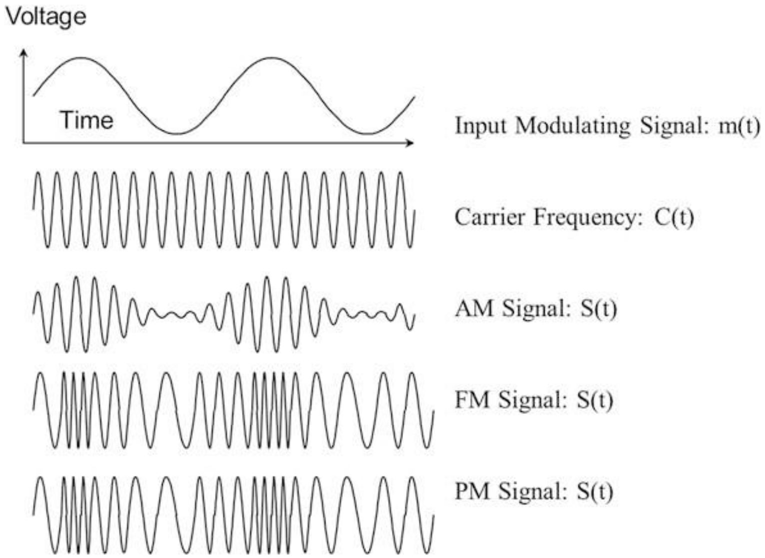

Fig. 1.2 Modulation by analog signal

As shown in the figure, the audio waveform changes the amplitude of the carrier to determine the envelope of the modulated carrier. This enables the receiver to extract the audio signal by demodulation. Notice that the amplitude of the carrier changes in accordance with the input signal, while the frequency of the carrier does not change after modulation. It can be shown that the modulated carrier $S(t)$ contains several spectral components, requiring frequency-domain analysis, which will be addressed in Chap. 2. It may be noted that AM is vulnerable to signal amplitude fading.

In Frequency Modulation (FM), the frequency of the carrier changes in accordance with the input modulation signal as shown in Fig. 1.2 [5]. Notice that in FM, only the frequency changes while the amplitude remains the same. Unlike AM, FM is more robust against signal amplitude fading. For this reason, FM is more attractive in commercial FM radio. In Chap. 3, it will be shown that in FM, the modulated carrier contains an infinite number of sideband due to modulation. For this reason, FM is also bandwidth inefficient.

Similarly, in Phase Modulation (PM), the phase of the carrier changes in accordance with the phase of the carrier, while the amplitude of the carrier does not change. PM is closely related to FM. In fact, FM is derived from the rate of change of phase of the carrier frequency. Both FM and PM belong to the same mathematical family. We will discuss this more elaborately in Chap. 3.

1.2.2 AM and FM Bandwidth at a Glance

The bandwidth occupied by the modulated signal depends on bandwidth of the input signal and the modulation method as shown in Fig. 1.3. Note that the unmodulated carrier itself has zero bandwidth.

In AM:

- The modulated carrier has two sidebands (upper and lower) and
- Total bandwidth = 2 × base band.

In FM:

- The carrier frequency shifts back and forth from the nominal frequency by Δf, where Δf is the frequency deviation.
- During this process, the modulated carrier creates an infinite number of spectral components, where higher-order spectral components are negligible.
- The approximate FM bandwidth is given by the Carson's rule:
  - FM BW = $2f\,(1 + \beta)$
  - f = Base band frequency
  - β = Modulation index
  - $\beta = \Delta f/f$
  - Δf = Frequency deviation.

1.3 Modulation by Digital Signal

For digital signals, there are several modulation techniques available. The three main digital modulation techniques are as follows:

- Amplitude shift keying (ASK),
- Frequency shift keying (FSK), and
- Phase shift keying (PSK).

Figure 1.4 illustrates the modulated waveforms for an input modulating digital signal. Brief descriptions of each of these digital modulation techniques along with the respective spectral responses and bandwidth are presented below.

1.3.1 Amplitude Shift Keying (ASK) Modulation

Amplitude shift keying (ASK), also known as on–off keying (OOK), is a method of digital modulation that utilizes amplitude shifting of the relative amplitude of the

career frequency [6–8]. The signal to be modulated and transmitted is binary; this is referred to as ASK, where the amplitude of the carrier changes in discrete levels, in accordance with the input signal, as shown.

- Binary 0 (bit 0): Amplitude = Low and
- Binary 1 (bit 1): Amplitude = High.

Figure 1.4 shows the ASK-modulated waveform where

- Input digital signal is the information we want to transmit.
- Carrier is the radio frequency without modulation.
- Output is the ASK-modulated carrier, which has two amplitudes corresponding to the binary input signal. For binary signal 1, the carrier is ON. For the binary signal 0, the carrier is OFF. However, a small residual signal may remain due to noise, interference, etc.

1.3.2 Frequency Shift Keying (FSK) Modulation

Frequency shift keying (FSK) is a method of digital modulation that utilizes frequency shifting of the relative frequency content of the signal [6–8]. The signal to be modulated and transmitted is binary; this is referred to as binary FSK (BFSK), where the carrier frequency changes in discrete levels, in accordance with the input signal as shown below:

- Binary 0 (bit 0): Frequency = $f + \Delta f$.
- Binary 1 (bit 1): Frequency = $f - \Delta f$.

Figure 1.4 shows the FSK-modulated waveform where

- Input digital signal is the information we want to transmit.
- Carrier is the radio frequency without modulation.
- Output is the FSK-modulated carrier, which has two frequencies ω_1 and ω_2, corresponding to the binary input signal.
- These frequencies correspond to the messages binary 0 and 1, respectively.

1.3.3 Phase Shift Keying (PSK) Modulation

Phase shift keying (PSK) is a method of digital modulation that utilizes phase of the carrier to represent digital signal [6–8]. The signal to be modulated and transmitted is binary; this is referred to as binary PSK (BPSK), where the phase of the carrier changes in discrete levels, in accordance with the input signal as shown below:

- Binary 0 (bit 0): $\text{Phase}_1 = 0°$.
- Binary 1 (bit 1): $\text{Phase}_2 = 180°$.

Figure 1.4 shows the modulated waveform where

- Input digital signal is the information we want to transmit.
- Carrier is the radio frequency without modulation.
- Output is the BPSK-modulated carrier, which has two phases φ_1 and φ_2 corresponding to the two information bits.

1.4 Bandwidth Occupancy in Digital Modulation

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth. The transmission bandwidth depends on the following:

- Spectral response of the encoded data,
- Spectral response of the carrier frequency, and
- Modulation type (ASK, FSK, PSK), etc.

Let us take a closer look!

1.4.1 Spectral Response of the Encoded Data

In digital communications, data is generally referred to as a non-periodic digital signal. It has two values:

- Binary-1 = High, Period = T.
- Binary-0 = Low, Period = T.

Also, data can be represented in two ways:

- Time-domain representation and
- Frequency-domain representation.

The time-domain representation (Fig. 1.5a), known as non-return-to-zero (NRZ), is given by

$$\begin{aligned} V(t) &= V \qquad &< 0 < t < T \\ &= 0 \qquad &\text{elsewhere} \end{aligned} \tag{1.1}$$

The frequency-domain representation is given by "Fourier transform" [9]:

$$V(\omega) = \int_0^T V \cdot e^{-j\omega t} dt \tag{1.2}$$

$$|V(\omega)| = VT\left[\frac{\sin(\omega T/2)}{\omega T/2}\right]$$

$$P(\omega) = \left(\frac{1}{T}\right)|V(\omega)|^2 = V^2 T\left[\frac{\sin(\omega T/2)}{\omega T/2}\right]^2 \tag{1.3}$$

Here, $P(\omega)$ is the power spectral density. This is plotted in (Fig. 1.5b). The main lobe corresponds to the fundamental frequency and side lobes correspond to harmonic components. The bandwidth of the power spectrum is proportional to the frequency. In practice, the side lobes are filtered out since they are relatively insignificant with respect to the main lobe. Therefore, the one-sided bandwidth is given by the ratio $f/fb = 1$. In other words, the one-sided bandwidth $= f = f_b$, where $f_b = R_b = 1/T$, T being the bit duration.

The general equation for two-sided response is given by

$$V(\omega) = \int_{-\alpha}^{\alpha} V(t) \cdot e^{-j\omega t} \mathrm{d}t$$

In this case, $V(\omega)$ is called two-sided spectrum of $V(t)$. This is due to both positive and negative frequencies used in the integral. The function can be a voltage

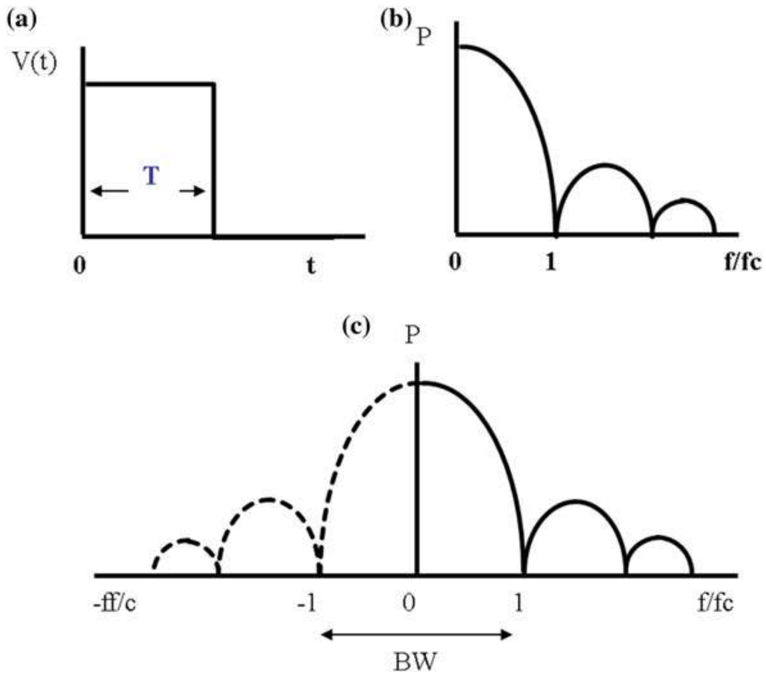

Fig. 1.5 **a** Discrete time digital signal, **b** it is one-sided power spectral density, and **c** two-sided power spectral density. The bandwidth associated with the non-return-to-zero (NRz) data is $2R_b$, where R_b is the bit rate

or a current (Fig. 1.5c) shows the two-sided response, where the bandwidth is determined by the main lobe as shown below:

$$\text{Two sided bandwidth (BW)} = 2R_b \; (R_b = \text{Bit rate before coding}) \tag{1.4}$$

1.4.2 *Spectral Response of the Carrier Frequency Before Modulation*

A carrier frequency is essentially a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component. For example, the sine wave is described by the following time-domain equation:

$$V(t) = V_p \sin(\omega t_c) \tag{1.5}$$

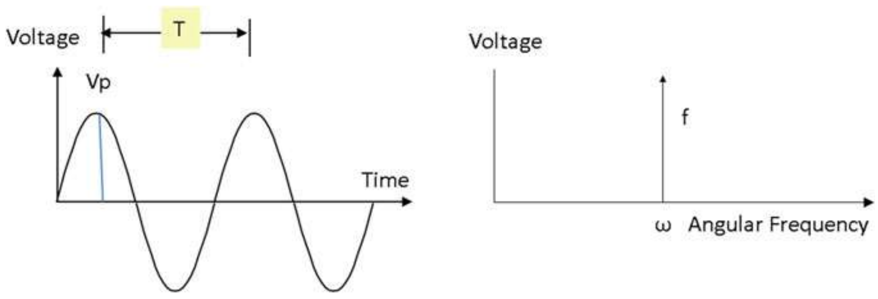

Fig. 1.6 A sine wave and its frequency response

where

$$V_p = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$
- f_c = Carrier frequency in Hz

Figure 1.6 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

1.4.3 ASK Bandwidth at a Glance

In ASK, the amplitude of the carriers changes in discrete levels, in accordance with the input signal where

- Input data: $m(t) = 0$ or 1.
- Carrier frequency: $C(t) = A_c \cos(\omega_c t)$.
- Modulated carrier: $S(t) = m(t)C(t) = m(t)A_c \cos(\omega_c t)$.

Since $m(t)$ is the input digital signal and it contains an infinite number of harmonically related sinusoidal waveforms and that we keep the fundamental and filter out the higher-order components, we write:

$$m(t) = A_m \sin(\omega_m t)$$

The ASK-modulated signal then becomes:

$$\begin{aligned} S(t) &= m(t)S(t) = A_m A_c \sin(\omega_m t)\cos(\omega_c) \\ &= A_m A_c \cos\left(\omega_c \pm \omega_m\right) \end{aligned}$$

Fig. 1.7 ASK bandwidth at a glance. **a** Spectral response of NRZ data before modulation. **b** Spectral response of the carrier before modulation. **c** Spectral response of the carrier after modulation. The transmission bandwidth is $2f_b$, where f_b is the bit rate and $T = 1/f_b$ is the bit duration for NRZ data

The spectral response is depicted in Fig. 1.7. Notice that the spectral response after ASK modulation is the shifted version of the NRZ data. Bandwidth is given by,

BW = $2R_b$ (coded), where R_b is the coded bit rate.

1.4.4 FSK Bandwidth at a Glance

In FSK, the frequency of the carrier changes in two discrete levels, in accordance with the input signals. We have:

- Input data: $m(t) = 0$ or 1
- Carrier frequency: $C\ (t) = A\ \cos\ (\omega t)$
- Modulated carrier: $S(t) = A\ \cos(\omega - \Delta\ \omega)t$, For $m(t) = 1$
  $S(t) = A\ \cos(\omega + \Delta\omega)t$, For $m(t) = 0$

where

- $S(t)$ = The modulated carrier,
- A = Amplitude of the carrier,

Fig. 1.8 FSK bandwidth at a glance. **a** Spectral response of NRZ data before modulation. **b** Spectral response of the carrier before modulation. **c** Spectral response of the carrier after modulation. The transmission bandwidth is $2(f_b + \Delta f_c)$. f_b is the bit rate and Δf_c is the frequency deviation = $1/f_b$ is the bit duration for NRZ data

- ω = Nominal frequency of the carrier frequency, and
- $\Delta\omega$ = Frequency deviation.

The spectral response is depicted in Fig. 1.8. Notice that the carrier frequency after FSK modulation varies back and forth from the nominal frequency f_c by $\pm\,\Delta f_c$, where Δf_c is the frequency deviation. The FSK bandwidth is given by

$$\mathrm{BW} = 2(f_b + \Delta f_c) = 2f_b(1 + \Delta f_c/f_b) = 2f_b(1 + \beta),$$

where $\beta = \Delta f/f_b$ is known as the modulation index and f_b is the coded bit frequency (bit rate R_b).

1.4.5 BPSK Bandwidth at a Glance

In BPSK, the phase of the carrier changes in two discrete levels, in accordance with the input signal. Here, we have:

- Input data: $m(t) = 0$ or 1
- Carrier frequency: $C(t) = A \cos(\omega t)$
- Modulated carrier: $S(t) = A \cos(\omega + \varphi)t$

where

- A = Amplitude of the carrier frequency,
- ω = Angular frequency of the carrier, and
- φ = Phase of the carrier frequency.

Table below shows the number of phases and the corresponding bits per phase for MPSK modulation schemes for $M = 2, 4, 8, 16, 32, 64$, etc. It will be shown that higher-order MPSK modulation schemes ($M > 2$) are spectrally efficient.

Modulation	Number of phases φ	Number of bits per phase
BPSK	2	1
QPSK	4	2
8PSK	8	3
16	16	4
32	32	5
64	64	6
:	:	:

Figure 1.9 shows the spectral response of the BPSK modulator. Since there are two phases, the carrier frequency changes in two discrete levels, one bit per phase, as follows:

$\varphi = 0°$ for bit 0 and
$\varphi = 180°$ for bit 1.

Notice that the spectral response after BPSK modulation is the shifted version of the NRZ data, centered on the carrier frequency f_c. The transmission bandwidth is given by

$$\text{BW(BPSK)} = 2R_b/\text{Bit per Phase} = 2R_b/1 = 2R_b$$

where

- R_b is the coded bit rate (bit frequency).
- For BPSK, $\varphi = 2$, one bit per phase.

Also, notice that the BPSK bandwidth is the same as the one in ASK modulation. This is due to the fact that the phase of the carrier changes in two discrete levels, while the frequency remains the same.

1.5 Conclusions

This chapter presents a brief overview of modulation techniques covered in this book. Numerous illustrations are used to bring students up-to-date in key concepts and underlying principles of various analog and digital modulation techniques. In particular, following topics will be presented in this book:

- Amplitude Modulation (AM),
- Frequency Modulation (FM),
- Bandwidth occupancy in AM and FM,
- Amplitude shift keying (ASK),
- Frequency shift keying (FSK),
- Phase shift keying (PSK), and
- Bandwidth occupancy in ASK, FSK, and PSK.

2.1 Introduction

By inventing the wireless transmitter or radio in 1897, the Italian physicist Tomaso Guglielmo Marconi added a new dimension to the world of communications [1, 2]. This enabled the transmission of the human voice through space without wires. For this epoch-making invention, this illustrious scientist was honored with the Nobel Prize for Physics in 1909. Even today, students of wireless or radio technologies remember this distinguished physicist with reverence. A new era began in Radio Communications.

The classical Marconi radio used a modulation technique known today as "Amplitude Modulation" or just AM, which is the main topic of this chapter. In AM, the amplitude of the carrier changes in accordance with the input analog signal, while the frequency of the carrier remains the same. This is shown in Fig. 2.1, where

- $m(t)$ is the input modulating audio signal,
- $C(t)$ is the carrier frequency, and
- $S(t)$ is the AM-modulated carrier frequency.

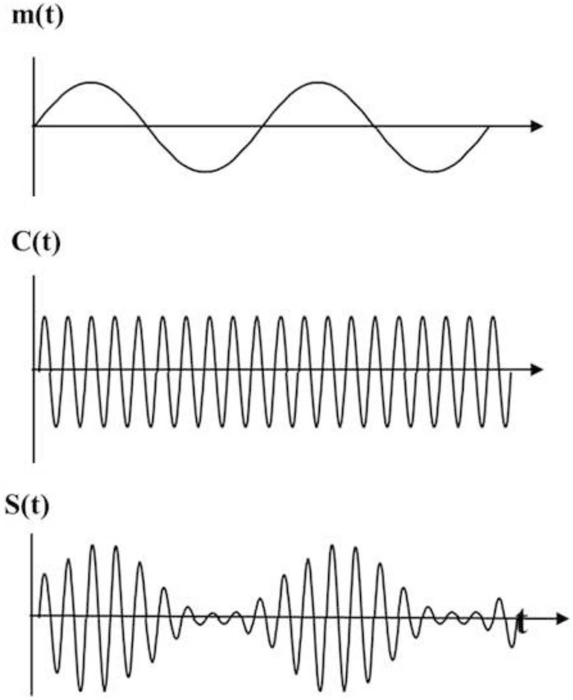

Fig. 2.1 AM waveforms. The amplitude of the carrier changes in accordance with the input analog signal. The frequency of the carrier remains the same

As shown in the figure, the audio waveform changes the amplitude of the carrier to determine the envelope of the modulated carrier. This enables the receiver to extract the audio signal by demodulation. Notice that the amplitude of the carrier changes in accordance with the input signal, while the frequency of the carrier does not change after modulation. However, it can be shown that the modulated carrier $S(t)$ contains several spectral components, requiring frequency domain analysis. In an effort to examine this, this chapter will present the following topics:

- Amplitude Modulation (AM) and AM spectrum
- Double Sideband-suppressed carrier (DSBSC) and DSBSC spectrum
- Single sideband (SSB) carrier and SSB spectrum

In the following sections, the above disciplines in AM modulation will be presented along with the respective spectrum and bandwidth. These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

2.2 Amplitude Modulation

Amplitude Modulation (AM) is a method of analog modulation that utilizes amplitude variations of the relative amplitude of the career frequency [3–5]. The signal to be modulated and transmitted is analog. This is referred to as AM, where the amplitude of the carrier changes in accordance with the input signal.

Figure 2.2 shows a functional diagram of a typical AM modulator for a single tone. Here, $m(t)$ is the input analog signal we want to transmit, $C(t)$ is the carrier frequency without modulation, and $S(t)$ is the output AM-modulated carrier frequency. These parameters are described below:

$$\begin{aligned} &\bullet\ m(t) = A_m \cos(2\pi f_m t) \\ &\bullet\ C(t) = A_c \cos(2\pi f_c t) f_c \gg f_m \\ &\bullet\ \begin{aligned} S(t) &= [1 + m(t)]C(t) \\ &= C(t) + m(t)C(t) \end{aligned} \end{aligned} \tag{2.1}$$

Therefore,
When $m(t) = 0$:

$$\bullet\ S(t) = A_c \cos(2\pi f_c t) \tag{2.2}$$

When $m(t) = A_m \cos(2\pi f_m t)$:

$$\bullet\ S(t) = A_c \cos(2\pi f_c t) + A_c A_m \cos(2\pi f_m t) \cos(2\pi f_c t) \tag{2.3}$$

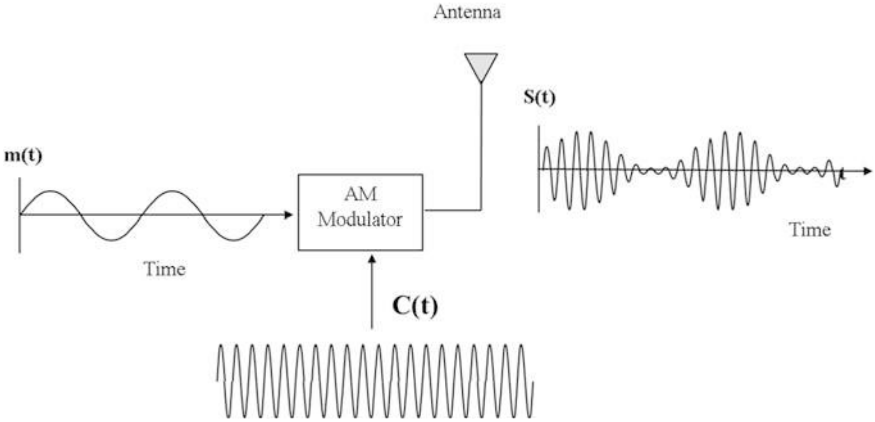

Fig. 2.2 Illustration of amplitude modulation. The amplitude of the carrier $C(t)$ changes in accordance with the input modulating signal $m(t)$. $S(t)$ is the modulated waveform which is transmitted by the antenna

In the above equation, we see that:

- The first term is the carrier only, which does not have information
- The second **term** contain**s the** information, which has several spectral components, requiring further analysis to quantify them.

2.3 AM Spectrum and Bandwidth

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth and modulation. The transmission bandwidth depends on the following:

- Spectral response of the input modulating signal
- Spectral response of the carrier frequency and
- Modulation type (AM, FM ASK, FSK, PSK, etc.)

Let us take a closer look!

2.3.1 Spectral Response of the Input Modulating Signal

In AM, the input modulating signal is a continuous time low-frequency analog signal. For simplicity, we use a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component. For example, the sine wave is described by the following time domain equation:

$$V(t) = V_p \sin(\omega_m t) \tag{2.4}$$

where

- Vp = Peak voltage
- $\omega_m = 2\pi f_m$
- f_m = Input modulating frequency in Hz

Figure 2.3 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis at f_m, and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

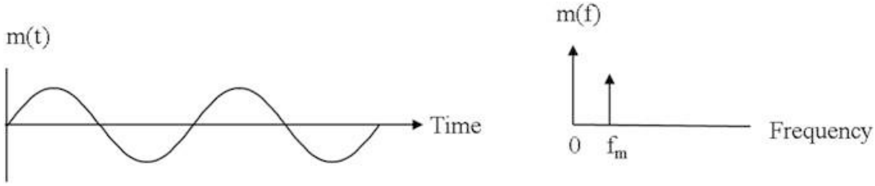

Fig. 2.3 A low-frequency sine wave and its frequency response

2.3.2 Spectral Response of the Carrier Frequency

A carrier frequency (f_c) is essentially a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component, which is much higher than the input modulating frequency ($f_c \gg f_m$). For example, the sine wave is described by the following time domain equation:

$$V(t) = V_p \sin(\omega_c t) \tag{2.5}$$

where

$$V_p = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$
- f_c = Carrier frequency in Hz

Figure 2.4 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis at f_c and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

2.3.3 AM Spectrum and Bandwidth

Let us consider the AM signal again, which was derived earlier:

$$S(t) = A_c \cos(2\pi f_c t) + A_c A_m \cos(2\pi f_m t) \cos(2\pi f_c t) \tag{2.6}$$

Using the following trigonometric identity:

$$\cos A \cos B = 1/2 \cos(A + B) + 1/2 \cos(A - B) \tag{2.7}$$

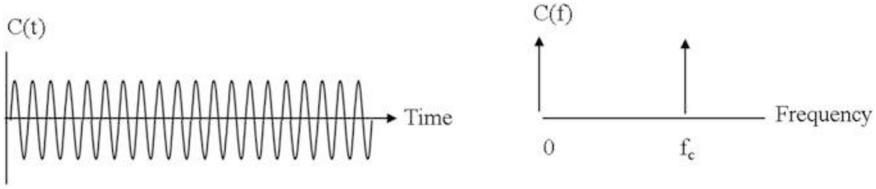

Fig. 2.4 A high-frequency sine wave and its frequency response

where

- $A = 2\pi\ (f_c + f_m)t$
- $B = 2\pi\ (f_c - f_m)t$

we get

$$S(t) = A_c \cos(2\pi f_c t) + (1/2)A_c A_m \cos[2\pi(f_c + f_m)t] + (1/2)A_c A_m \cos[2\pi(f_c - f_m)t] \tag{2.8}$$

This is the spectral response of the AM-modulated signal. It has three spectral components:

- The carrier: f_c
- Upper sideband: $f_c + f_m$
- Lower sideband: $f_c - f_m$

where f_c is the carrier frequency and f_m is the input modulating frequency. This is shown in Fig. 2.5. The AM bandwidth (BW) is given by

$$\mathrm{BW} = 2f_m \tag{2.9}$$

Notice that the power is distributed among the sidebands and the carrier, where the carrier does not contain any information. Only the sidebands contain the information. Therefore, AM is inefficient in power usage.

2.3.4 AM Response Due to Low and High Modulating Signals

If $m(t)$ has a peak positive value of less than +1 and a peak negative value of higher than −1, then the modulation is less than 100 %. This is shown in Fig. 2.7.

On the other hand, if $m(t)$ has a peak positive value of +1 and a peak negative value of −1, then the modulation is 100 % [3–5]. Therefore,

- For $m(t) = -1: \quad S(t) = A_c[1-1]\cos(2\pi_c t) = 0 \qquad (2.10)$
- For $m(t) = +1: S(t) = A_c[1+1]\cos(2\pi f_c t) = 2A_c\cos(2\pi f_c t) \qquad (2.11)$

This is called 100 % modulation, as shown in Fig. 2.6. The percent modulation is described by the following equation:

$$\begin{aligned}&\text{The overall modulation percentage is:}\\ &\%\,\text{Overall Modulation} = \frac{A_{\max} - A_{\min}}{A_c} \times 100\\ &= \frac{\max[m(t)] - \min[m(t)]}{2A_c} \times 100.\end{aligned} \tag{2.12}$$

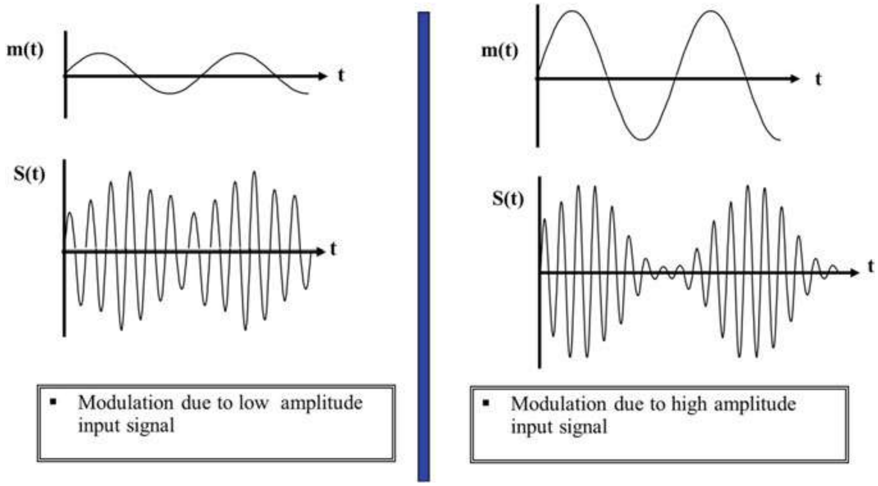

Fig. 2.6 Amplitude modulation due to low and high modulating signals

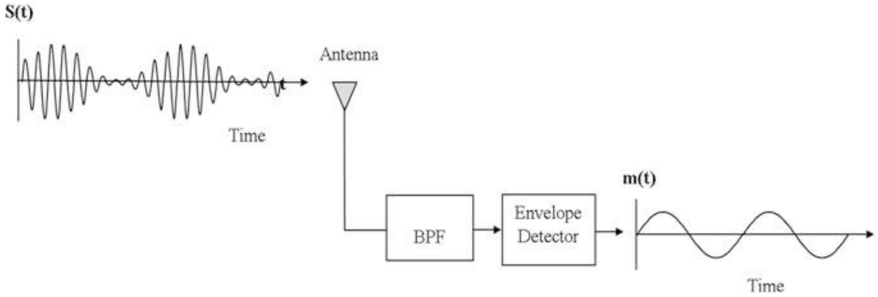

Fig. 2.7 AM demodulation technique. As the signal enters the receiver, it passes through the band-pass filter, which is tuned to the carrier frequency f_0. Next, the recovered signal is passed through an envelope detector to recover the original signal that was transmitted

2.3.5 AM Demodulation

Once the modulated analog signal has been transmitted, it needs to be received and demodulated. This is accomplished by the use of a band-pass filter that is tuned to the appropriate carrier frequency. Figure 2.7 shows the conceptual model of the AM receiver. As the signal enters the receiver, it passes through the band-pass filter, which is tuned to the carrier frequency f_0. Next, the recovered signal is passed through an envelope detector to recover the original signal that was transmitted.

2.3.6 Drawbacks in AM

- The modulated signal contains the carrier; carrier takes power and it does not have the information
- Therefore, AM is inefficient in power usage
- Moreover, there are two sidebands, containing the same information
- It is bandwidth inefficient
- AM is also susceptible to interference, since it affects the amplitude of the carrier.

Therefore, a solution is needed to improve bandwidth and power efficiency.

Problem 2.1 Given:

- Input modulating frequency $f_m = 10$ kHz
- Carrier frequency $f_c = 400$ kHz

Find

- Spectral components
- Bandwidth

Solution
Spectral Components:

- $f_c = 400$ kHz
- $f_c + f_m = 400$ kHz + 10 kHz = 410 kHz
- $f_c - f_m = 400$ kHz − 10 kHz = 390 kHz

Bandwidth

- BW = $2\,f_m = 2 \times 10$ kHz = 20 kHz.

2.4 Double Sideband-Suppressed Carrier (DSBSC)

2.4.1 DSBSC Modulation

Double sideband-suppressed carrier (DSBSC), also known as product modulator, is an AM signal that has a suppressed carrier [3–5]. Let us take the original AM signal once again, as given below:

$$S(t) = A_c\cos(2\pi f_c t) + (1/2)A_cA_m\cos[2\pi(f_c + f_m)t] + (1/2)A_cA_m\cos[2\pi(f_c - f_m)t] \tag{2.13}$$

Notice that there are three spectral components:

- The first term is the carrier only, which does not have any information
- The second and third terms contain information.

In DSBSC, we suppress the carrier, which is the first term that does not have any information. Therefore, by suppressing the first term we obtain the following:

$$S(t) = (1/2)A_cA_m\cos[2\pi(f_c + f_m)t] + (1/2)A_cA_m\cos[2\pi(f_c - f_m)t] \tag{2.14}$$

Next, we use the following trigonometric identities:

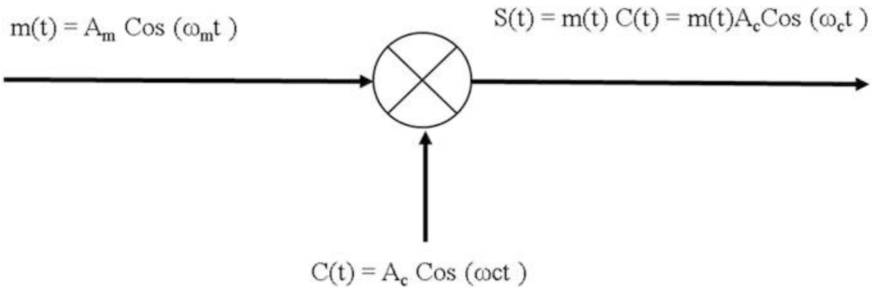
- $\cos(A + B) = \cos A \cos B - \sin A \sin B$
- $\cos(A - B) = \cos A \cos B + \sin A \sin B$

With $A = 2\pi f_m t = \omega_m t$ and $B = 2\pi f_c t = \omega_c t$, we obtain:

$$S(t) = A_cA_m \cos(\omega_m t)\ \cos(\omega_c t) \tag{2.15}$$

Now, define

- $m(t) = A_m \cos(\omega_m t)$
- $C(t) = A_c \cos(\omega_c t)$



m(t) = A_m Cos (ω_m t)
S(t) = m(t) C(t) = m(t)A_c Cos (ω_c t)
C(t) = A_c Cos (ωct)

Fig. 2.8 Symbolic representation of DSBSC, also known as product modulator

Then, we can write the above equations as:

$$S(t) = m(t)\,C(t) \tag{2.16}$$

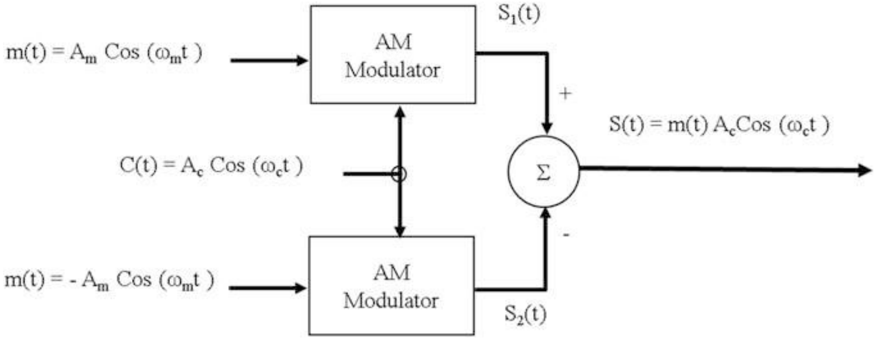
This is the DSBSC waveform. Since the output is the product of two signals, it is also known as product modulator. The symbolic representation is given in Fig. 2.8, where *m*(*t*) is the input modulating signal and *C*(*t*) is the carrier frequency.

2.4.2 Generation of DSBSC Signal

A DSBSC signal can be generated using two AM modulators arranged in a balanced configuration as shown in Fig. 2.9 [3–5]. The outcome is a cancellation of the discrete carrier. Also, the output is the product of two inputs: $S(t) = m(t)\ C(t)$. This is why it is called "product modulator."

Proof of DSBSC

Consider the DSBSC modulator as shown in Fig. 2.9. Here, the AM modulators generate $S_1(t)$ and $S_2(t)$, which are given by:



m(t) = A_m Cos (ω_m t)
AM Modulator
S_1(t)
+
S(t) = m(t) A_c Cos (ω_c t)
C(t) = A_c Cos (ω_c t)
Σ
-
m(t) = - A_m Cos (ω_m t)
AM Modulator
S_2(t)

Fig. 2.9 Construction of DSBSC modulator. The output is the product of two signals

$$S_1(t) = A_c[1 + m(t)]\cos(\omega_c t) \tag{2.17}$$

$$S_2(t) = A_c[1 - m(t)]\cos(\omega_c t)$$

Subtracting $S_2(t)$ from $S_1(t)$, we essentially cancel the carrier to obtain:

$$\begin{aligned} S(t) &= S_1(t) - S_2(t) \\ &= 2\,m(t)\,A_c\,\cos(\omega_c t) \end{aligned} \tag{2.18}$$

Therefore, except for the scaling factor 2, the above equation is exactly the same as the desired DSBSC waveform shown earlier, which does not have the carrier. In other words, the carrier has been suppressed, hence the name double sideband-suppressed carrier (DSBSC).

2.4.3 DSBSC Spectrum and Bandwidth

We begin with the DSBSC-modulated signal:

$$S(t) = 2\,m(t)\,A_c\cos(\omega_c t) \tag{2.19}$$

where

$$m(t) = A_m\cos(\omega_m t)$$

Therefore,

$$S(t) = 2\,A_c A_m\cos(\omega_m t)\,\cos(\omega_c t) \tag{2.20}$$

This is the desired DSBSC waveform for spectral analysis.

Now, use the trigonometric identity:

- $\cos A\,\cos B = 1/2\,\cos(A+B) + 1/2\,\cos(A-B)$ (2.21)

where

$$A = \omega_m t = 2\pi f_m t \text{ and } B = \omega_c t = 2\pi f_c t$$

Therefore,

$$\begin{aligned} S(t) &= A_c[\cos(\omega_c + \omega_m)t + \cos(\omega_c - \omega_m)t] \\ &= A_c[\cos 2\pi(f_c + f_m)t + \cos 2\pi(f_c - f_m)t] \end{aligned} \tag{2.22}$$

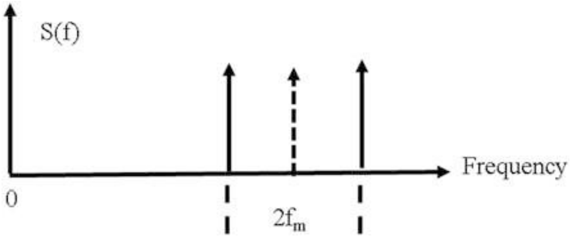


Fig. 2.10 DSBSC spectrum where the carrier frequency is suppressed. The bandwidth is given by 2 f_m

Notice that the carrier power is distributed among the sidebands (Fig. 2.10). Therefore, it is more efficient. The bandwidth is given by:

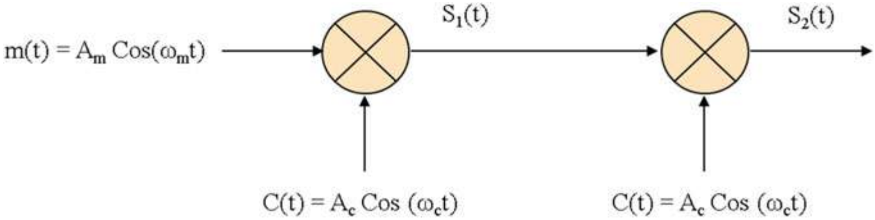
$$BW = 2f_m \tag{2.23}$$

2.4.4 DSBSC Drawbacks

- There are two identical sidebands.
- Each sideband contains the same information
- Bandwidth is 2 f_m
- Unnecessary power usage

Therefore, a solution is needed to improve bandwidth efficiency.

Problem 2.2 Given:Two product modulators using identical carriers are connected in a series, as shown below:



Find

(a) The output waveform $S_2(t)$
(b) What is the function of this circuit?

Solution

(a)
$$S_1(t) = m(t)\,C(t)$$
$$S_2(t) = S_1(t)\,C(t) = m(t)C^2(t) = A_m\cos(\omega_m t)\,Ac^2\cos\,2(\omega_c t)$$

(b) The function of the circuit is to demodulate DSBSC signals, where the carrier frequency is filtered out.

2.5 Single Sideband (SSB) Modulation

2.5.1 *Why SSB Modulation?*

- The basic AM has a carrier which does not carry information—*Inefficient power usage*
- The basic AM has two sidebands contain the same information—*Additional loss of power*
- DSBSC has two sidebands, containing the same information—*Loss of power*
- Therefore, the basic AM and DSBSC are bandwidth and power inefficient
- SSB is bandwidth and power efficient.

2.5.2 *Generation of SSB-Modulated Signal*

Single sideband (SSB) modulation uses two product modulators as shown in Fig. 2.11 [3–5], where

$$\bullet \quad m(t) = A_m \cos(\omega_m t) \tag{2.24}$$

$$\bullet \quad m(t)^* = A_m \sin(\omega_m t) - (\text{Hilbert Transform}) \tag{2.25}$$

$$\bullet \quad C(t) = A_m \cos\,(\omega_c t) \tag{2.26}$$

$$\bullet \quad C(t)^* = A_c \sin(\omega_c t) - (\text{Hilbert Transform}) \tag{2.27}$$

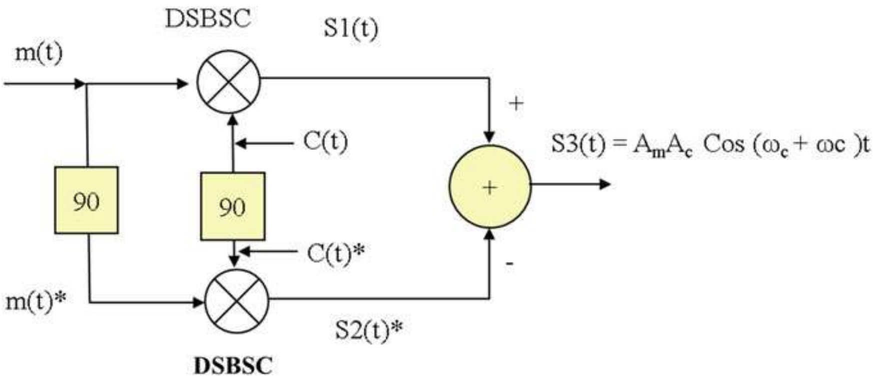


Fig. 2.11 Generation of SSB signal

Solving for S_1, S_2, and S_3, we obtain:

- $S_1(t) = A_c A_m \cos(\omega_m t)\cos(\omega_c t)$ (2.28)
- $S_2(t) = A_c A_m \sin(\omega_m t)\sin(\omega_c t)$ (2.29)

$$\begin{aligned} S_3(t) &= S_1(t) - S_2(t) \\ &= A_c A_m \cos(\omega_m t)\cos(\omega_c t) - A_c A_m \sin(\omega_m t)\sin(\omega_c t) \end{aligned} \quad (2.30)$$

Using the following formula:

- cos$A$ cos$B$ = 1/2cos(A + B) + 1/2cos(A − B)
- sin$A$ sin$B$ =1/2cos(A − B) − 1/2cos(A + B)

Solving for S_3, we get:

$$S_3 = A_c A_m \cos(\omega_c + \omega_m)t \quad (2.31)$$

In the above equation, $S_3(t)$ is the desired SSB signal, which is the upper sideband only.

2.5.3 SSB Spectrum and Bandwidth

Let us consider the SSB signal again:

$$\begin{aligned} S_3 &= A_c A_m \cos(\omega_c + \omega_m)t \\ &= A_c A_m \cos\, 2\pi(f_c + f_m)t \end{aligned} \quad (2.32)$$

Here, we see that the SSB spectrum contains only one sideband. Therefore, it is more efficient. The SSB bandwidth is given by:

$$\text{SSB BW} = f_m \quad (2.33)$$

Figure 2.12 displays the SSB spectrum.

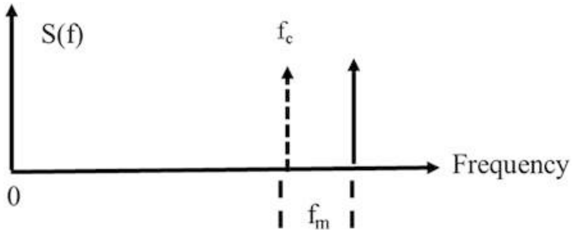

Fig. 2.12 SSB spectrum showing the upper sideband. The SSB bandwidth is f_m

Problem 2.3

Given:

- $m(t) = A_m \cos(\omega_m t)$
- $m(t)^* = A_m \sin(\omega_m t)$ − (Hilbert Transform)
- $C(t) = A_c \cos(\omega_c t)$
- $C(t)^* = A_c \sin(\omega_c t)$ − (Hilbert Transform)

Design an SSB modulator to realize the lower sideband. Sketch the spectral response.

Solution

Solving for S_1 and S_2, we obtain:

- $S_1(t) = A_c A_m \cos(\omega_m t) \cos(\omega_c t)$
- $S_2(t) = A_c A_m \sin(\omega_m t) \sin(\omega_c t)$

Obtain S_3 as:

$$\begin{aligned} S_3(t) &= S_1(t) + S_2(t) \\ &= A_c A_m \cos(\omega_m t) \cos(\omega_c t) + A_c A_m \sin(\omega_m t) \sin(\omega_c t) \end{aligned}$$

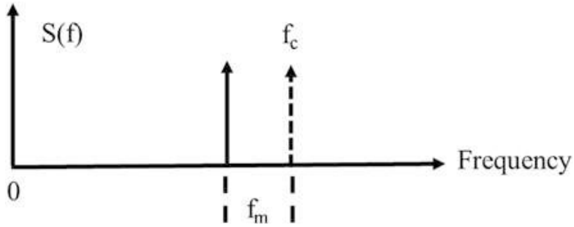
Using the following formula:

- $\cos A \cos B = 1/2\cos(A + B) + 1/2\cos(A - B)$
- $\sin A \sin B = 1/2\cos(A - B) - 1/2\cos(A + B)$

Solving for S_3, we get:

$$\begin{aligned} S_3 &= A_c A_m \cos(\omega_m - \omega_c)t \\ &= A_c A_m \cos 2\pi(f_c - f_m)t \end{aligned}$$

In the above equation, S_3(t) is the desired SSB signal, which is the lower sideband only. The spectral response, showing the lower sideband, is presented below.



2.6 Conclusions

This chapter presents the key concepts and underlying principles of Amplitude Modulation. It was shown how the audio waveform changes the amplitude of the carrier to determine the envelope of the modulated carrier. It was also shown that the modulated carrier contains several spectral components that lead to DSBSC and SSB modulation techniques. In particular, the following topics were presented in this chapter:

- Amplitude Modulation (AM)
- AM spectrum and bandwidth
- Double sideband-suppressed carrier (DSBSC)
- DSBSC spectrum and bandwidth
- Single sideband (SSB)
- SSB spectrum and bandwidth

Chapter 3
Frequency Modulation (FM)

Topics

- Introduction
- Frequency Modulation (FM)
- FM Spectrum
- Carson's Rule & FM Bandwidth
- Bessel Function & FM Bandwidth
- FM bandwidth Dilemma

3.1 Introduction

In Frequency Modulation (FM), the frequency of the carrier changes in accordance with the input analog signal, while the amplitude of the carrier remains the same [1–5]. This is shown in Fig. 3.1, where

- $m(t)$ is the input modulating audio signal,
- $C(t)$ is the carrier frequency, and
- $S(t)$ is the FM-modulated carrier frequency.

As shown in the figure, the audio waveform changes the frequency of the carrier. This enables the receiver to extract the audio signal by demodulation. Notice that the frequency of the carrier changes in accordance with the input signal, while the amplitude of the carrier does not change after modulation. However, it can be shown that the modulated carrier $S(t)$ contains an infinite number of spectral components, requiring frequency domain analysis [3]. In an effort to examine this, this chapter will present the following topics:

- The basic Frequency Modulation (FM),
- FM spectrum, and
- FM bandwidth.

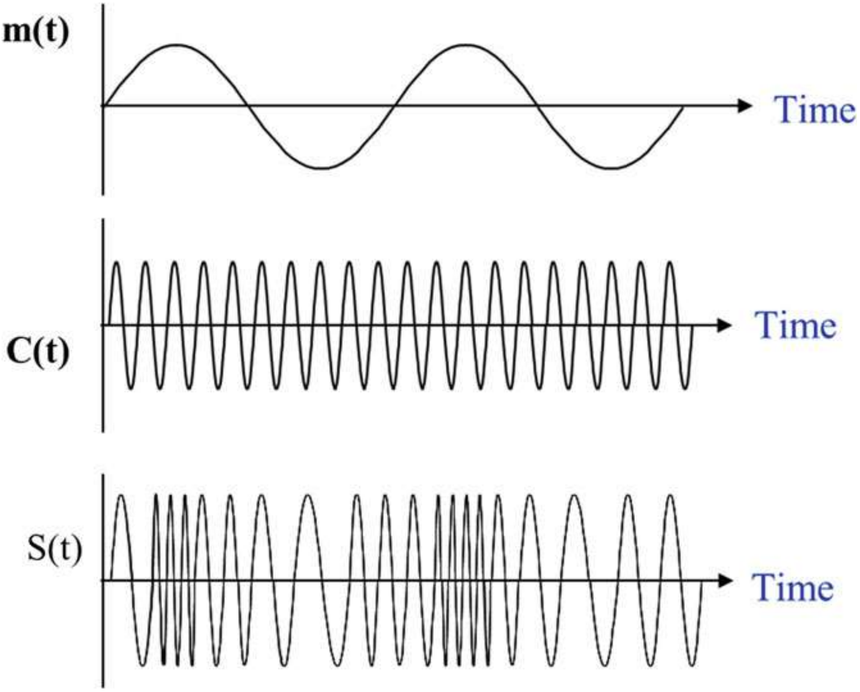

Fig. 3.1 Illustration of FM

3.2 Frequency Modulation (FM)

3.2.1 Background

FM is a form of angle modulation, where the frequency of the carrier varies in accordance with the input signal. Here, the angle refers to the angular frequency (ω). The angular frequency ω is also recognized as angular speed or circular frequency. It is a measure of rotation rate or the rate of change of the phase of a sinusoidal waveform as illustrated in Fig. 3.2.

Magnitude of the angular frequency ω is defined by one revolution or 2π radians:

$$\omega = 2\pi f = \mathrm{d}\theta/\mathrm{d}t \quad \text{Radians per second} \tag{3.1}$$

where,

- ω = Angular frequency in radians per seconds,
- f = Frequency in Hertz (Hz) or cycles per second, and
- θ = Phase angle.

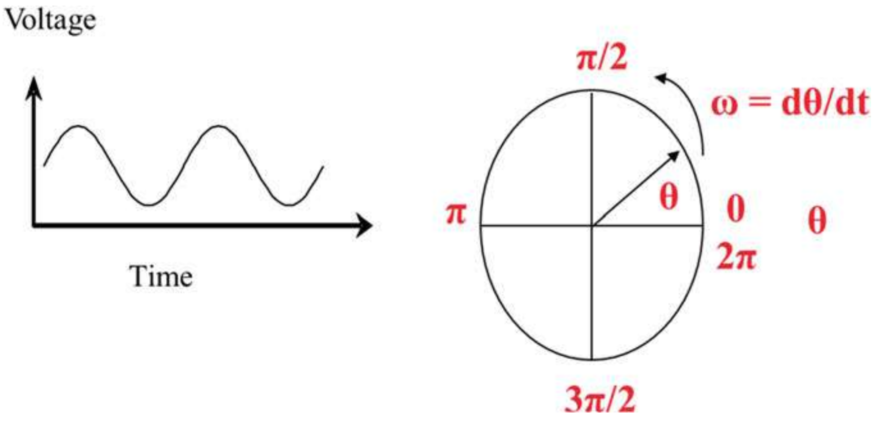

Fig. 3.2 A sinusoidal waveform in the time domain and its representation in the phase domain

Notice that in Eq. 3.1, the angular frequency ω is greater than the frequency f by a factor of 2π. Now solving for the phase angle, we obtain,

$$\theta_i(t) = 2\pi \int_0^t f_i dt \tag{3.2}$$

- θ_i = Instantaneous phase angle and
- f_i = Instantaneous frequency.

This forms the basis of our derivation of FM as presented in the following section.

3.2.2 *The Basic FM*

Frequency Modulation (FM) is a method of analog modulation that utilizes frequency variation of the relative frequency of the career [1]. The signal to be modulated and transmitted is analog. This is referred to as FM, where the frequency of the carrier changes in accordance with the input signal. The modulated carrier frequency f_c varies back and forth and depends on amplitude A_m and frequency f_m of the input signal.

Figure 3.3 shows the functional diagram of a typical FM, using a single-tone modulating signal. Here, $m(t)$ is the input analog signal we want to transmit, $C(t)$ is the carrier frequency without modulation, and $S(t)$ is the output FM-modulated carrier frequency. These parameters are described below.

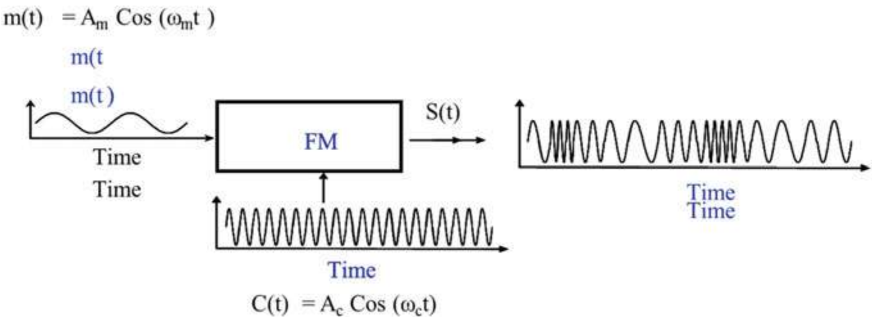

Fig. 3.3 A functional diagram of a typical FM modulator using a single-tone input modulating signal. Here, $m(t)$ is the input analog signal we want to transmit, $C(t)$ is the carrier frequency without modulation, and $S(t)$ is the output FM-modulated carrier frequency

We examine this by means of a single-tone input modulating signal and its angular frequency as shown in Fig. 3.2. Since the frequency of the carrier varies in accordance with the input signal, the instantaneous frequency of the carrier is given by

$$f_i(t) = f_c(t) + D_f m(t) \tag{3.3}$$

where,

- f_i = Instantaneous frequency,
- f_c = Carrier frequency,
- D_f = Constant, and
- $m(t) = A_m \cos(wmt)$.

The FM-modulated signal is given by

$$S(t) = A_c \cos(\theta_i) \tag{3.4}$$

where Ac is the amplitude of the carrier frequency and θ_i is the instantaneous angle. Substituting Eq. (3.2) into Eq. (3.4) for θi, we get

$$S(t) = A_c \cos[2\pi \int_0^t f_i dt] \tag{3.5}$$

where f_i is the instantaneous frequency. Substituting Eq. (3.3) into Eq. (3.5) for fi, we obtain

$$S(t) = A_c \cos[2\pi \int_0^t \{fc(t) + Df\, m(t)\} dt] \tag{3.6}$$

where $m(t) = A_m \cos(\omega_m t)$ is the input modulating signal. Integrating the above equation, we obtain the desired FM signal as follows:

$$\begin{aligned} S(t) &= A_c \cos\left[2\pi f_c t + \left(\frac{\Delta f}{f_m}\right)\sin(2\pi f_m t)\right] \\ &= A_c \cos[2\pi f_c t + \beta \sin(2\pi f_m t)] \qquad (3.7) \\ \beta &= \left(\frac{\Delta f}{f_m}\right) = \text{Modulation Index} \quad \Delta f = DfAm = \text{Freq. Deviation} \end{aligned}$$

where,

- $S(t)$ = FM-modulated carrier signal,
- f_c = Frequency of the carrier,
- A_c = Amplitude of the carrier frequency,
- $\Delta f = D_f A_m$ = Frequency deviation,
- f_m = Input modulating frequency,
- Am = Amplitude of the input modulating signal,
- D_f = A constant parameter, and
- $\beta = \Delta f / f_m$ = Modulation index.

Note that the modulation index β is an important design parameter in FM. It is directly related to FM bandwidth. It may also be noted that FM bandwidth depends on both frequency and amplitude of the input modulating signal. Let us take a closer look.

3.3 FM Spectrum and Bandwidth

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth and modulation. The transmission bandwidth depends on the following:

- Spectral response of the input modulating signal,
- Spectral response of the carrier frequency, and
- Modulation type.

Let's take a closer look!

3.3.1 Spectral Response of the Input Modulating Signal

In FM, the input modulating signal is a continuous time low-frequency analog signal. For simplicity, we use a sinusoidal waveform, which is periodic and

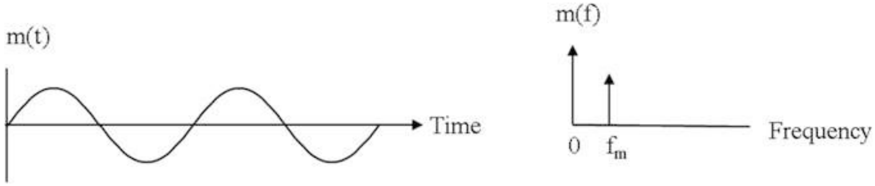

Fig. 3.4 A low-frequency sine wave and its frequency response

continuous with respect to time. It has one frequency component. For example, the sine wave is described by the following time domain equation:

$$V(t) = V_p \sin(\omega_m t) \tag{3.8}$$

where,

- Vp = Peak voltage,
- $\omega_m = 2\pi f_m$, and
- f_m = Input modulating frequency in Hz.

Figure 3.4 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis at f_m and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

3.3.2 Spectral Response of the Carrier Frequency

A carrier frequency (f_c) is essentially a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component, which is much higher than the input modulating frequency ($f_c \gg f_m$). For example, the sine wave is described by the following time domain equation:

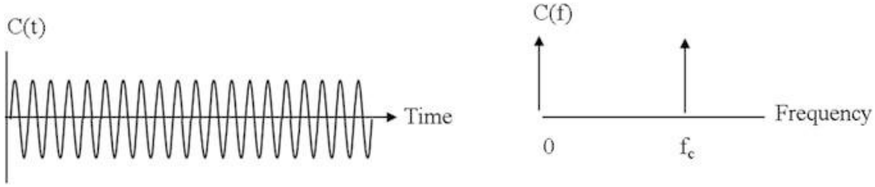

Fig. 3.5 A high-frequency sine wave and its frequency response before modulation

$$V(t) = V_p \sin(\omega_c t) \tag{3.9}$$

where

$$V_p = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$ *and*
- f_c = Carrier frequency in Hz.

Figure 3.5 shows the characteristics of a high-frequency sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis at f_c and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

3.3.3 FM Spectrum

In FM, the frequency of the carrier changes in accordance with the input signal. Here, we have:

$$\begin{aligned} &\bullet\ \text{Input Signal :} && m(t) = A_m \cos(\omega_m t) \\ &\bullet\ \text{Carrier Frequency :} && C(t) = A_c \cos(\omega_c t) \\ &\bullet\ \text{Modulated Carrier :} && S(t) = A_c \cos[(\omega_c t) + \beta \sin(\omega_m t)] \end{aligned} \tag{3.10}$$

where

- $S(t)$ = The modulated carrier,
- Ac = Frequency of the carrier,
- ω_c = Nominal frequency of the carrier frequency,
- $\beta = \Delta f/fm$ = Modulation index,
- $\Delta f = D_f A_m$ = Frequency deviation,
- D_f = Constant, and
- A_m = Amplitude of the input modulating signal.

By inspecting the modulated carrier frequency, we observe that $S(t)$ depends on both frequency and amplitude of the input signal. The spectral response is given in Fig. 3.6. Notice that the carrier frequency after modulation varies back and forth from the nominal frequency f_c as depicted in the figure. In Fig. 3.6, we see that:

- As time passes, the carrier moves back and forth in frequency in exact step with the input signal.
- Frequency deviation is proportional to the input signal voltage.
- A group of many sidebands is created, spaced from carrier by amounts $N \times f_i$.
- Relative strength of each sideband depends on Bessel function.
- Strength of individual sidebands far away from the carrier is proportional to (freq. deviation × input frequency).
- Higher order spectral components are negligible.

Fig. 3.6 FM spectrum. As time passes, the carrier moves back and forth in frequency in exact step with the input signal and generates an infinite number of sidebands

- Carson's rule can be used to determine the approximate bandwidth: bandwidth required = 2 × (highest input frequency + frequency deviation).

3.3.4 Carson's Rule and FM Bandwidth

The Carson's rule, a rule of thumb, states that more than 98 % of the power of FM signal lies within a bandwidth given by the following approximation:

$$\text{FM Bandwidth (BW)} = 2f_m(1+\beta) \tag{3.11}$$

where

Table 3.1 Bessel function table

β	J0	J1	J2	J3	J4	J5
0	1					
0.25	0.98	0.12				
0.5	0.94	0.24	0.03			
1	0.77	0.44	0.11	0.02		
1.5	0.51	0.56	0.23	0.06	0.01	
2	0.22	0.58	0.35	0.13	0.03	

- $\beta = \Delta f/fm$ = Modulation index,
- Δf = Peak deviation of the instantaneous frequency from the center of the carrier frequency, and
- fm = Highest frequency of the modulating signal.

3.3.5 Bessel Function and FM Bandwidth

FM bandwidth can be estimated by means of Bessel function of the first kind. For a single-tone modulation, it can be obtained as a function of the sideband number and the modulation index.

For a given β, the solution for $S(t)$ is given as follows:

$$\begin{aligned} S(t) &= A_c\cos[(\omega_c t) + \beta\sin(\omega_m t)] \\ &= J_0\,(\beta)\cos(\omega_c t) \\ &\quad + J_1(\beta)\cos(\omega_c t + \omega_m t) + J_2(\beta)\cos(\omega_c t + 2\omega_m t) + J_3(\beta)\cos(\omega_c t + 3\omega_m t) + \ldots \\ &\quad - J_1(\beta)\cos(\omega_c t - \omega_m t) - J_2(\beta)\cos(\omega_c t - 2\omega_m t) - J_3(\beta)\cos(\omega_c t - 3\omega_m t) + \ldots \end{aligned} \tag{3.12}$$

Here, J's are the Bessel functions, representing the amplitude of the sidebands. J_0 (β) is the amplitude of the fundamental spectral component, and the remaining spectral components are the sidebands. Each sideband is separated by the input modulating frequency. These values are also available as a standard Bessel function table.

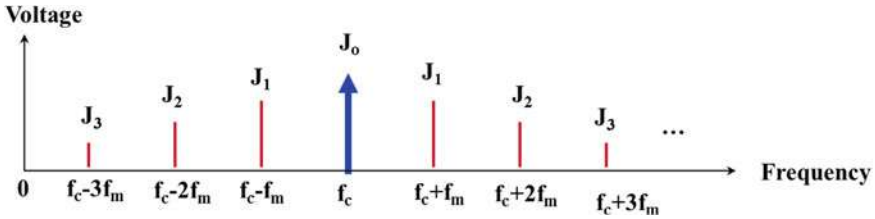

Fig. 3.7 FM sidebands. Power is taken from the carrier $J0$ and distributed among the sidebands $J1$, $J2$, $J3$,…, etc. Each sideband is separated by the modulating frequency f_m

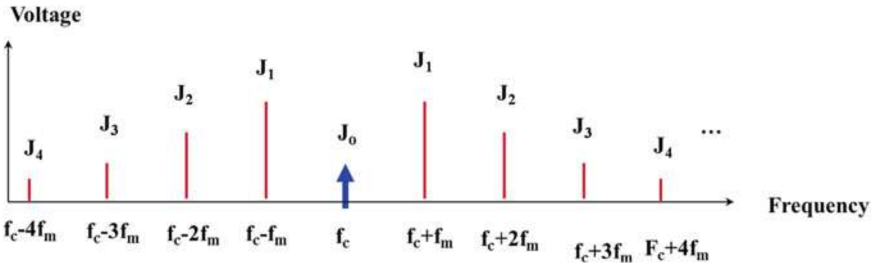

Fig. 3.8 FM sidebands for large β. More power is taken from the carrier $J0$ and distributed among the sidebands $J1$, $J2$, $J3$, $J4$,… Each sideband is separated by the modulating frequency f_m

As an example, Table 3.1 provides a few Bessel parameters to illustrate the concept. In this table, the carrier and sideband amplitude powers, $J0$, $J1$, $J2$,…, etc., are presented for different values of β. Here, $J0$ is carrier power before modulation. After modulation, with a given value of β, power is taken from the carrier and distributed among the sidebands. Also, there is a unique value of β, for which the carrier amplitude becomes zero and all the signal power is in the sidebands.

Note that, in FM, the sidebands are on both sides of the carrier. Therefore, the total bandwidth includes spectral components from both sides of the carrier. For a given low β, this is shown in Fig. 3.7. Here, J0 is the spectral component of the carrier. $J1$, $J2$, $J3$, etc., are the sidebands. Each sideband is separated by the input modulating frequency f_m. After modulation, power is taken from the carrier J0 and distributed among the sidebands, depending on the modulation index β.

Figure 3.8 shows another scenario where β is large. In this case, more power is taken from the carrier and distributed among the sideband, while creating more significant sidebands, requiring more bandwidth.

3.3.6 FM Bandwidth Dilemma

In FM, we notice that if the modulation index is low, the occupied bandwidth is low and the sidebands take less power from the carrier, making the modulation less efficient. On the other hand, if the modulation index is high, the occupied bandwidth is also high, while the sidebands retain most of the power, making the modulation more efficient at the expense of bandwidth. This is a dilemma in FM. However, FM is more popular because it is less sensitive to noise.

Problem 3.1
Given:

$$f_m = 1\,\text{kHz}$$
$$f_c = 1\,\text{MHz}$$
$$\beta = 1$$

Find:

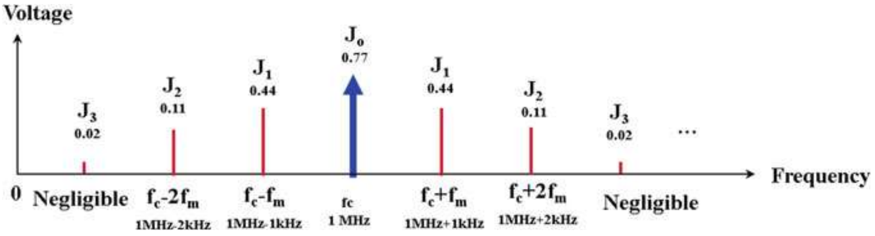
(a) The FM bandwidth using Carson's rule and
(b) The FM bandwidth using Bessel function

Solution:

(a) FM BW (Carson's rule) = $2\,f_m\,(1 + \beta) = 2 \times 1$ kHz $(1 + 1) = 4$ kHz.
(b) For $\beta = 1$, See Table 3.1:

- $J0 = 0.77$, $J1 = 0.44$, $J2 = 0.11$, $J3 = 0.02$

where $J0$ is the carrier and $J1$, $J2$, and $J3$ are the sidebands. Here, we can neglect $J3$ since it has a negligible power. Therefore, there are two significant upper and lower sidebands, and each sideband is 1 kHz apart. Therefore, FM bandwidth is 2 × Number of significant sidebands = 2 × 2 = 4 kHz. See figure below.



Problem 3.2
Given:

$$fm = 1\,\text{kHz}$$
$$fc = 1\,\text{MHz}$$
$$\beta = 2$$

Find:

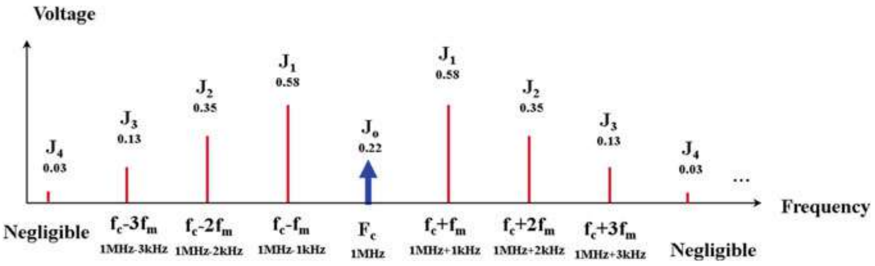
(a) The FM bandwidth using Carson's rule and
(b) The FM bandwidth using Bessel function

Solution:

(a) FM BW (Carson's rule) = $2\,f_m\,(1 + \beta) = 2 \times 1$ kHz $(1 + 2) = 6$ kHz.
(b) For $\beta = 2$, See Table 3.1:

- $J0 = 0.22$, $J1 = 0.58$, $J2 = 0.35$, $J3 = 0.13$, $J4 = 0.03$

Here, we have 4 upper and 4 lower sidebands, and each sideband is separated by 1 kHz. Since the J4 is negligible, we take 3 upper sidebands and 3 lower sidebands. Therefore, the FM bandwidth is 2 × 3 = 6 kHz. See figure below.



3.4 Conclusions

- This chapter presents a brief overview of Frequency Modulation (FM) and its attributes.
- The key concept and the underlying principle of FM are presented with numerous illustrations to make them easier for readers to grasp.
- FM spectrum is addressed with illustrations.
- FM bandwidth is estimated by means of Carson’s rule and Bessel function.
- FM bandwidth dilemma is explained, and problems are given to illustrate the concept.

Chapter 4
Amplitude Shift Keying (ASK)

Topics

- Introduction
- Amplitude Shift Keying (ASK)
- ASK spectrum
- ASK Bandwidth
- Performance Analysis

4.1 Introduction

In amplitude shift keying (ASK), the amplitude of the carrier changes in discrete levels in accordance with the input digital signal, while the frequency of the carrier remains the same. This is shown in Fig. 4.1, where

- $m(t)$ is the input modulating digital signal,
- $C(t)$ is the carrier frequency, and
- $S(t)$ is the ASK-modulated carrier frequency.

As shown in the figure, the digital binary signal changes the amplitude of the carrier in two discrete levels. This enables the receiver to extract the digital signal by demodulation. Notice that the amplitude of the carrier changes in accordance with the input signal, while the frequency of the carrier does not change after modulation. However, it can be shown that the modulated carrier $S(t)$ contains several spectral components, requiring frequency domain analysis.

In the following sections, the above disciplines in ASK modulation will be presented along with the respective spectrum and bandwidth. These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

4.2 ASK Modulation

Amplitude shift keying (ASK), also known as on–off keying (OOK), is a method of digital modulation that utilizes amplitude shifting of the relative amplitude of the career frequency [1–3]. The signal to be modulated and transmitted is binary, which is encoded before modulation. This is an indispensable task in digital communications, where redundant bits are added with the raw data that enables the receiver to detect and correct bit errors, if they occur during transmission [4–16].

While there are many error-coding schemes available, we will use a simple coding technique, known as "Block Coding" to illustrate the concept.

Figure 4.2 shows an encoded ASK modulation scheme using (15, 8) block code where an 8-bit data block is formed as M-rows and N-columns ($M = 4, N = 2$). The product $MN = k = 8$ is the dimension of the information bits before coding. Next, a horizontal parity P_H is appended to each row and a vertical parity P_V is appended to each column. The resulting augmented dimension is given by the product $(M + 1)(N + 1) = n = 15$, which is then ASK modulated and transmitted row by row. The rate of this coding scheme is given by

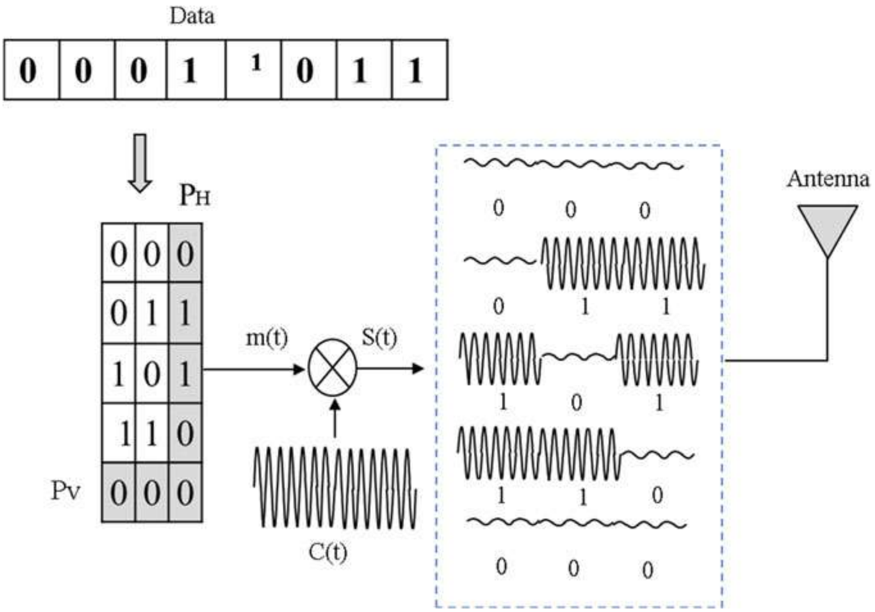

Fig. 4.2 Amplitude shift keying (ASK) is also known as on–off keying (OOK). The input encoded data block is transmitted row by row. The amplitude of the carrier frequency changes in accordance with the input digital signal

$$\text{Code Rate: } r = (MN)/[(M+1)(N+1)] = (4 \times 2)/(5 \times 3) = 8/15 \tag{4.1}$$

The coded bit rate R_{b2} is given by

$$R_{b2} = \text{Uncoded Bit Rate}/\text{Code Rate} = R_{b1}/r = R_{b1}\,(15/8) \tag{4.2}$$

Next, the coded bits are modulated by means of the ASK modulator as shown in the figure. Here,

- The Input digital signal is the encoded bit sequence we want to transmit
- Carrier is the radio frequency without modulation
- Output is the ASK-modulated carrier, which has two amplitudes corresponding to the binary input signal. For binary signal 1, the carrier is ON. For the binary signal 0, the carrier is OFF; however, a small residual signal may remain due to noise, interference, etc., as indicated in the figure.

As shown in the figure, the amplitude of the carrier changes in discrete levels, in accordance with the input signal, where

$$\begin{aligned} &\bullet\ \text{Input Data :} && m(t) = 0 \text{ or } 1 \text{ (coded data)} \\ &\bullet\ \text{Carrier Frequency :} && C(t) = A\cos(\omega t) \\ &\bullet\ \text{Modulated Carrier :} && S(t) = m(t)C(t) = m(t)A\cos(\omega t) \end{aligned} \tag{4.3}$$

Therefore,

$$\begin{aligned} &\text{For } m(t) = 1 : S(t) = A\cos(\omega t) \text{ i.e. the carrier is ON} \\ &\text{For } m(t) = 1 : S(t) = 0, \text{ i.e. the carrier is OFF} \end{aligned} \tag{4.4}$$

where A is the amplitude and ω is the frequency of the carrier.

4.3 ASK Demodulation

Once the modulated binary data has been transmitted, it needs to be received and demodulated. This is often accomplished with the use of a band-pass filter. In the case of ASK, the receiver needs to utilize one band-pass filter that is tuned to the appropriate carrier frequency. As the signal enters the receiver, it passes through the filter and a decision as to the value of each bit is made to recover the encoded data block, along with horizontal and vertical parities. Next, the receiver appends horizontal and vertical parities P_H* and P_V* to check parity failures and recovers the data block. This is shown in Fig. 4.3 having no errors. If there is an error, there will be a parity failure in P_H* and P_V* to pinpoint the error.

4.4 ASK Bandwidth

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth in error control coding and modulation. The transmission bandwidth depends on:

- Spectral response of the encoded data
- Spectral response of the carrier frequency, and
- Modulation type.

4.4.1 Spectral Response of the Encoded Data

In digital communications, data is generally referred to as a non-periodic digital signal. It has two values:

- Binary-1 = High, Period = T
- Binary-0 = Low, Period = T

Also, data can be represented in two ways:

- Time domain representation and
- Frequency domain representation

The time domain representation (Fig. 4.4a), known as non-return-to-zero (NRZ), is given by:

$$\begin{aligned} V(t) &= V \qquad <0<t<T \\ &= 0 \qquad \text{elsewhere} \end{aligned} \tag{4.5}$$

The frequency domain representation is given by "Fourier transform":

$$V(\omega) = \int_0^T V \cdot e^{-j\omega t} dt \tag{4.6}$$

$$\begin{aligned} |V(\omega)| &= VT\left[\frac{\sin(\omega T/2)}{\omega T/2}\right] \\ P(\omega) &= \left(\frac{1}{T}\right)|V(\omega)|^2 = V^2 T\left[\frac{\sin(\omega T/2)}{\omega T/2}\right]^2 \end{aligned} \tag{4.7}$$

Here, $P(\omega)$ is the power spectral density. This is plotted in Fig. 4.4b. The main lobe corresponds to the fundamental frequency and side lobes correspond to harmonic components. The bandwidth of the power spectrum is proportional to the frequency. In practice, the side lobes are filtered out since they are relatively insignificant with respect to the main lobe. Therefore, the one-sided bandwidth is given by the ratio $f/f_b = 1$. In other words, the one-sided bandwidth $= f = f_b$, where $f_b = R_b = 1/T$, T being the bit duration.

The general equation for two-sided response is given by:

$$V(\omega) = \int_{-\propto}^{\propto} V(t) \cdot e^{-j\omega t} dt$$

In this case, $V(\omega)$ is called two-sided spectrum of $V(t)$. This is due to both positive and negative frequencies used in the integral. The function can be a voltage or a current. Figure 4.4c shows the two-sided response, where the bandwidth is determined by the main lobe as shown below:

$$\text{Two-sided bandwidth (BW)} = 2R_b \; (R_b = \text{Bit rate before coding}) \tag{4.8}$$

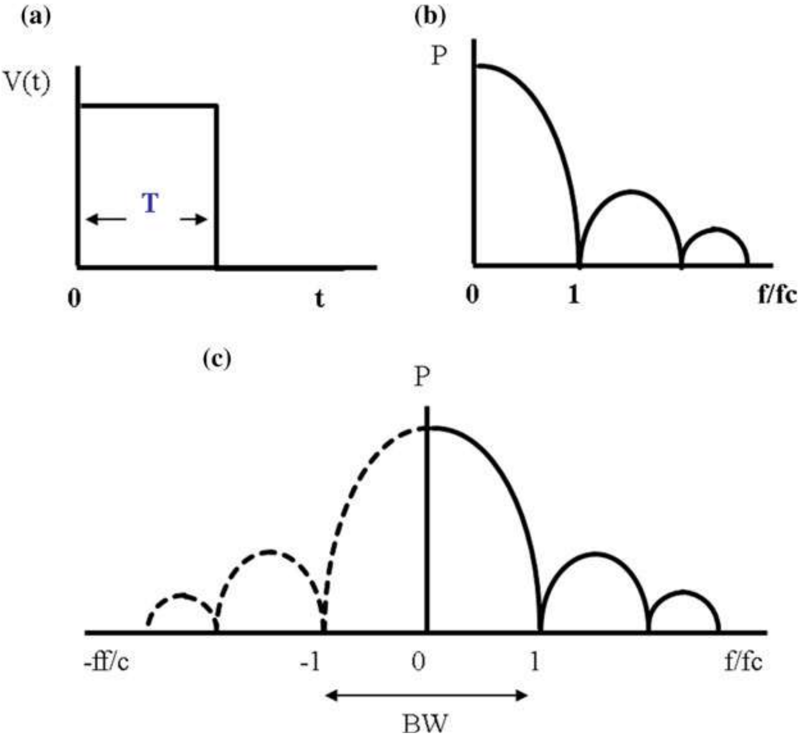

Fig. 4.4 **a** Discrete time digital signal **b** it is one-sided power spectral density and **c** two-sided power spectral density. The bandwidth associated with the non-return-to-zero (NRZ) data is $2R_b$, where R_b is the bit rate

Important Notes

1. If R_b is the bit rate before coding, and if the data is NRZ, then the bandwidth associated with the raw data will be $2R_b$. For example, if the bit rate before coding is 10 kb/s, then the bandwidth associated with the raw data will be 2 × 10 kb/s = 20 kHz.
2. If R_b is the bit rate before coding, code rate is r, and if the data is NRZ, then the bit rate after coding will be R_b (coded) = R_b (uncoded)r. The corresponding bandwidth associated with the coded data will be $2R_b$ (coded) = $2R_b$ (uncoded)/r. For example, if the bit rate before coding is 10 kb/s and the code rate $r = 1/2$, then the coded bit rate will be R_b (coded) = R_b (uncoded)/r = 10/0.5 = 20 kb/s. The corresponding bandwidth associated with the coded data will be 2 × 20 = 40 kHz.

4.4.2 Spectral Response of the Carrier Frequency Before Modulation

A carrier frequency is essentially a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component. For example, the sine wave is described by the following time domain equation:

$$V(t) = V_p \sin(\omega t_c) \tag{4.9}$$

where

$$V_P = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$
- f_c = Carrier frequency in Hz

Figure 4.5 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

4.4.3 ASK Bandwidth at a Glance

In ASK, the amplitude of the carriers changes in discrete levels, in accordance with the input signal, where

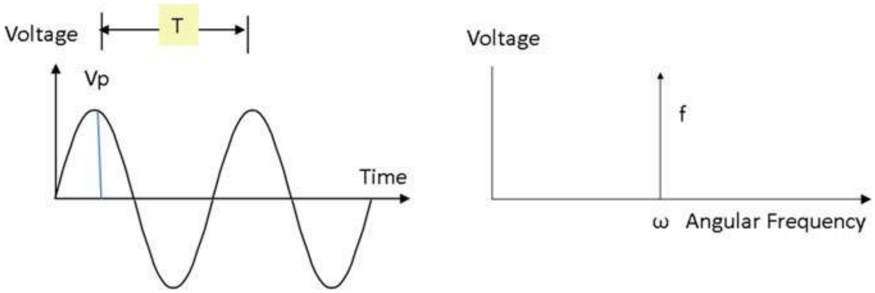

Fig. 4.5 High-frequency carrier frequency response

- Input Data : $m(t) = 0 \text{ or } 1$
- Carrier Frequency : $C(t) = Ac\cos(\omega_c t)$
- Modulated Carrier : $S(t) = m(t)C(t) = m(t)A_c\cos(\omega_c t)$

Since $m(t)$ is the input digital signal and it contains an infinite number of harmonically related sinusoidal waveforms and that we keep the fundamental and filter out the higher-order components, we write:

$$m(t) = A_m \sin(\omega_m t)$$

The ASK-modulated signal then becomes:

$$\begin{aligned} S(t) = m(t)S(t) &= A_m A_c \sin(\omega_m t)\cos(\omega_m t) \\ &= 1/2\,A_m A_c\,[\sin(\omega_c - \omega_m)t + \sin(\omega_c + \omega_m)t] \end{aligned} \tag{4.10}$$

The spectral response is depicted in Fig. 3.14. Notice that the spectral response after ASK modulation is the shifted version of the NRZ data. Bandwidth is given by:

BW = $2R_b$ (coded), where R_b is the coded bit rate (Fig. 4.6).

Problem 1

Given:

- Bit rate before coding: R_{B1} = 10 kb/s
- Code rate: r = 8/15
- Modulation: ASK

Find:

(a) the bit rate after coding: R_{B2}
(b) Transmission bandwidth: BW

Solution

(a) Bit rate after coding (R_{B2})
$R_{B2} = R_{B1}/r$ = 10 kb/s (15/8) = 18.75 kb/s
(b) Transmission BW = 2 × 18.75 kb/s = 37.5 kHz.

4.5 BER Performance

It is well known that an (n, k) bock code, where k = number of information bits, n = number of coded bits, can correct t errors [4, 5]. A measure of coding gain is then obtained by comparing the uncoded word error WER_U with the coded word WER_C. We examine this by means of the following analytical means.

Let the uncoded word error be defined as (WER_U). Then, with ASK modulation, the uncoded BER will be given by:

$$\mathrm{BER}_U = 0.5\,\mathrm{EXP}(-E_B/2N_0) \tag{4.11}$$

The probability that the uncoded word (WER_U) will be received in error is 1 minus the product of the probabilities that each bit will be received correctly. Thus, we write:

$$\mathrm{WER}_U = 1 - (1 - \mathrm{BER}_U)^k \tag{4.12}$$

Let the coded word error be defined as (WER_C). Since $n > k$, the coded bit energy to noise ratio will be modified to E_c/N_O, where $E_c/N_O = E_b/N_O + 10\log(k/n)$. Therefore, the coded BERc will be:

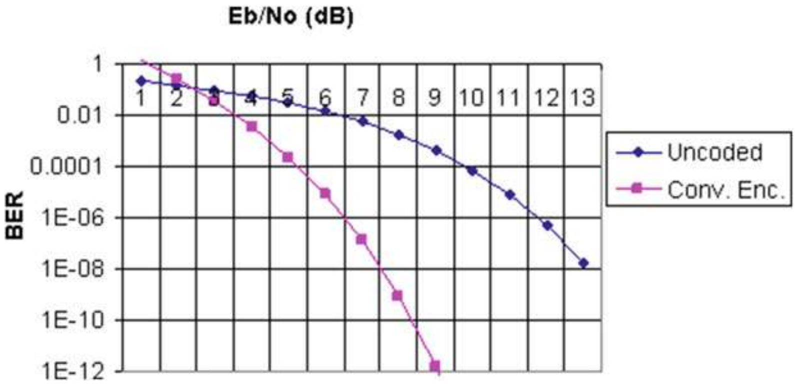

Fig. 4.7 Typical error performance in AWGN

$$\mathrm{BER}_C = 0.5\,\mathrm{EXP}(-E_C/2N_0) \tag{4.13}$$

The corresponding coded word error rate is given as:

$$\mathrm{WER}_C = \sum_{k=t+1}^{n} \binom{n}{k} \mathrm{BER}_C^K (1 - \mathrm{BER}_C)^{n-k} \tag{4.14}$$

When $\mathrm{BER}_c < 0.5$, the first term in the summation is the dominant one; therefore, Eq. (4.14) can be simplified as

$$\mathrm{WER}_C \approx \binom{n}{k} \mathrm{BER}_c^k (1 - \mathrm{BER}_c)^{n-k} \tag{4.15}$$

Using (15, 8) block code ($n = 15$, $k = 8$, $t = 1$), we obtain the coded and the uncoded WER as shown in Fig. 4.7. Coding gain is the difference in E_b/N_0 between the two curves. Notice that at least 3–4 db coding gain is available in this example where $r = k/n = 8/15$.

4.6 Conclusions

- This chapter presents ASK modulation and its attributes.
- Numerous illustrations are provided to show how amplitude of the carrier changes in discrete levels in accordance with the input digital signal, while the frequency of the carrier remains the same.
- The Fourier transform is used to derive the spectral components and ASK bandwidth is calculated.

- Bit error rate (BER) performance is presented.
- These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

Chapter 5
Frequency Shift Keying (FSK)

Topics

- Introduction
- Frequency Shift Keying (FSK)
- FSK spectrum
- FSK Bandwidth
- Performance Analysis

5.1 Introduction

In frequency shift keying (FSK), the frequency of the carrier changes in discrete levels in accordance with the input digital signal, while the amplitude of the carrier remains the same. This is shown in Fig. 5.1 where

- $m(t)$ is the input modulating digital signal,
- $C(t)$ is the carrier frequency, and
- $S(t)$ is the FSK-modulated carrier frequency.

As shown in the figure, the digital binary signal changes the frequency of the carrier on two discrete levels. This enables the receiver to extract the digital signal by demodulation. Notice that the frequency of the carrier changes in accordance with the input signal, while the amplitude of the carrier does not change after modulation. However, it can be shown that the modulated carrier $S(t)$ contains several spectral components, requiring frequency-domain analysis.

In the following sections, the above disciplines in FSK modulation will be presented, along with the respective spectrum and bandwidth. These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

5.2 Frequency Shift Keying (FSK) Modulation

Frequency shift keying (FSK) is a method of digital modulation that utilizes frequency shifting of the relative frequency content of the signal [1–3]. The signal to be modulated and transmitted is binary, which is encoded before modulation. This is an indispensable task in digital communications, where redundant bits are added with the raw data that enables the receiver to detect and correct bit errors, if they occur during transmission [4–16]. While there are many error-coding schemes available, we will use a simple coding technique, known as "block coding" to illustrate the concept.

Figure 5.2 shows an encoded FSK modulation scheme using (15, 8) block code where an 8-bit data block is formed as M rows and N columns ($M = 4$, $N = 2$). The product $MN = k = 8$ is the dimension of the information bits before coding. Next, a horizontal parity P_H is appended to each row and a vertical parity P_V is appended to each column. The resulting augmented dimension is given by the product $(M + 1)$

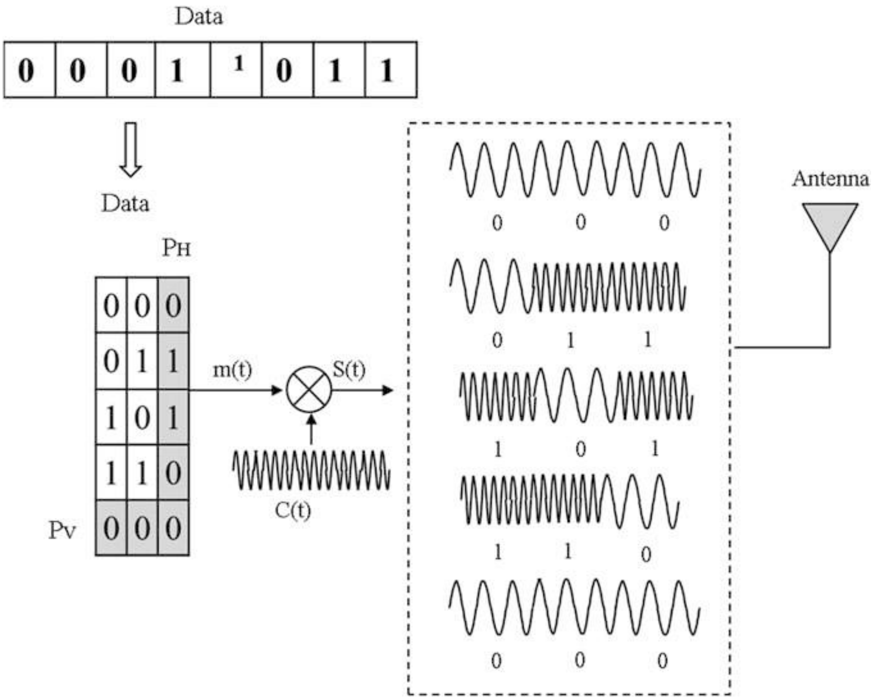

Fig. 5.2 Binary frequency shift keying (BFSK) modulation. The input encoded data block is transmitted row by row. The frequency of the carrier changes in accordance with the input digital signal

$(N + 1) = n = 15$, which is then FSK-modulated and transmitted row by row. The rate of this coding scheme is given by:

$$\text{Code Rate} : r = (MN)/[(M+1)(N+1)] = (4 \times 2)/5 \times 3) = 8/15 \qquad (5.1)$$

The coded bit rate R_{b2} is given by:

$$R_{b2} = \text{Uncoded Bit Rate}/\text{Code Rate} = R_{b1}/r = R_{b1}(15/8) \qquad (5.2)$$

Next, the coded bits are modulated by means of the FSK modulator as shown in the figure. Here,

- The input digital signal is the encoded bit sequence we want to transmit.
- Carrier is the radio frequency without modulation.
- Output is the FSK-modulated carrier, which has two frequencies corresponding to the binary input signal.
- For binary signal 1, the carrier changes to $f_c - \Delta f$.
- For binary signal 0, the carrier changes to $f_c + \Delta f$.
- The total frequency deviation is $2\Delta f$.

As shown in Fig. 3.8, the frequency of the carrier changes in discrete levels, in accordance with the input signals. We have:

$$\begin{array}{lll} \bullet & \text{Input Data:} & m(t) = 0 \text{ or } 1 \\ \bullet & \text{Carrier Frequency:} & C(t) = A\cos(\omega t) \\ \bullet & \text{Modulated Carrier:} & S(t) = A\cos(\omega - \Delta\omega)t, \text{For } m(t) = 1 \\ & & S(t) = A\cos(\omega + \Delta\omega)t, \text{For } m(t) = 0 \end{array} \tag{5.3}$$

where

$$\begin{array}{ll} \bullet & A = \text{Frequency of the carrier} \\ \bullet & \omega = \text{Nominal frequency of the carrier frequency} \\ \bullet & \Delta\omega = \text{Frequency deviation.} \end{array} \tag{5.4}$$

5.3 Frequency Shift Keying (FSK) Demodulation

Once the modulated binary data has been transmitted, it needs to be received and demodulated. This is often accomplished by the use of band-pass filters. In the case of binary FSK, the receiver needs to utilize two band-pass filters that are tuned to the appropriate frequencies. Since the nominal carrier frequency and the frequency deviation are known, this is relatively straightforward. One band-pass filter will be centered at the frequency ω_1 and the other at ω_2. As the signal enters into the receiver, it passes through the respective filter and the corresponding bit value is made. This is shown in Fig. 5.3. In order to assure that the bits are decoded correctly, the frequency deviation needs to be chosen with the limitations of the filters in mind to eliminate crossover.

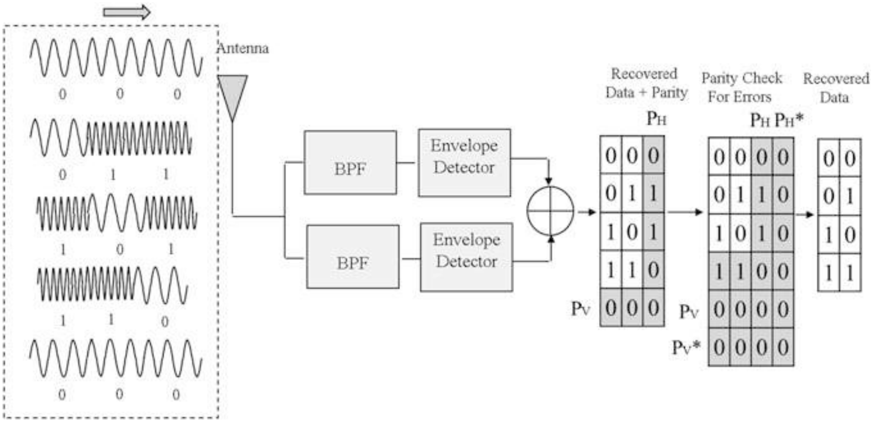

Fig. 5.3 Binary FSK detector utilizing two matched band-pass filters

5.4 FSK Bandwidth

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth in error control coding and modulation. The transmission bandwidth depends on the following:

- Spectral response of the encoded data
- Spectral response of the carrier frequency and
- Modulation type.

5.4.1 Spectral Response of the Encoded Data

In digital communications, data is generally referred to as a non-periodic digital signal. It has two values:

- Binary 1 = high, period = T
- Binary 0 = low, period = T

Also, data can be represented in two ways:

- Time-domain representation and
- Frequency-domain representation

The time-domain representation (Fig. 5.4a), known as non-return-to-zero (NRZ), is given by:

$$\begin{aligned} V(t) &= V \quad < 0 < t\ < T \\ &= 0 \quad ;\text{elsewhere} \end{aligned} \tag{5.5}$$

The frequency-domain representation is given by “Fourier transform”:

$$V(\omega) = \int_0^T V \cdot e^{-j\omega t} dt \tag{5.6}$$

$$|V(\omega)| = VT\left[\frac{\sin(\omega T/2)}{\omega T/2}\right] \tag{5.7}$$

$$P(\omega) = \left(\frac{1}{T}\right)|V(\omega)|^2 = V^2 T\left[\frac{\sin(\omega T/2)}{\omega T/2}\right]^2$$

Here, $P(\omega)$ is the power spectral density. This is plotted in Fig. 5.4b. The main lobe corresponds to the fundamental frequency, while side lobes correspond to harmonic components. The bandwidth of the power spectrum is proportional to the

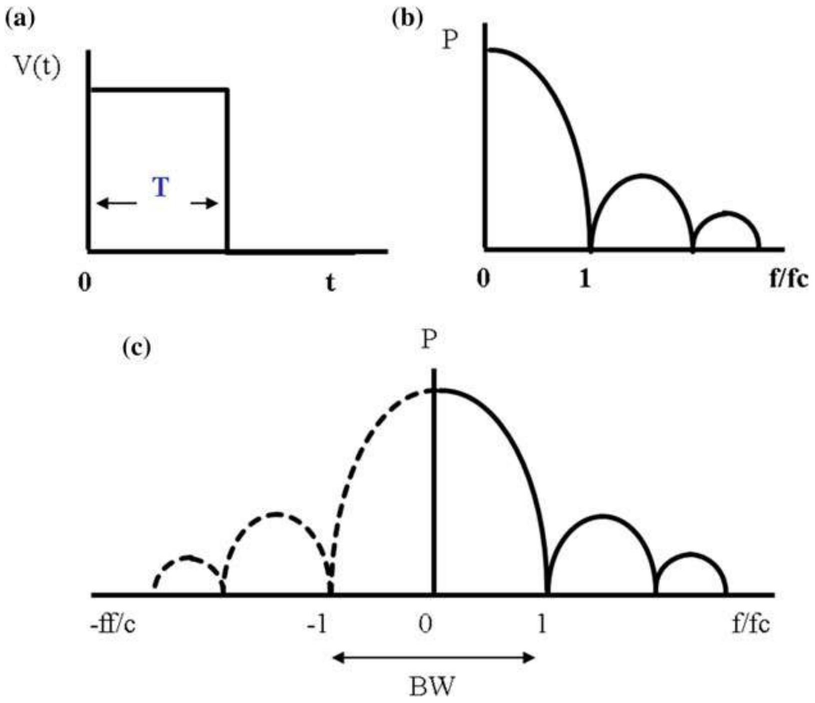

Fig. 5.4 **a** Discrete-time digital signal, **b** its one-sided power spectral density, and **c** two-sided power spectral density. The bandwidth associated with the non-return-to-zero (NRz) data is $2R_b$, where R_b is the bit rate

frequency. In practice, the side lobes are filtered out, since they are relatively insignificant with respect to the main lobe. Therefore, the one-sided bandwidth is given by the ratio $f/f_b = 1$. In other words, the one-sided bandwidth $= f = f_b$, where $f_b = R_b = 1/T$, T being the bit duration.

The general equation for two-sided response is given by:

$$V(\omega) = \int_{-\propto}^{\propto} V(t) \cdot e^{-j\omega t} dt$$

In this case, $V(\omega)$ is called the two-sided spectrum of $V(t)$. This is due to both positive and negative frequencies used in the integral. The function can be either a voltage or a current. Figure 5.4c shows the two-sided response, where the bandwidth is determined by the main lobe as shown below:

$$\text{Two sided bandwidth (BW)} = 2R_b(R_b = \text{Bit rate before coding}) \tag{5.8}$$

Important Notes:

1. If R_b is the bit rate before coding, and if the data is NRZ, then the bandwidth associated with the raw data will be $2R_b$. For example, if the bit rate before coding is 10 kb/s, then the bandwidth associated with the raw data will be 2×10 kb/s = 20 kHz.
2. If R_b is the bit rate before coding, code rate is r, and if the data is NRZ, then the bit rate after coding will be R_b (coded) = R_b(uncoded)r. The corresponding bandwidth associated with the coded data will be $2R_b$ (coded) = $2R_b$ (uncoded)/r. For example, if the bit rate before coding is 10 kb/s and the code rate $r = 1/2$, the coded bit rate will be R_b (coded) = R_b (uncoded)/r = 10/0.5 = 20 kb/s. The corresponding bandwidth associated with the coded data will be $2 \times 20 = 40$ kHz.

5.4.2 Spectral Response of the Carrier Frequency Before Modulation

A carrier frequency is essentially a sinusoidal waveform, which is periodic and continuous with respect to time. It has one frequency component. For example, the sine wave is described by the following time-domain equation:

$$V(t) = V_p \sin(\omega t_c) \tag{5.9}$$

where

$$V_P = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$
- f_c = Carrier frequency in Hz

Figure 5.5 shows the characteristics of a sine wave and its spectral response. Since the frequency is constant, its spectral response is located in the horizontal axis and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

5.4.3 FSK Bandwidth at a Glance

In FSK, the frequency of the carrier changes in two discrete levels, in accordance with the input signals. We have:

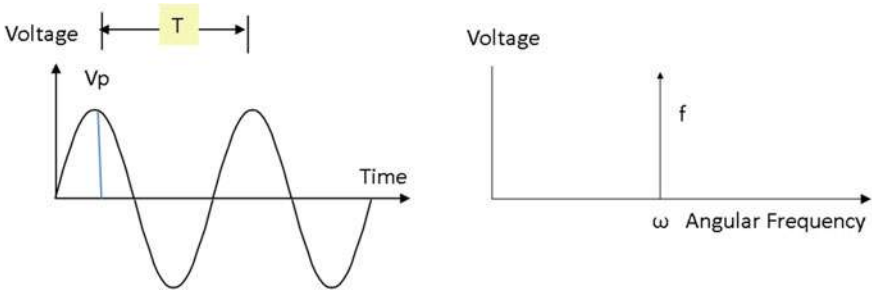

Fig. 5.5 High-frequency carrier response

- Input Data: $m(t) = 0 \text{ or } 1$
- Carrier Frequency: $C(t) = A\cos(\omega t)$
- Modulated Carrier: $S(t) = A\cos(\omega - \Delta\omega)t, \text{For } m(t) = 1$
  $S(t) = A\cos(\omega + \Delta\omega)t, \text{For } m(t) = 0$

where

- $S(t)$ = The modulated carrier
- A = Amplitude of the carrier
- ω = Nominal frequency of the carrier
- $\Delta\omega$ = Frequency deviation

The spectral response is depicted in Fig. 5.6. Notice that the carrier frequency after FSK modulation varies back and forth from the nominal frequency f_c by $\pm\Delta f_c$, where Δf_c is the frequency deviation. The FSK bandwidth is given by:

$$\begin{aligned} \mathrm{BW} &= 2(f_b + \Delta f_c) \\ &= 2f_b(1 + \Delta f_c/f_b) \\ &= 2f_b(1 + \beta) \end{aligned} \tag{5.10}$$

where $\beta = \Delta f/f_b$ is known as the modulation index and f_b is the coded bit frequency (bit rate R_b). The above equation is also known as "Carson's rule."

Problem

Given:

- Bit rate before coding: $R_{B1} = 10$ kb/s
- Code rate: $r = 8/15$
- Modulation: FSK
- Modulation index $\beta = 1$

Find:

(a) the bit rate after coding: R_{B2}
(b) Transmission bandwidth: BW

Solution

(a) Bit rate after coding (R_{B2}):
$R_{B2} = R_{B1}/r = 10$ kb/s $(15/8) = 18.75$ kb/s
(b) Transmission BW $= 2\ R_{B2}(1+\beta)$
$= 2 \times 18.75$ kb/s $(1 + 1) = 75$ kHz.

5.5 BER Performance

It is well known that an (n, k) bock code, where k = number of information bits and n = number of coded bits, can correct t errors [4, 5]. A measure of coding gain is then obtained by comparing the uncoded word error WER_U, to the coded word WER_C. We examine this by means of the following analytical means.

Let the uncoded word error be defined as (WER_U). Then, with FSK modulation, the uncoded BER will be given by:

$$\mathrm{BER}_U = 0.5\,\mathrm{EXP}(-E_B/2N_0) \tag{5.11}$$

The probability that the uncoded word (WER_U) will be received in error is 1 minus the product of the probabilities that each bit will be received correctly. Thus, we write:

$$\mathrm{WER}_U = 1-(1-\mathrm{BER}_U)^k \tag{5.12}$$

Let the coded word error be defined as (WER_C). Since $n > k$, the ratio of coded bit energy to noise will be modified to E_c/N_0, where $E_c/N_0 = E_b/N_0 + 10\log(k/n)$. Therefore, the coded BER_c will be:

$$\mathrm{BER}_C = 0.5\,\mathrm{EXP}(-E_c/2N_0) \tag{5.13}$$

The corresponding coded word error rate is:

$$\mathrm{WER}_C = \sum_{k=t+1}^{n} \binom{n}{k} \mathrm{BER}_C^K (1 - \mathrm{BER}_C)^{n-k} \tag{5.14}$$

When $\mathrm{BER}_c < 0.5$, the first term in the summation is the dominant one; therefore, equation can be simplified as

$$\mathrm{WER}_C \approx \binom{n}{k} \mathrm{BER}_c^k (1 - \mathrm{BER}_c)^{n-k} \tag{5.15}$$

Using (15, 8) block code ($n = 15$, $k = 8$, $t = 1$), we obtain the coded and the uncoded WER as shown in Fig. 5.7. Coding gain is the difference in E_b/N_0 between the two curves. Notice that at least 3–4-db coding gain is available in this example where $r = k/n = 8/15$.

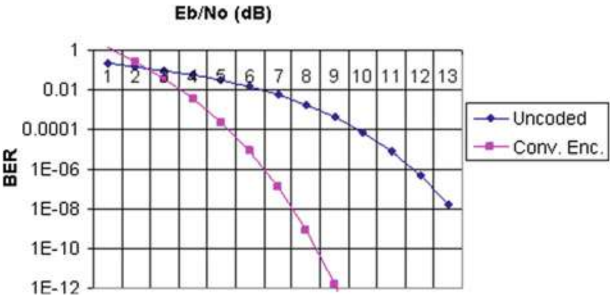

Fig. 5.7 Typical error performance in AWGN

5.6 Conclusions

- This chapter presents FSK modulation and its attributes.
- Numerous illustrations are provided to show how frequency of the carrier changes in discrete levels in accordance with the input digital signal, while the amplitude of the carrier remains the same.
- The Fourier transform is used to derive the spectral components, and FSK bandwidth is calculated.
- Bit error rate (BER) performance is presented.
- These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

Chapter 6
Phase Shift Keying (PSK)

Topics

- Introduction
- Binary Phase Shift Keying (BPSK) Modulation
- QPSK Modulation
- 8PSK Modulation
- 16PSK Modulation
- PSK spectrum and Bandwidth
- SSB Spectrum and Bandwidth

6.1 Introduction

In phase shift keying (PSK), the phase of the carrier changes in discrete levels in accordance with the input digital signal, while the amplitude of the carrier remains the same. This is shown in Fig. 6.1, where

- $m(t)$ is the input modulating digital signal,
- $C(t)$ is the carrier frequency, and
- $S(t)$ is the PSK-modulated carrier frequency.

As shown in the figure, the digital binary signal changes the phase of the carrier on two discrete levels. This enables the receiver to extract the digital signal by demodulation. Notice that the phase of the carrier changes in accordance with the input signal, while the amplitude of the carrier does not change after modulation. However, it can be shown that the modulated carrier $S(t)$ contains several spectral components, requiring frequency domain analysis.

In the following sections, the above disciplines in PSK modulation will be presented, along with the respective spectrum and bandwidth. These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

6.2 Binary Phase Shift Keying (BPSK)

6.2.1 BPSK Modulation

Phase shift keying (PSK) is a method of digital modulation that utilizes phase shifting of the relative phase content of the signal [1–3]. The signal to be modulated and transmitted is binary, which is encoded before modulation. This is an indispensable task in digital communications, where redundant bits are added with the raw data that enable the receiver to detect and correct bit errors, if they occur during transmission [4–16]. While there are many error-coding schemes available, we will use a simple coding technique, known as “Block Coding” to illustrate the concept.

Figure 6.2 shows an encoded BPSK modulation scheme using (15, 8) block code where an 8-bit data block is formed as M-rows and N-columns ($M = 4$, $N = 2$). The product $MN = k = 8$ is the dimension of the information bits before coding. Next, a horizontal parity P_H is appended to each row and a vertical parity P_V is appended to each column. The resulting augmented dimension is given by the product $(M + 1)\ (N + 1) = n = 15$, which is then PSK modulated and transmitted row by row. The rate of this coding scheme is given by

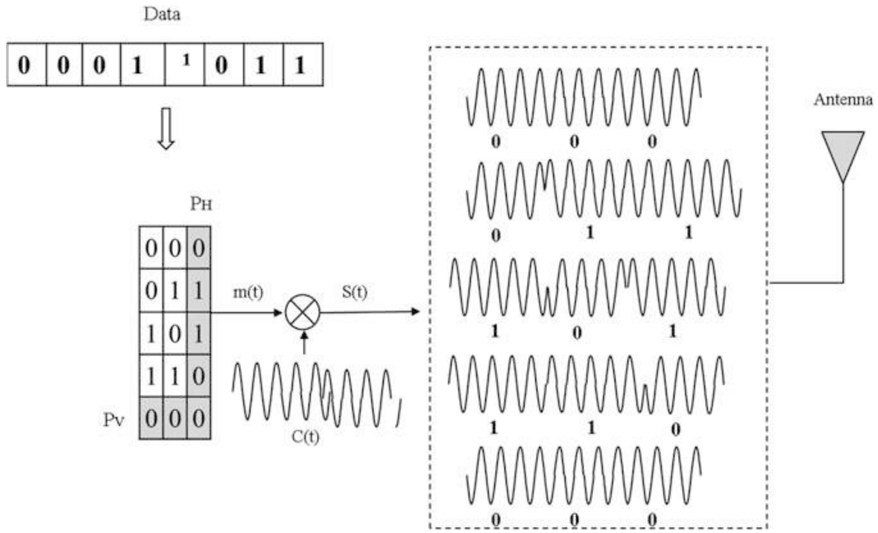

Fig. 6.2 Binary phase shift keying (BPSK) modulation. The input encoded data block is transmitted row by row. The phase of the carrier changes in accordance with the input digital signal

$$\text{Code Rate} : r = (MN)/[(M+1)(N+1)] = (4 \times 2)/5 \times 3) = 8/15 \tag{6.1}$$

The coded bit rate R_{b2} is given by:

$$R_{b2} = \text{Uncoded Bit Rate}/\text{Code Rate} = R_{b1}/r = R_{b1}(15/8) \tag{6.2}$$

Next, the coded bits are modulated by means of the PSK modulator as shown in the figure. Here,

- The Input digital signal is the encoded bit sequence we want to transmit;
- Carrier is the radio frequency without modulation;
- Output is the PSK-modulated carrier, which has two phases corresponding to the binary input signals;
- For binary signal 0, $\varphi = 0^\circ$; and
- For binary signal 1, $\varphi = 180^\circ$.

As shown in Fig. 6.2, the phase of the carrier changes in two discrete levels, in accordance with the input signals. Here, we have the following:

- Input Data : $m(t) = 0 \text{ or } 1$
- Carrier Frequency : $C(t) = A\cos(\omega_{ct})$
- Modulated Carrier : $S(t) = A_c \cos[\omega_c t + 2\pi/M)m(t)] \quad m(t) = 0,\ 1,\ 2,\ 3, \ldots M-1$ (6.3)

where,

- A_c = Amplitude of the carrier frequency
- ω_c = Angular frequency of the carrier
- $M = 2, 4, 8, 16, \ldots$
- In BPSK, there are two phases 1 bit/phase($M = 2$) (6.4)
- In QPSK, there are four phases, 2-bits/phase, $M = 4$
- In 8PSK, there are 8 phases, 3-bits/phase, $M = 8$
- In 16PSK, there are 16 phases, 4-bits/phase, $M = 16$

We can also represent the BPSK modulator as a signal constellation diagram with $M = 2$, 1 bit per phase. This is shown in Fig. 6.3, where the input raw data, having a bit rate R_{b1}, is encoded by means of a rate r encoder. The encoded data, having a bit rate R_{b2}, = $R_{b1}r$ ($r < 1$), is modulated by the BPSK modulator as shown in Fig. 6.3.

The BPSK modulator takes one bit at a time to construct the phase constellation having two phases, also known as "Symbols," where each symbol represents one bit. The symbol rate is therefore the same as the encoded bit rate R_{b2}.

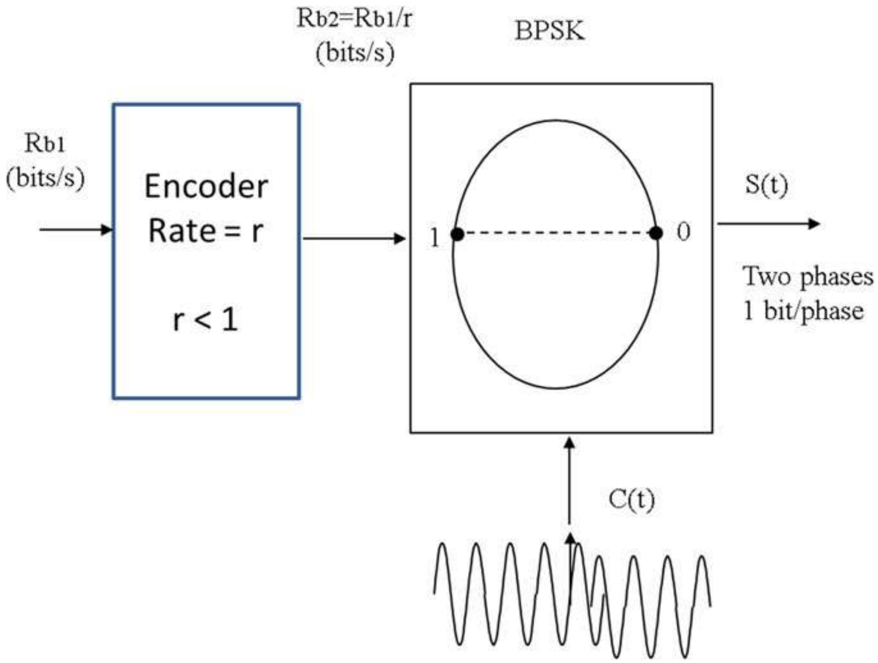

Fig. 6.3 BPSK signal constellation having 2 symbols, 1-bit per symbol

Therefore, the BPSK modulator has the following specifications:

- 2 phases or 2 symbols;
- 1-bit/symbol,

The above specifications govern the transmission bandwidth, as we shall see later.

6.2.2 BPSK Demodulation

Once the modulated binary data has been transmitted, it needs to be received and demodulated. This is often accomplished with the use of a phase detector, typically known as phase-locked loop (PLL). As the signal enters the receiver, it passes through the PLL. The PLL locks the incoming carrier frequency and tracks the variations in frequency and phase. This is known as coherent detection technique, where the knowledge of the carrier frequency and phase must be known to the receiver.

Figure 6.4 shows a simplified diagram of a BPSK demodulator along with the data recovery process. In order to assure that the bits are decoded correctly, the phase deviation needs to be chosen with the limitations of the PLL in mind to eliminate crossover.

6.3 QPSK Modulation

In QPSK, the input raw data, having a bit rate R_{b1}, is encoded by a rate r ($r < 1$) encoder. The encoded data, having a bit rate $R_{b2} = R_{b1}/r$, is serial to parallel converted into two parallel streams. The encoded bit rate, now reduced in speed by a factor of two, is modulated by the QPSK modulator as shown in Fig. 6.5.

The QPSK modulator takes one bit from each stream to construct the phase constellation having four phases, also known as "Symbols," where each symbol represents two bits. The symbol rate is therefore reduced by a factor of two. The QPSK modulator has four phases or 4 symbols, 2-bits/symbol as shown in the figure.

Therefore, the QPSK modulator has the following specifications:

- 4 phases or 4 symbols
- 2-bits/symbol

The above specifications govern the transmission bandwidth, as we shall see later.

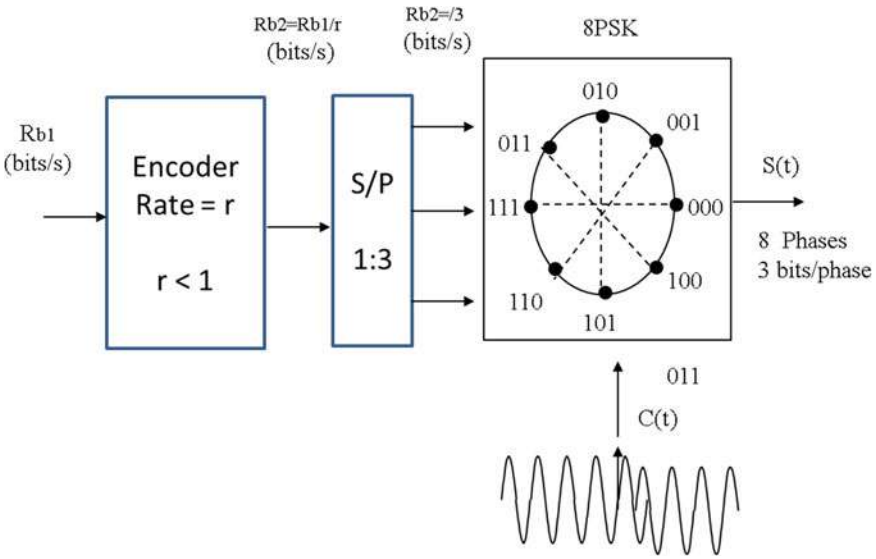

Fig. 6.6 8PSK signal constellation having 8 symbols, 3-bits per symbol

6.4 8PSK Modulation

In 8PSK, the input raw data, having a bit rate R_{b1}, is encoded by a rate r ($r < 1$) encoder. The encoded data, having a bit rate $R_{b2} = R_{b1}/r$, is serial to parallel converted into three parallel streams. The encoded bit rate, now reduced in speed by a factor of three, is modulated by the 8PSK modulator as shown in Fig. 6.6.

The 8PSK modulator takes one bit from each stream to construct the phase constellation having 8 phases, also known as "Symbols," where each symbol represents 3-bits. The symbol rate is therefore reduced by a factor of 3. The 8PSK modulator has 8 phases or 8 symbols, 3-bits/symbol as shown in the figure.

Therefore, the 8PSK modulator has the following specifications:

- 8 phases or 8 symbols;
- 3-bits/symbol.

The above specifications govern the transmission bandwidth, as we shall see later.

6.5 16PSK Modulation

In 16PSK, the input raw data, having a bit rate R_{b1}, is encoded by means of a rate r ($r < 1$) encoder. The encoded data, having a bit rate $R_{b2} = R_{b1}/r$, is serial to parallel converted into four parallel streams. The encoded bit rate, now reduced in speed by a factor of four, is modulated by the 16PSK modulator as shown in Fig. 6.7.

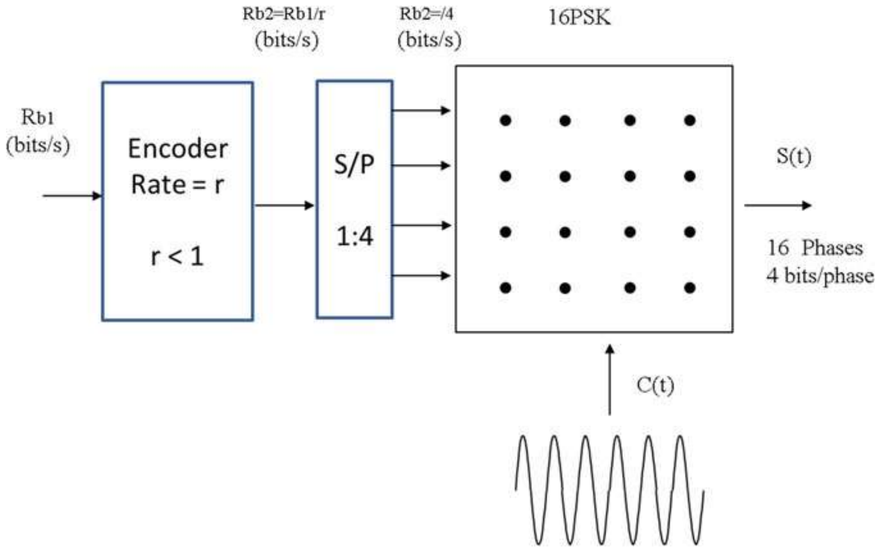

Fig. 6.7 16PSK signal constellation having 16 symbols, 4-bits per symbol. Here, each symbol is represented by a *dot*, where each dot represents 4-bits

The 16PSK modulator takes one bit from each stream to construct the phase constellation having 16 phases, also known as “Symbols,” where each symbol represents four bits. The symbol rate is therefore reduced by a factor of four. Therefore, the 16PSK modulator has 16 phases or 16 symbols, 4-bits/symbol as shown in the figure.

Therefore, the 16PSK modulator has the following specifications:

- 16 phases or 16 symbols;
- 4-bits/symbol.

The above specifications govern the transmission bandwidth, as we shall see later.

Table 6.1 shows the number of phases and the corresponding bits per phase for MPSK modulation schemes for $M = 2, 4, 8, 16, 32, 64$, etc.

6.6 PSK Spectrum and Bandwidth

In wireless communications, the scarcity of RF spectrum is well known. For this reason, we have to be vigilant about using transmission bandwidth in error control coding and modulation. The transmission bandwidth depends on:

- Spectral response of the encoded data;
- Spectral response of the carrier phase; and
- Modulation type.

Let us take a closer look:

6.6.1 Spectral Response of the Encoded Data

In digital communications, data is generally referred to as a non-periodic digital signal. It has two values:

- Binary-1 = High, Period = T
- Binary-0 = Low, Period = T

Also, data can be represented in two ways:

- Time domain representation and
- Frequency domain representation

The time domain representation (Fig. 6.8a), known as non-return-to-zero (NRZ), is given by:

$$\begin{aligned} V(t) &= V \quad < 0 < t < T \\ &= 0 \quad \text{elsewhere} \end{aligned} \tag{6.5}$$

The frequency domain representation is given by “Fourier Transform”:

$$V(\omega) = \int_{0}^{T} V \cdot e^{-j\omega t} dt \tag{6.6}$$

$$\begin{aligned} |V(\omega)| &= 2\left(\frac{V}{\omega}\right)\sin\left(\frac{\omega T}{2}\right) = VT\left[\frac{\sin(\omega T/2)}{\omega T/2}\right] \\ P(\omega) &= \left(\frac{1}{T}\right)|V(\omega)|^2 = V^2 T\left[\frac{\sin(\omega T/2)}{\omega T/2}\right]^2 \end{aligned} \tag{6.7}$$

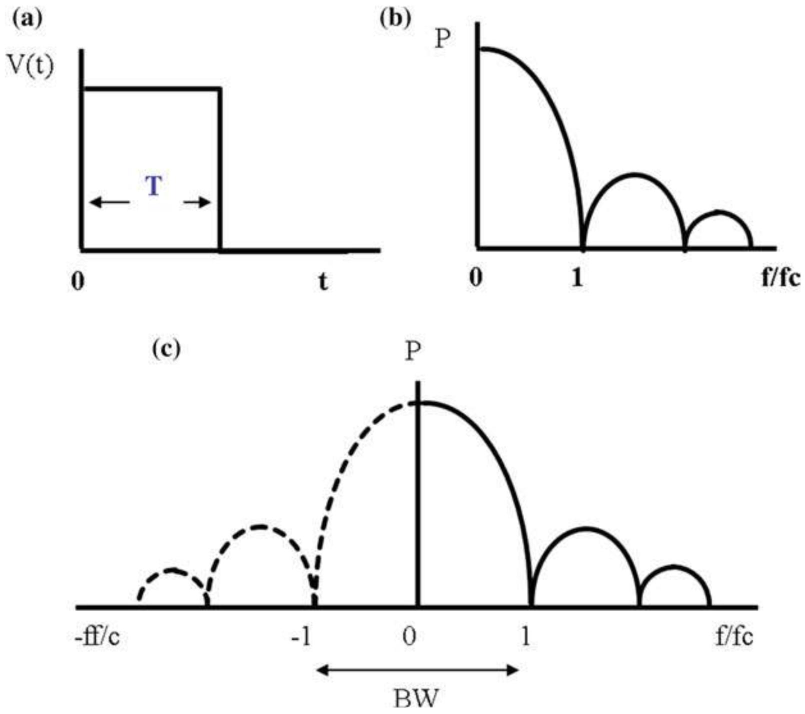

Fig. 6.8 **a** Discrete time digital signal **b** it is one-sided power spectral density and **c** two-sided power spectral density. The bandwidth associated with the non-return-to-zero (NRz) data is $2R_b$, where R_b is the bit rate

Here, $P(\omega)$ is the power spectral density. This is plotted in Fig. 6.8b. The main lobe corresponds to the fundamental frequency, while the side lobes correspond to harmonic components. The bandwidth of the power spectrum is proportional to the frequency. In practice, the side lobes are filtered out, since they are relatively insignificant with respect to the main lobe. Therefore, the one-sided bandwidth is given by the ratio $f/fb = 1$. In other words, the one-sided bandwidth $= f = f_b$, where $f_b = R_b = 1/T$, T being the bit duration.

The general equation for two-sided response is given by:

$$V(\omega) = \int_{-\propto}^{\propto} V(t) \cdot e^{-j\omega t} dt$$

In this case, $V(\omega)$ is called the two-sided spectrum of $V(t)$. This is due to both positive and negative frequencies used in the integral. The function can be either a voltage or a current. Figure 6.8c shows the two-sided response, where the bandwidth is determined by the main lobe as shown below:

$$\text{Two-sided bandwidth (BW)} = 2R_b\ (R_b = \text{Bit rate before coding}) \tag{6.8}$$

6.6.2 Spectral Response of the Carrier Before Modulation

A carrier frequency is a sinusoidal waveform, which is periodic and continuous with respect to time. It has one phase component. For example, the sine wave is described by the following time domain equation:

$$V(t) = V_p \sin(\omega_c t) \tag{6.9}$$

Where

$$Vp = \text{Peak voltage}$$

- $\omega_c = 2\pi f_c$
- f_c = Carrier phase in Hz

Figure 6.9 shows the characteristics of a sine wave and its spectral response. Since the phase is constant, its spectral response is located in the horizontal axis and the peak voltage is shown in the vertical axis. The corresponding bandwidth is zero.

6.6.3 BPSK Spectrum

In BPSK, the input is a digital signal and it contains an infinite number of harmonically related sinusoidal waveforms. This is given by (see Sect. 6.6.1):

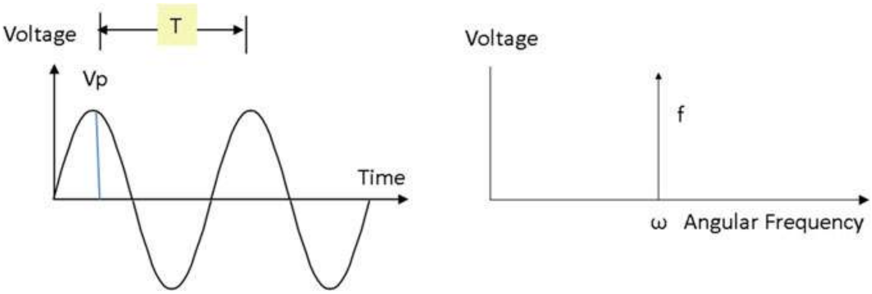

Fig. 6.9 High-frequency carrier response

$$|V(\omega)| = 2\left(\frac{V}{\omega}\right)\sin\left(\frac{\omega T}{2}\right) = VT\left[\frac{\sin(\omega T/2)}{\omega T/2}\right] \tag{6.10}$$

Here, $V(\omega)$ is the frequency domain representation of the input digital signal, which has a $\sin(x)/x$ response that governs the phase of the carrier frequency.

With $V(t) = m(t)$, we write the following as:

$$S(t) = A_c \cos[\omega_c t + \beta m(t)] \tag{6.11}$$

where β is the phase deviation index of the carrier and $m(t)$ has a $\sin(x)/x$ response, which is given by

$$m(t) = VT\left[\frac{\sin(\omega m T/2)}{\omega m T/2}\right] \tag{6.12}$$

Therefore, the spectral response after BPSK modulation also has a $\sin(x)/x$ response, which is the shifted version of the NRZ data, centered on the carrier frequency f_c, as shown in Fig. 6.10. The transmission bandwidth associated with the main lobe is given by

$$\begin{aligned} \text{BW (BPSK)} &\approx 2R_{b2}/\text{Bit per Phase} \\ &\approx 2R_{b2}/1 \approx 2R_{b2} \end{aligned} \tag{6.13}$$

where R_{b2} is the coded bit rate (bit frequency). Notice that the BPSK bandwidth is the same the ASK bandwidth. It may be noted that the higher-order spectral components are filtered out.

Problem 6.1
Given:

- Uncoded input bit rate: R_{b1} = 10 kb/s
- Code rate: r = 8/15
- Carrier frequency fc = 1 MHz
- Modulation: BPSK, QPSK, 8PSK, and 16PSK

Find:

(a) Coded bit rate R_{b2}
(b) BPSK bandwidth (BW)
(c) QPSK bandwidth (BW)
(d) 8PSK bandwidth (BW)
(e) 16PSK bandwidth (BW)

Solution:

(a) Coded bit rate: $R_{B2} = R_{B1}/r$ = 10 kb/(15/8) = 18.75 kb/s
(b) BPSK bandwidth: $BW = 2R_{B2}/1 = 2 \times 18.75 = 37.5$ kHz
(c) QPSK bandwidth: $BW = 2R_{B2}/2 = 2 \times 18.75/2 = 18.75$ kHz
(d) 8PSK bandwidth: $BW = 2R_{B2}/3 = 2 \times 18.75/3 = 12.5$ kHz
(e) 16PSK bandwidth: $BW = 2R_{B2}/4 = 2 \times 18.755/4 = 9.375$ kHz

NOTE: Higher-order PSK modulation is bandwidth efficient.

Problem 6.2
Given:

- Input bit rate R_{b1} = 10 kb/s
- Code rate r = 1/2
- Modulation: BPSK, QPSK, 8PSK, 16PSK

Find:

(a) Bit rate after coding R_{b2}
(b) Transmission bandwidth BW

Solution:

(a) $R_{b2} = R_{b1}/r$ = 10 kb/s × 2 = 20 kb/s
(b) Transmission bandwidth:

- BPSK $BW = 2R_{b2}$/Bits per Symbol = 2 × 20 kb/s/1 = 40 kHz
- QPSK $BW = 2R_{b2}$/Bits per symbol = 2 × 20 kb/s/2 = 20 kHz
- 8PSK $BW = 2R_{b2}$/Bits per symbol = 2 × 20 kb/s/3 = 13.33 kHz
- 16PSK $BW = 2R_{b2}$/Bits per symbol = 2 × 20 kb/s/4 = 10 kHz

NOTE: Higher-order PSK modulation is bandwidth efficient.

6.7 Conclusions

- This chapter presents PSK modulation and its attributes.
- Numerous illustrations are provided to show how phase of the carrier changes in discrete levels in accordance with the input digital signal, while the amplitude of the carrier remains the same.
- The Fourier transform is used to derive the spectral components and PSK bandwidth is calculated.
- These materials have been augmented by diagrams and associated waveforms to make them easier for readers to grasp.

Chapter 7
N-Ary Coded Modulation

Topics

- Introduction
- N-ary Complementary Convolutional Coding and M-ary Modulation
- N-ary Complementary Orthogonal Coding and M-ary Modulation
- Coding Gain and Bandwidth
- Conclusions

7.1 Introduction

N-ary coded modulation is a multi-level channel coding and multi-level modulation technique, where instead of coding one bit at a time two or more bits are encoded simultaneously and then modulated by means of M-ary modulation. In its most basic construction, the input serial data is converted into several parallel streams. These parallel bit streams, now reduced in speed, are mapped into a bank of *N* unique convolutional or orthogonal codes. The coded information bits are then modulated by an M-ary PSK modulator and transmitted through a channel. At the receiver, the decoder recovers the data by means of code correlation. A lookup table at the receiver contains the input/output bit sequences. Upon receiving an encoded data pattern, the receiver validates the received data pattern by means of code correlation.

In this chapter, we will present the key concept, underlying principles and practical application of N-ary coded modulation schemes, offering spectrum efficiency with improved error correction capabilities. Construction of N-ary coded modulation schemes based on convolutional and orthogonal codes will be presented to illustrate the concept.

7.2 N-Ary Convolutional Coding and M-Ary Modulation

7.2.1 Background

In convolutional coding, a sequence of data signals is transformed into a longer sequence that contains enough redundancy to protect the data [1–6]. This type of error control is also classified as forward error control coding (FECC), because these methods are often used to correct errors that are caused by channel noise. In a typical convolutional encoder, k information bits enter into the encoder sequentially. The convolutional encoder generates n parity bits as encoded bits ($n > k$). The code rate is defined as $r = k/n$. The coded information bits are modulated and transmitted through a channel.

Another class of convolutional codes, known as parallel concatenated codes or turbo codes [7–9], is popular in wireless communications because of its superior error control capabilities. Yet, turbo codes are limited to two convolutional codes connected in parallel, where delays are introduced due to concatenation and interleaving, thereby limiting high-speed data communications in wireless communications. In addition, it is also too complex to realize.

In this section, a modified technique, defined as N-ary complementary convolutional coding, along with M-ary modulation, is presented to overcome these problems. N-ary complementary convolutional coding is a multi-level convolutional code, where more than two convolutional codes can be used simultaneously to further enhance coding gain without concatenation and interleaving.

7.2.2 Generation of Complementary Convolutional Codes

In a typical convolutional encoder, k information bits enter into the encoder sequentially. The encoder generates n parity bits as encoded bits ($n > k$). The code rate is defined as $r = k/n$. The proposed N-ary convolutional codes are a block of n-convolutional codes and their complements.

In its most basic construction, as shown in Fig. 7.1, a typical convolutional encoder is taken as the basis to generate a block of n-convolutional codes. Next, each convolutional code is inverted to construct a block of n-antipodal codes. Therefore, a block of N-ary convolutional code has n-convolutional codes and n-antipodal codes, for a total of $2n = N$ complementary convolutional codes. In short, we shall define this as N-ary complementary convolutional codes.

Let us consider Fig. 7.1 once again and assume that the input bit sequence to the encoder is:

$$m(t) = 1\ 0\ 1 \tag{7.1}$$

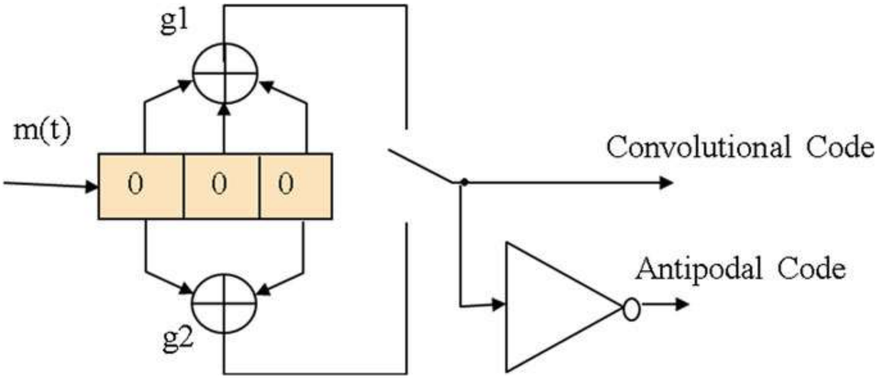

Fig. 7.1 Generation of N-ary complimentary convolutional codes

Which is described by the following polynomial?

$$\begin{aligned} m(X) &= 1 + 0X + 1X^2 \\ &= 1 + X^2 \end{aligned} \tag{7.2}$$

The encoder is described by the following generator polynomials:

$$\begin{aligned} g1(X) &= 1 + X + X^2 \\ g2(X) &= 1 + X^2 \end{aligned} \tag{7.3}$$

Then, the product of polynomials for the encoder can be described as follows:

$$\begin{aligned} m(X)g1(X) &= (1 + X^2)(1 + X + X^2) = 1 + X + X^3 + X^4 \\ m(X)g2(X) &= (1 + X^2)(1 + X^2) = 1 + X^4 \end{aligned} \tag{7.4}$$

with $X^2 + X^2 = 0$, the output bit sequence can be found as $U(X) = m(X)g1(\mathrm{X})$ multiplexed with $m(X)g2(X)$, where $m(X)$ is the input bit sequence [7]. We write the above two equations as follows:

$$\begin{array}{l} \mathrm{m(X)g1(X)} = 1 + 1\mathrm{X} + 0\mathrm{X}^2 + 1\mathrm{X}^3 + 1\mathrm{X}^4 \\ \mathrm{m(X)g2(X)} = 1 + 0\mathrm{X} + 0\mathrm{X}^2 + 0\mathrm{X}^3 + 1\mathrm{X}^4 \\ \hline \mathrm{U1U2} = (1,1) + (1,0) + (0,0) + (1,0) + (1,1) \end{array} \tag{7.5}$$

11 01 10 01 11	00 10 01 10 00

Fig. 7.2 N-ary complimentary convolutional code blocks

Taking only the coefficients, we obtain the desired convolutional code sequence corresponding to the input bit sequence $m(T) = 101$ as follows:

$$\text{Convolutional Code} = 1\,1 \quad 1\,0 \quad 0\,0 \quad 1\,0 \quad 1\,1 \tag{7.6}$$

The corresponding antipodal code is obtained simply by inverting the convolutional code as shown in the figure. This is given by:

$$\text{Antipodal Code} = 0\,0 \quad 0\,1 \quad 1\,1 \quad 0\,1 \quad 0\,0 \tag{7.7}$$

As can be seen, each 3-bit data corresponds to a unique 10-bit convolutional code. Antipodal code is just the inverse of the convolutional codes. Since a 3-bit sequence has 8 combinations, the above convolutional encoder generates 8 unique convolutional codes and 8 unique antipodal codes, for a total of 16 complementary convolutional codes. These code blocks are displayed in Fig. 7.2.

7.2.3 2-Ary Convolutional Coding with QPSK Modulation

A 2-ary ($N = 2$) coded QPSK modulator can be constructed by inverse multiplexing the incoming traffic into 6-parallel streams as shown in Fig. 7.3. These bit streams, now reduced in speed by a factor of 6, are partitioned into two 8 × 3 data blocks. The first 8 × 3 data block maps the 8 × 10 convolutional code block, and the next 8 × 3 data block maps the next 8 × 10 antipodal code block. These code blocks are stored in two 8 × 10 ROMs. The output of each ROM is a unique 10-bit

convolutional/antipodal code, which is modulated by a QPSK modulator using the same carrier frequency. The code rate is given by:

$$\text{Code Rate: } r = 6/10 = 3/5 \tag{7.8}$$

Since there are two convolutional waveforms (one convolutional and one antipodal), the number of errors that can be corrected is doubled. Moreover, the transmission bandwidth is also reduced, which is given by:

Transmission bandwidth: $BW = 2R_{b2}/\text{bits per symbol Hz}$

$$B = 2R_{b2}/2 = R_{b2} \tag{7.9}$$

where $R_{b2} = R_{b1}/r$. R_{b2} is the coded bit rate, and R_{b1} is the uncoded bit rate.

7.2.4 4-Ary Convolutional Coding with 16PSK Modulation

A 4-ary ($N = 4$) coded 16PSK modulator can be constructed by inverse multiplexing the incoming traffic into 8-parallel streams as shown in Fig. 7.4. These bit streams, now reduced in speed by a factor of 8, are partitioned into four 4 × 2 data

blocks. Each 4 × 2 data block maps corresponding 4 × 10 convolutional code blocks. These code blocks are stored in four 4 × 10 ROMs. The output of each ROM is a unique 10-bit convolutional/antipodal code, which is modulated by a 16PSK modulator using the same carrier frequency. The code rate is given by:

$$\text{Code Rate:} r = 8/10 = 4/5 \tag{7.10}$$

Since there are four convolutional waveforms (two convolutional and two antipodal), the number of errors that can be corrected is quadrupled. Moreover, the transmission bandwidth is further reduced, which is given by:

Transmission bandwidth: $BW = 2R_{b2}$/bits per symbol Hz

$$= 2R_{b2}/4 = R_{b2}/2 \tag{7.11}$$

where $R_{b2} = R_{b1}/r$. R_{b2} is the coded bit rate, and R_{b1} is the uncoded bit rate.

7.3 N-Ary Convolutional Decoder

7.3.1 Correlation Receiver

Decoding is a process of code correlation. In this process, the receiver compares the received data with the expected data set to recover the actual data. The expected data is stored into a lookup table [see Table 7.1]:

- The lookup table at the receiver contains the input/output bit sequences.
- For $m = 3$, there are 8 possible output combinations of 3-bit data.
- For each combination of 3-bit data, there is a unique encoded 10-bit data (see table).
- The receiver receives one of 8 output sequences.
- Upon receiving an encoded data pattern, the receiver validates the received data pattern by means of code correlation.

Let us examine the correlation process using the following example:

- The input bit pattern $m = 0\ 1\ 1$
- Encoded transmit data: $U = 00\ 11\ 01\ 01\ 11$
- Received data with errors $U^* = 00\ 11\ 01\ 01$ **00**

Notice that the last two bits are in error, identified in bold. Now, let us determine how the receiver recovers the correct data, where the actual input data is $m = 0\ 1\ 1$. This is a correlation process, requiring several tests to validate the actual data. The correlation process is described below:

Test 0:

This test compares the received data with the 1st row of data stored in the lookup table and counts the number of positions it does not match. This is accomplished by MOD2 operation (EXOR operation). The result is presented below:

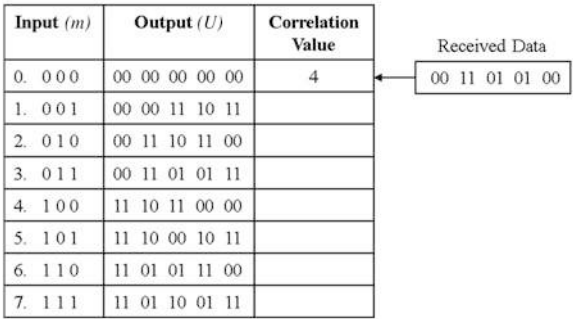
- Received data: 00 11 01 01 **00**
- 1st row of data in the lookup table: 00 00 00 00 00
- Mod-2 Add: 00 11 01 01 00

Table 7.1 Lookup table a

Input (m)	Output (U)
0. 0 0 0	00 00 00 00 00
1. 0 0 1	00 00 11 10 11
2. 0 1 0	00 11 10 11 00
3. 0 1 1	00 11 01 01 11
4. 1 0 0	11 10 11 00 00
5. 1 0 1	11 10 00 10 11
6. 1 1 0	11 01 01 11 00
7. 1 1 1	11 01 10 01 11

- Correlation value = 4 (count the number of 1’s in MOD2 Add)
- Verdict: No match, continue search.

Test-0: Look Up Table



Input (*m*)	Output (*U*)	Correlation Value
0. 0 0 0	00 00 00 00 00	4
1. 0 0 1	00 00 11 10 11	
2. 0 1 0	00 11 10 11 00	
3. 0 1 1	00 11 01 01 11	
4. 1 0 0	11 10 11 00 00	
5. 1 0 1	11 10 00 10 11	
6. 1 1 0	11 01 01 11 00	
7. 1 1 1	11 01 10 01 11	

Received Data

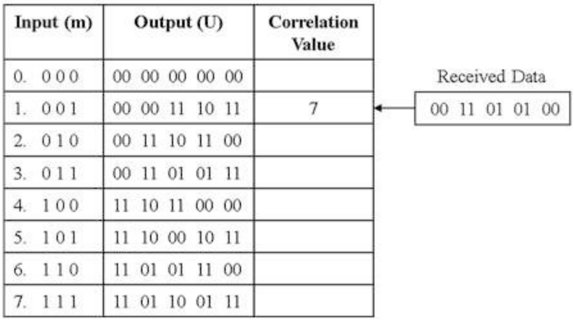
00 11 01 01 00

Test 1:

This test compares the received data with the 2nd row of data stored in the lookup table and counts the number of positions it does not match. This is accomplished by MOD2 operation (EXOR operation). The result is presented below:

- Received data: 00 11 01 01 00
- 2nd row of data in the lookup table: 00 00 11 10 11
- Mod-2 Add: 00 11 10 111 11
- Correlation value = 7
- Verdict: No match, continue search

Test 1: Look Up Table



Input (m)	Output (U)	Correlation Value
0. 0 0 0	00 00 00 00 00	
1. 0 0 1	00 00 11 10 11	7
2. 0 1 0	00 11 10 11 00	
3. 0 1 1	00 11 01 01 11	
4. 1 0 0	11 10 11 00 00	
5. 1 0 1	11 10 00 10 11	
6. 1 1 0	11 01 01 11 00	
7. 1 1 1	11 01 10 01 11	

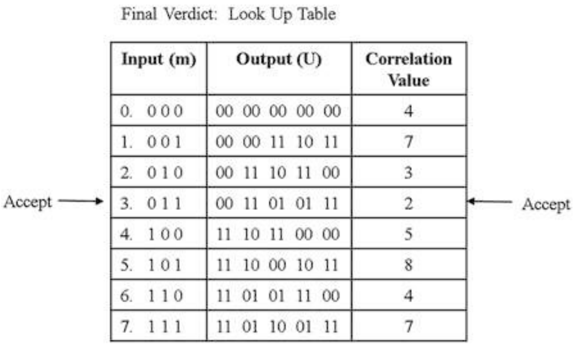
Received Data

00 11 01 01 00

The remaining tests may be conducted by using the same method to reach the final verdict as given below:

Final Verdict:

Collect the correlation values and validate the data that indicates the lowest correlation value. This is presented in the following lookup table.



Final Verdict: Look Up Table

Input (m)	Output (U)	Correlation Value
0. 0 0 0	00 00 00 00 00	4
1. 0 0 1	00 00 11 10 11	7
2. 0 1 0	00 11 10 11 00	3
3. 0 1 1	00 11 01 01 11	2
4. 1 0 0	11 10 11 00 00	5
5. 1 0 1	11 10 00 10 11	8
6. 1 1 0	11 01 01 11 00	4
7. 1 1 1	11 01 10 01 11	7

Accept
Accept

In examining the above table, we find that:

- The lowest correlation value is 2.
- The corresponding data is $m = 0\ 1\ 1$.
- This is the data which has been transmitted to the receiver.

7.3.2 *Error Correction Capabilities of N-Ary Convolutional Codes*

An n-bit convolutional code is generated by a rate ½ encoder of constraint length K where

$$n = 4K - 2 \tag{7.12}$$

In the above equation, K is the length of the shift register and the factor −2 is due to the initial content of the shift register, which is 000. For example, a rate ½ convolutional encoder with $K = 3$ generates 00 when the initial content of the shift register is 000. Therefore, the value of n is reduced by 2. Therefore, each 3-bit data sequence corresponds to a unique 10-bit convolutional code. The antipodal code is just the inverse of the convolutional codes. Since a 3-bit sequence has 8 combinations, the above convolutional encoder generates 8 unique convolutional codes and 8 unique antipodal codes, for a total of 16 complementary convolutional codes.

These code blocks are displayed in Fig. 7.2. As can be seen, each code is unique and there is a minimum distance $d_{\min}$ between any two convolutional codes where

$$d_{\min} \leq n/2 \tag{7.13}$$

This distance property can be used to detect an impaired received code by setting a threshold midway between two convolutional codes. It can be shown that an n-bit convolutional code can correct the errors, where

Table 7.2 Error correction capabilities of N-ary convolutional codes

Constraint length (K)	Number of errors corrected if the modulation scheme is (BPSK)	Number of errors corrected if the modulation scheme is (QPSK)	Number of errors corrected if the modulation scheme is (16PSK)
3	2	4	8
5	4	8	16
7	6	12	24
9	8	16	32

$$t \leq d_{\min}/2 \leq n/4 \leq (4K - 2)/4 \tag{7.14}$$

where

- t = Number of errors that can be corrected by means of a single convolutional code
- n = Code length
- K = Constraint length

The proposed N-ary coded modulation is a multi-level channel coding technique, where instead of coding one bit at a time two or more bits are encoded simultaneously. Therefore, we modify the above equation to obtain

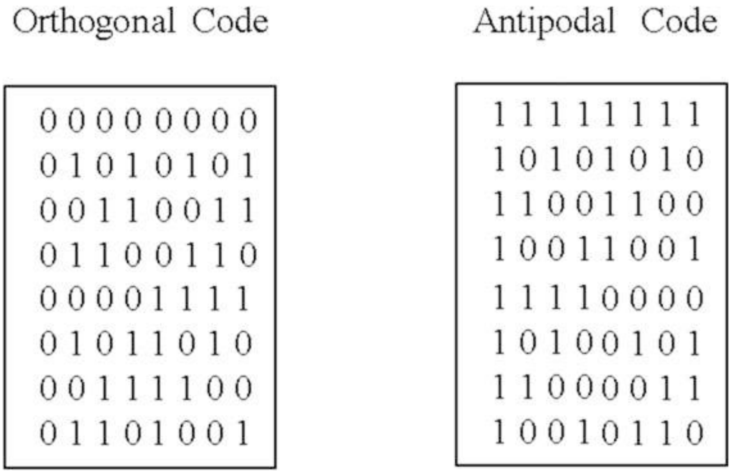
$$N\,t \leq N\,d_{\min}/2 \leq Nn/4 \leq N(4K - 2)/4 \tag{7.15}$$

Table 7.2 displays error correction capabilities of N-ary convolutional codes.

7.4 N-Ary Orthogonal Coding and M-Ary Modulation

7.4.1 Background

Orthogonal codes are used in CDMA cellular communications for spectrum spreading and user ID [10–13]. The use of orthogonal codes for forward error control coding has also been investigated by a limited number of authors [14–16]. This chapter presents a method of channel coding based on N-ary orthogonal codes [17–20]. N-ary orthogonal coding is a multi-level channel coding technique, where instead of coding one bit at a time two or more bits are encoded simultaneously. This type of channel coding is bandwidth efficient and further enhances the coding gain with bandwidth efficiency. In the proposed scheme, the input serial data is converted into several parallel streams. These parallel bit streams, now reduced in speed, are mapped into N-ary orthogonal codes. The coded information bits are then modulated by means of MPSK modulator and transmitted through a channel. At the receiver, the decoder recovers the data by means of code correlation. The proposed coded modulation scheme is bandwidth efficient and offers a coding gain near the Shannon’s limit.



Orthogonal Code	Antipodal Code
0 0 0 0 0 0 0 0	1 1 1 1 1 1 1 1
0 1 0 1 0 1 0 1	1 0 1 0 1 0 1 0
0 0 1 1 0 0 1 1	1 1 0 0 1 1 0 0
0 1 1 0 0 1 1 0	1 0 0 1 1 0 0 1
0 0 0 0 1 1 1 1	1 1 1 1 0 0 0 0
0 1 0 1 1 0 1 0	1 0 1 0 0 1 0 1
0 0 1 1 1 1 0 0	1 1 0 0 0 0 1 1
0 1 1 0 1 0 0 1	1 0 0 1 0 1 1 0

Fig. 7.5 Bi-orthogonal code set for $n = 8$. An 8-bit orthogonal code has 8 orthogonal codes and 8 antipodal codes for a total of 16 bi-orthogonal codes

7.4.2 *Orthogonal Codes*

Orthogonal codes are binary-valued and have equal numbers of 1's and 0's. Antipodal codes, on the other hand, are just the inverse of orthogonal codes. Antipodal codes are also orthogonal among them. Therefore, an n-bit orthogonal code has n-orthogonal codes and n-antipodal codes, for a total of 2n bi-orthogonal codes. For example, an 8-bit orthogonal code has 8 orthogonal codes and 8 antipodal codes, for a total of 16 bi-orthogonal codes, as shown in Fig. 7.5 [12]. Similarly, a 16-bit orthogonal code has 16 orthogonal codes and 16 antipodal codes for a total of 32 bi-orthogonal codes, as shown in Fig. 7.6.

We note that orthogonal codes are essentially (n, k) block codes, where a k-bit data set is represented by a unique n-bit orthogonal code ($k < n$). We now show that code rates such as rate ½, rate ¾, and rate 1 are indeed available out of orthogonal codes. The principle is presented below.

7.4.3 *2-Ary Orthogonal Coding with QPSK Modulation*

A 2-ary orthogonal coded QPSK modulator with $n = 8$, having 16 complementary orthogonal codes, can be constructed by inverse multiplexing the incoming traffic into 6-parallel streams, as shown in Fig. 7.7. These bit streams, now reduced in speed by a factor of 6, are partitioned into two data blocks. Each data block is mapped into an 8 × 8 code block, as depicted in the figure.

Antipodal Code

Fig. 7.7 2-ary orthogonal coding with $N = 2$

According to the communication scheme, when a 3-bit data pattern needs to be transmitted, the corresponding orthogonal/antipodal code is transmitted instead, requiring a QPSK modulator. The modulated waveforms are in orthogonal space and have fewer errors. The code rate is given by:

$$\text{Code Rate: } r = 6/8 = 3/4$$

Since there are two orthogonal waveforms (one orthogonal and one antipodal), the number of errors that can be corrected is doubled. Moreover, the transmission bandwidth is also reduced, which is given by:

Transmission Bandwidth: $BW = 2R_{b2}$/bits per symbol Hz

$$= 2R_{b2}/2 = R_{b2}\,\text{Hz} \tag{7.16}$$

where $R_{b2} = R_{b1}/r$. R_{b2} is the coded bit rate and R_{b1} is the uncoded bit rate.

7.4.4 4-Ary Orthogonal Coding with 16PSK Modulation

A 4-ary orthogonal coded 16PSK modulator, with $n = 8$, having 16 complementary orthogonal codes, can be constructed by inverse multiplexing the incoming traffic into 8-parallel streams, as shown in Fig. 7.8. The bit streams, now reduced in speed by a factor of 8, are partitioned into four data blocks. Each data block is mapped into a 4×8 code block as depicted in the figure. According to the communication scheme, when a 2-bit data pattern needs to be transmitted, the corresponding orthogonal/antipodal code is transmitted instead, requiring a 16PSK modulator. The modulated waveforms are in orthogonal space and have fewer errors. The code rate is given by:

$$\text{Code Rate: } r = 8/8 = 1 \tag{7.17}$$

This is achieved without bandwidth expansion.

Since there are four orthogonal waveforms (two orthogonal and two antipodal), the number of errors that can be corrected is quadrupled. Moreover, the transmission bandwidth is further reduced, which is given by:

Transmission bandwidth: $BW = 2R_{b2}$/bits per symbol Hz

$$= 2R_{b2}/4 = R_{b2}/2\ \text{Hz} \tag{7.18}$$

where $R_{b2} = R_{b1}/r$. R_{b2} is the coded bit rate, and R_{b1} is the uncoded bit rate.

7.4.5 2-Ary Orthogonal Decoding

Decoding is a correlation process. Notice that the entire biorthogonal code block is partitioned into two code blocks. Each code block represents a data block as shown in Fig. 7.9. Upon receiving an impaired code, the receiver compares it with each

entry in the code block and appends a correlation value for each comparison. A valid code is declared when the closest approximation is achieved. As can be seen, the minimum correlation value in each block is 1 as depicted in the figure. The corresponding data is 1 1, 1 0, 1 1, 1 0, respectively.

Since there are two orthogonal waveforms (one orthogonal and one antipodal), the number of errors that can be corrected is given by 2 × 1 = 2. Moreover, the bandwidth is also reduced, as presented below:

$$BW = 2Rb2/\text{bits per symbol} = 2_{Rb2}/2 = \mathrm{R}_{b2} \tag{7.19}$$

7.4.6 4-Ary Orthogonal Decoding

Decoding is a correlation process. Notice that the entire biorthogonal code block is partitioned into four code blocks. Each code block represents a data block, as shown in Fig. 7.10. Upon receiving an impaired code, the receiver compares it with each entry in the code block and appends a correlation value for each comparison. A valid code is declared when the closest approximation is achieved. As can be seen, the minimum correlation value in each block is 1 as depicted in the figure. The corresponding data is 1 1, 1 0, 1 1, 1 0, respectively.

Since there are four orthogonal waveforms (two orthogonal and two antipodal), the number of errors that can be corrected is given by 4 × 1 = 4. Moreover, the bandwidth is further reduced as presented below:

$$BW = 2Rb2/\text{bits per symbol} = 2_{Rb2}/4 = R_{b2}/2 \tag{7.20}$$

7.4.7 Error Correction Capabilities of N-Ary Orthogonal Codes

Error correction capabilities of orthogonal codes have been discussed earlier [16]. We present it again for convenience. An n-bit orthogonal code has $n/2$ 1's and $n/2$ 0's; i.e., there are $n/2$ positions where 1's and 0's differ. Therefore, the distance between two orthogonal codes is $d = n/2$. This distance property can be used to detect an impaired received code by setting a threshold midway between two orthogonal codes as shown in Fig. 7.11, where the received code is shown as a dotted line. This is given by:

$$d_{th} = \frac{n}{4} \tag{7.21}$$

where n is the code length and d_{th} is the threshold, which is midway between two valid orthogonal codes. Therefore, for the given 8-bit orthogonal code, we have

Code Y: y1 y2, ... yn

$d_{th} = 8/4 = 2$. This mechanism offers a decision process, where the incoming impaired orthogonal code is examined for correlation with the neighboring codes for a possible match.

The received code is examined for correlation with the neighboring codes for a possible match. The acceptance criterion for a valid code is that an n-bit comparison must yield a good autocorrelation value; otherwise, a false detection will occur. The following correlation process governs this, where an impaired orthogonal code *i*s compared with a pair of n-bit orthogonal codes to yield:

$$R(x, y) = \sum_{i=1}^{n} x_i y_i \geq (n - d_{th}) + 1 \tag{7.22}$$

where *x* and *y* are two *n*-bit orthogonal codes, *R*(*x*, *y*) is the autocorrelation function, *n* is the code length, and d_{th} is the threshold as defined earlier. Since the threshold is in the midway between two valid codes, an additional 1-bit offset is added to Eq. 7.21 for reliable detection. The average number of errors that can be corrected by means of this process can be estimated by combining Eq. 7.21 and Eq. 7.22, yielding:

$$t = n - R(x, y) = \frac{n}{4} - 1 \tag{7.23}$$

In the above equation, *t* is the number of errors that can be corrected by means of an *n*-bit orthogonal code. For example, a single-error-correcting orthogonal code can be constructed by means of an 8-bit orthogonal code ($n = 8$). Similarly, a three-error-correcting orthogonal code can be constructed by means of a 16-bit orthogonal code ($n = 16$) and so on. Table 7.3 shows a few orthogonal codes and the corresponding error-correcting capabilities.

Problem 7.1 This problem relates to N-ary convolutional codes and M-ary PSK modulation.

Given:

- Input bit rate before coding: $R_{b1} = 10$ kb/s
- $K = 3$, Rate ½ complementary convolutional codes
- 4-ary convolutional coding ($N = 4$)

Table 7.3 Error correction capabilities of N-ary orthogonal codes

Code length *n*	Number of errors corrected per code *t*	Number of errors corrected by N-ary code *Nt* $N = 1, 2, 4, 8, \ldots$
8	1	N
16	3	3 N
32	7	7 N
64	15	15 N

Find:

(a) Modulation level M
(b) Code rate r
(c) Bit rate after coding R_{b2}
(d) Transmission bandwidth BW
(e) Number of errors corrected

Solution:

(a) A 4-ary ($N = 4$) coded modulator can be constructed by inverse multiplexing the incoming traffic into 8-parallel stream. These bit streams, now reduced in speed by a factor of 8, are partitioned into four 4 × 2 data blocks. Each 4 × 2 data block maps a corresponding 4 × 10 convolutional code blocks. These code blocks are stored in four 4 × 10 ROMs. The output of each ROM is a unique 10-bit convolutional/antipodal code, which is modulated by a $2^4 = 16$ PSK modulator using the same carrier frequency. Therefore, $M = 16$.

(b) The code rate is given by:

$$\text{Code Rate: } r = 8/10 = 4/5$$

(c) Bit rate after coding $R_{b2} = R_{b1}/r = (5/4)\ 10\ \text{kb/s} = 12.5\ \text{kb/s}$

(d) Transmission bandwidth: $BW = 2R_{b2}/\text{bits per symbol Hz}$

$$= 2R_{b2}/4 = R_{b2}/2 = (12.50\,\text{kb/s})/2 = 6.25\,\text{kHz}$$

(e) Since there are four convolutional waveforms (two convolutional and two antipodal), the number of errors that can be corrected is quadruple, $4t = 4 \times 2 = 8$ [Each code corrects 2 errors.]

Problem 7.2 This example relates to N-ary orthogonal codes and M-ary PSK modulation.

Given:

- Input bit rate before coding: $R_{b1} = 10$ kb/s
- $n = 8$ orthogonal codes having 16 complementary orthogonal codes
- 4-ary orthogonal Coding

Find:

(a) Modulation level M
(b) Code rate r
(c) Bit rate after coding R_{b2}
(d) Transmission bandwidth BW
(e) Number of errors corrected

Solution:

(a) A 4-ary orthogonal coded modulator, with $n = 8$, having 16 complementary orthogonal codes, can be constructed by inverse multiplexing the incoming traffic into 8-parallel streams. The bit streams, now reduced in speed by a factor of 8, are partitioned into four data blocks. Each data block is mapped into a 4×8 code block. According to the communication scheme, when a 2-bit data pattern needs to be transmitted, the corresponding orthogonal/antipodal code is transmitted instead, requiring a $2^4 = 16$ PSK modulator. Therefore, $M = 416$.

(b) The code rate is given by:

$$\text{Code Rate:}\, r = 8/8 = 1$$

(c) The bit rate after coding is given by:

$$R_{b2} = R_{b1} r = 10\,\text{kb/s}\ (r = 1)$$

(d) The transmission bandwidth is given by:

$$\begin{aligned} BW &= 2Rb2/\text{bits per symbol Hz} \\ &= 2R_{b2}/4 = 2 \times 10\,\text{kb/s}/4 = 5\ \text{k Hz} \end{aligned}$$

(e) Since there are four orthogonal waveforms (two orthogonal and two antipodal), the number of errors that can be corrected is quadrupled, i.e.,

$$4t = 4 \times 1 = 4$$

7.5 Conclusions

A method of coded modulation, based on N-ary complementary codes and M-ary PSK (MPSK) modulation, is presented. N-ary coded modulation is a multi-level channel coding and multi-level modulation technique, where instead of coding one bit at a time two or more bits are encoded simultaneously and then modulated by means of M-ary modulation. At the receiver, the decoder recovers the data by means of code correlation. A lookup table at the receiver contains the input/output bit sequences. Upon receiving an encoded data pattern, the receiver validates the received data pattern by means of code correlation. Construction of N-ary coded modulation schemes based on convolutional and orthogonal codes is presented to illustrate the concept. The proposed coded modulation schemes are bandwidth efficient and offer a coding gain near the Shannon's limit.

“A” BATTERY—An appliance for furnishing electrical current to light the *filaments* of a *vacuum tube*, and cause emission of *electrons* (see *Theory of Vacuum Tube Operation*). This battery may be in any of several forms, the two in popular use being the storage type (see *Storage Battery*), and the dry cell (see *Dry Cell*). Fig. 1 shows method of connecting the “A” Battery in a vacuum tube circuit.

Fig. 2. A storage battery such as used for “A” battery current supply

In Fig. 2 a popular type of storage battery is shown. Batteries of this type come in many individual forms, the usual voltage being standardized at 6 volts. However, for use with certain tubes, 2 and 4 volt storage batteries are available. For general radio work, using the low-consumption tubes, the battery, as shown in Fig. 2, can hold a charge of from 60-80 ampere hours. (*See Storage Battery.*)

The other common form of “A” Battery is the dry cell, usually having a difference of potential (voltage) of 1.5 volts. Fig. 3 illustrates a popular type of dry cell. In connecting a number of cells for use with a vacuum tube, the method of connecting will depend on the voltage rating of the particular tube. If the tube is rated at 1.5 volts, a single dry cell may be used as in Fig. 4, or several may be connected in *parallel* (*q.v.*) shown in Fig. 5, the total voltage however, being only the voltage of one cell. Three dry cells connected in *series* (*q.v.*) will give 4½ volts, Fig. 6. A connection for dry cells, known as *series-parallel* or *multiple* (*q.v.*), is shown in Fig. 7. This connection will also produce 4½ volts and at the same time increase the life of the cells. Four dry cells connected in series will give six volts for use with a standard six-volt tube, Fig. 8. Dry cells are only used with six-volt tubes where the tube has a current rating of ¼ ampere, and seldom more than one tube is used in this manner due to the relatively high discharge and consequent short life of the battery.

A storage battery can be used for the “A” Battery current with a 4-volt tube if the connection is made as in Fig. 9. Here a standard 6-volt storage battery is tapped at the four volt terminal.

Another connection for low voltage tubes can be made as illustrated in Fig. 10. Here only one cell of the storage battery is used. This cell can be used until exhausted when the other cells can be used in the same manner. When the three cells are exhausted, the storage battery may be charged by means of a *charger* (*q.v.*).

ABAMPERE—A unit of current used in special theoretical work. It has a value of 10 *amperes* (*q.v.*) and is not generally used in electrical work.

ABBREVIATIONS, AMATEUR—The transmitting amateurs of the United States use their own peculiar abbreviations in their inter-communication work. These are used to lessen the interference between transmitting stations as it permits conversation in a much quicker manner. The abbreviations generally used are listed below. Simplified spelling is always resorted to, words being spelled according to their sounds. Some such words are given, but others are so obvious that they are not listed. There are also the standard "Q" signals adopted by the International Radiotelegraphic Convention, to be found in official publications and given under the heading "Abbreviations, International Radiotelegraphic Convention."

ACCW—A transmitter using rectified alternating current as the plate supply.

AFTRN or P.M.—Afternoon.

AMMTR—Ammeter.

ARRL—American Radio Relay League.

BCL—Broadcast listener, one who does not have a transmitting station.

BC STATION—Broadcast Station.

BFRE—or B4—Before.

BLO—Blow.

BOTTLE or V.T.—Vacuum Tube.

C—See or Call.

CGE—Cage.

CM—City Manager of A. R. R. L.

CTPSE—Counterpoise.

CUL—See you later or call you later.

CW—Continuous wave transmitter.

DCCW—A transmitter using direct current as the supply for the plate.

DM—District Manager of A. R. R. L.

DOPE—Information, or in another sense, a varnish for coating inductance coils.

DS—District Superintendent of the A. R. R. L.

DX—Distance, receiving or transmitting.

FB—Fine Business.

FONE—Phone.

GA—Good afternoon.

GLD—Glad.

GM—Good morning.

GN—Good night.

FRQ—Frequency.

HAM—Being a term for the transmitting amateur.

HI—High or I am laughing—it's funny, according to use in sentence.

HI LOS—High loss.

HR—Here.

HV—Have.

KCK BCK—Kick back.

KONGRATS—Congratulations.

KY—Key.

LW LOS—Low loss.

LW WVE—Low waves.

MGHT—Might.

MIKE—Microphone.

MSG—Message.

NITE—Night.

OM—Old man.

OP—Operator.

OPS—Operators.

ORS—Official Radio Station.

OT—Oscillation transformer.

OW—Female operator.

PEEP-PEEP—Continuous wave transmitter.

QCW—Listen for my CW transmitter.

QCW?—Shall I listen to your CW transmitter?

QRMER—An operator who persists in interfering with other stations after being warned to stop.

QSR—I will relay the message.

QSR?—Will you relay the message?

QSS—You are fading.

QSS?—Is my signal fading?

RDO—Radio.

RECVR—Receiver.

RELY—Relay.

ROCKCRUSHER—Spark transmitter.

SA—Say.

SIGS—Signals.

SPIKE—Message file.

SPK—Speak.

SUREFIRE—Something positive in action.

THG—Thing.

THT—That.

TLL—Till.

TM—Traffic manager of A. R. R. L.

TMR—Tomorrow.

TRAFFIC—The handling of messages among the stations.

U—You.

UNLIS—Unlicensed.

UR—Your.

VLTMTR—Voltmeter.

WL—Will.

WRLS—Wireless.

WVL—Wavelength.

"X" LICENSE—Experimental License.

YL—Young lady.

"Z"—Special license.

73—Best regards.

ABBREVIATIONS — RADIO — ELECTRICAL—A letter or group of letters of the alphabet arranged so that there is a definite electrical meaning when used in radio telegraphy or telephony. These abbreviations are the means by which technical writings are simplified, *i.e.*, Alternating Current is simply A.C. when used in general telegraphy. As most of the latest radio text books use these abbreviations, the following are given to aid the reader in understanding the various abbreviations:

A.C.—Alternating Current.

A.F.—Audio Frequency.

B.E.M.F.—Back Electromotive Force.

B. & S.—Brown & Sharpe Wire Gauge.

B.S.W.G.—Birmingham Standard Wire Gauge.

C.—Capacity.

C.G.S. — Centimetre-gramme-second (*q.v.*).

C.W.—Continuous Waves.

D.C.—Direct Current.

D.C.C. — Double Cotton Covered (Wire).

D.S.C.—Double Silk Covered.

E.—Induced Pressure (See Abvolt).

E.M.F.—Electromotive Force.

H.F.—High Frequency.

H.F.C.—High Frequency Current.

I.R.E.—Institute of Radio Engineers.

L.—Inductance (in Formulae).

L.F.—Low Frequency.

L.F.C.—Low Frequency Current.

M.A.—Milliampere.

Mfd.—Microfarad.

P.D.—Potential Difference.

R.—Electrical Resistance.

R.F.—Radio Frequency.

R.P.M.—Revolutions per Minute.

R.P.S.—Revolutions per Second.

S.G.—Specific Gravity.

S.H.M.—Simple Harmonic Motion.

S.S.C.—Single Silk Covered.

S.W.G.—Standard Wire Gauge.

W/L—Wavelength.

X's—Atmospherics.

ABBREVIATIONS, INTERNATIONAL RADIO TELEGRAPHIC CONVENTION—All messages and conversations are not transmitted in regular form, various forms of abbreviations being widely used to increase the speed of transmission and to reduce cost. It also has the tendency to decrease the interference as messages are sent swiftly in half the time. In wireless telegraphy, abbreviations have been adopted as international, and today there are very few ships or shore stations that do not use at least part of them daily. Below we give the International Radiotelegraphic Abbreviations as adopted at The International Radiotelegraphic Convention. An example of the use of the abbreviations is as follows:

A station wishing to learn the name of a ship which is seen off the coast, sends in code the letters QRA?, which means, what is the name of your ship? The station or ship answers with the letters, QRA S.S. Lapland, thus in a few seconds the question had been answered.

Abbreviation	*Question*	*Answer or Notice*
CQ	—.—.—.—.—	Signal of inquiry made by a station desiring to communicate.
TR	— .—.	Signal announcing the sending of particulars concerning a station on shipboard.
	— —. .— —	Signal indicating that a station is about to send a high power.
PRB	Do you wish to communicate by means of the International Signal Code?	I wish to communicate by means of the International Signal Code.
QRA	What ship or coast station is that?	This is ....
QRB	What is your distance?	My distance is ....
QRC	What is your true bearing?	My true bearing is.........degrees.
QRD	Where are you bound for?	I am bound for.............
QRF	Where are you bound from?	I am bound from............
QRG	What line do you belong to?	I belong to the.............Line.
QRH	What is your wave length in meters?	My wave length is..........meters.
QRJ	How many words have you to send?	I have .... words to send.
QRK	How do you receive me?	I am receiving well.
QRL	Are you receiving badly? Shall I send 20? ...—. for adjustment?	I am receiving badly. Please send 20. ...—. for adjustment.
QRM	Are you being interfered with?	I am being interfered with.
QRN	Are the atmospherics strong?	Atmospherics are very strong.
QRO	Shall I increase power?	Increase power.
QRP	Shall I decrease power?	Decrease power.
QRQ	Shall I send faster?	Send faster.
QRS	Shall I send slower?	Send slower.
QRT	Shall I stop sending?	Stop sending.
QRU	....	I have nothing to transmit. I have nothing for you.
QRV	Are you ready?	I am ready. All right now.
QRW	Are you busy?	I am busy (or, I am busy with.... Please do not interfere).
QRX	Shall I stand by?	Stand by. I will call you when required.
QRY	When will be my turn?	Your turn will be No. ....
QRZ	Are my signals weak?	Your signals are weak.
QSA	Are my signals strong?	Your signals are strong.
QSB	Is my tone bad? Is my spark bad?	The tone is bad. The spark is bad.
QSC	Is my spacing bad?	Your spacing is bad.

(When an abbreviation is followed by a mark of interrogation, it refers to the question indicated for that abbreviation)

ABSCISSA—A term in geometry adapted to radio use in making *curves* to show various values. The abscissae are the horizontal lines, and the ordinates are the vertical lines. In the diagram, the line AY is the axis of *ordinates* (*q.v.*) and the line AX the axis of abscissae. Fig. 2 shows a simple curve indicating the relation between voltage and current (amperes) in an *arc* (*q.v.*). The volts are given as ordinates and the amperes are shown as abscissae.

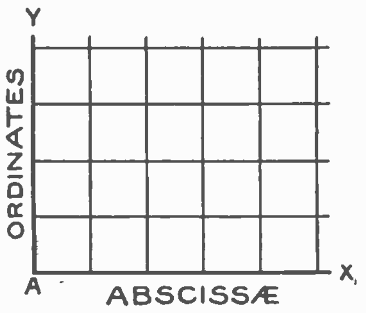

Fig. 1. Indicating axis of abscissae by the line A to X

The distance of any point from the axis of ordinates, measured on a line parallel to the other axis represents the value of the quantitv and locates a point on the curve. Where abscissae and ordinates are known, it is a simple matter to plot a series of points and then draw the curve through these points. (See *curve.*) Thus, in Figure 2, the curve shows the operation of the arc to be such that when the voltage is zero, the current is 20 amperes; when the voltage is 60, the current is 6 amperes, etc.

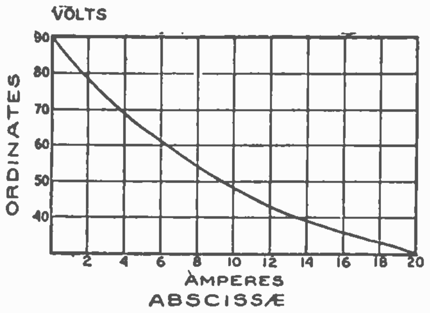

Fig. 2. A simple curve to illustrate the relation between volts and amperes

ABSORPTION, ELECTRIC—(See *Soaking-in.*)

ABSORPTION MODULATION—In the production of modulated (see *modulation*) waves, used to transmit speech in radio, it is necessary first to produce *undamped* (*q.v.*) waves of high or *radio frequency* (*q.v.*). Then other waves of low or *audio frequency* (*q.v.*) are superposed or run together with them. Now, if we insert a *microphone* (*q.v.*) in the *aerial circuit* (*q.v.*) of the transmitting station, providing that the *resistance* (*q.v.*) of that instrument is such as to reproduce accurately the vibrations of the voice or music, it is possible to vary the current output of the system producing the high frequency currents, so as to transmit the voice vibrations. If the microphone has resistance comparably low with the antenna or *antenna resistance* (*q.v.*), then the high frequency power output is handled (apportioned) equally between the aerial and microphone. The result is the production of fairly well modulated waves. There are, however, better methods of modulating the waves for which see *Modulation.*

ABVOLT—The *CGS unit* (*q.v.*) indicating the pressure or induced E.M.F. (*electromotive force*) (*q.v.*) set up between the ends of a wire one centimeter long, moving with a speed of one centimeter per second across the magnetic lines of force (*flux lines*) (*q.v.*) of a uniform magnetic field of unit intensity or flux density. An abvolt is therefore a very small unit and 100,000,000 (10^8) are required to equal one volt. In all formulae for determining the output or E.M.F. that can be expected to be produced by a certain *alternator* (*q.v.*), the result is in abvolts, and the complete formula usually provides for obtaining the actual volts. This is done by dividing the result in abvolts by 100,000,000 or 10^8 as it is generally expressed. (See *Alternator* also *abampere.*)

A. C.—Abbreviation for Alternating Current. (See *Alternating Current.*)

ACCELERATION—The rate at which the speed of a body in motion increases within a certain period of time. If we assume a train running at a certain rate of speed when the brakes are applied, the speed will decrease, and if measured over a period of one second, there will be a definite amount of decrease or a rate of decrease. This is known as *negative* acceleration or *deceleration.* When the train is speeded up there will be a definite change (increase) in velocity. The rate of change of velocity per unit of time is the acceleration. (*See Velocity* also *Frequency.*)

ACCEPTOR—A supplementary combination of *inductance* (*q.v.*) and *capacity* (*q.v.*) tuned to the frequency of the desired signal and connected in series in the receiving antenna. Generally, a *coil* (*q.v.*) and *condenser* (*q.v.*) of a value to correspond with a certain given wavelength—thus literally to "accept" the desired signal. (See also *Rejector.*)

A series combination of *inductance* (*q.v.*) and *capacity* (*q.v.*) connected in series with a high-frequency C.M.F. When tuned to resonance with the impressed E.M.F., the impedance drops to a low value, limited by the resistance of the system

ACCUMULATION OF ELECTRICITY—The process of storing electrical energy as (1)—a *storage battery* (*q.v.*) in which electric charges are placed to be later withdrawn and expended at will for various purposes, or (2)—the collection of energy by a *condenser* (*q.v.*) wherein the *electrons* (*q.v.*)

or minute charges of electricity are stored up momentarily on the plates or electrodes of the *condenser* (*q.v.*) and then released into the circuit.

ACCUMULATOR—(See *Storage Battery.*)

ACID—An active chemical compound formed by combining hydrogen with various acid radicals. Acids are much used in radio, particularly in *storage batteries* (*q.v.*). The most commonly used acid in this connection is sulphuric acid—a compound or union of hydrogen, sulphur and oxygen in certain definite proportions as indicated by the chemical symbol H_2SO_4. (See *Flux, Soldering.*)

ACIDIMETER or ACIDOMETER—An instrument used to determine the *specific gravity* (*q.v.*) of an acid solution. It is similar to a hydrometer and used in the same manner. Much used for testing strength or purity of acids or solutions. Operates on the principle that the strength of an acid will be directly proportional to the quantity of carbonic acid gas which it will liberate from a carbonate of soda or potash. (See *Hydrometer.*)

ACLINIC LINE—An imaginary line on the earth's surface assumed as passing through points where there is no magnetic inclination or dip of the needle of a compass. (See *Agonic Line.*)

ACOUSTICS—The science of sound or the study of the cause and effect of vibrations which effect the hearing. Generally speaking, the production and transmission of sound.

ACOUSTIC WAVE—The term occasionally used to denote a *sound wave.*

ACTINIC RAY—A light ray or beam of invisible *radiant energy* (*q.v.*). Rays of light, generally considered as lying at the blue or extreme left of the *spectrum* (*q.v.*) and being of such short *wavelength* as to be invisible to the eye. These rays have the power to induce or bring about chemical action. The most powerful actinic rays are the violet (X Ray) and the *ultraviolet.*

ACTIVE CONDUCTOR—(See *Conductor.*)

ACTIVE MATERIAL—The spongy part of a plate of a storage battery. The part which changes in nature and appearance due to the flow of electric current and having the ability to redevelop the current by a secondary chemical change.

ACTIVE PRESSURE—The active *electromotive force* (*q.v.*) or the pressure which produces a current. The term is used to distinguish this pressure from one impressed on the circuit.

A component in phase with the current in an *alternating current* (*q.v.*)

ACTIVE SPARK—A spark produced from energy contained in a charged condenser, which produces active *oscillations* (*q.v.*).

Thus, the spark discharge from a coil without any method of storing energy will be "inactive." When a condenser is inserted in such manner as to allow it to store up energy and then discharge, the resultant spark will be "active."

Fig. 1 shows a simple spark coil circuit with the secondary discharging across a gap. This is an Inactive Spark. Fig. 2 represents the same coil with a condenser in the circuit to store up the energy before discharging across the *gap* (*q.v.*). This is an Active Spark.

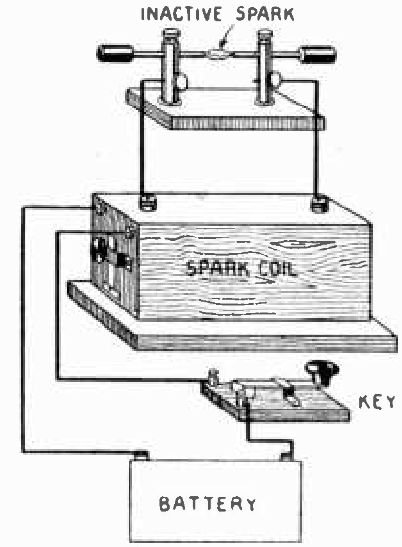

Fig. 1. Showing how an inactive spark is produced

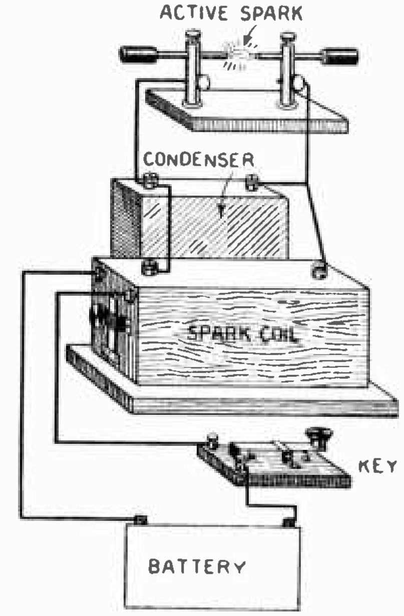

Fig. 2. The active spark is produced by means of a condenser in the circuit as shown

ADAPTER, AERIAL—A device for utilizing an electric light line as an aerial for the reception of radio signals. Essentially, two or more fixed mica condensers of comparatively high capacity, in series with two metal legs attached rigidly to a standard plug for insertion in socket of electric light fixture. Terminals are provided for connection to receiving apparatus. The illustration shows one of the popular types of Aerial Adapters which consists of merely a condenser to prevent the voltage of the line from passing directly to, or through, the instruments.

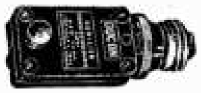

Illustration by courtesy of Dubilier Condenser and Radio Corp.

ADAPTER, TUBE—A device similar in form to a vacuum tube socket. Usually comprises a cylindrical form or shell of either metal or insulating material with legs identical with the tips or legs of a vacuum tube. A receptacle is allowed for the insertion of a tube, and the lead from each tip recess is so connected to a leg or tip at its base, as to permit the use of a non-standard base tube in a standard *socket* (*q.v.*). The illustration shows adapter for U.V. 199 or C-299 type of tube. When it is desired to employ a tube having a non-standard base in a set already equipped with standard sockets, without the necessity of changing the sockets, an adapter may be used. (See *Socket.*)

Illustsation by courtesy of Pacent Elec. Co., Inc.

ADHESION, ELECTRIC—Affinity of one body for another due to dissimilar charges of electricity passing through or being carried by them. The electrical equivalent of magnetic attraction.

ADJUSTABLE CONDENSER—(See *Variable Condenser.*)

ADJUSTABLE GRID LEAK—A form of *grid leak* (*q.v.*) that can be easily adjusted over a wide range of values without removal from the circuit. The illustration shows one type of Adjustable Grid Leak.

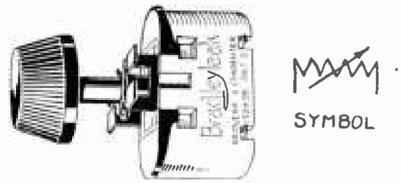

Illustration by courtesy of Allen-Bradley Co.

ADJUSTABLE RESISTANCE—(See *Variable Resistance.*)

ADMITTANCE—The inverse of *impedance* (*q.v.*). In an *alternating current* (*q.v.*) the Admittance acts in the opposite manner to impedance. A circuit having low impedance is said to have relatively high Admittance.

AERIAL—A system of wires suspended in the air or in any form in which they may be insulated or kept free from surrounding objects, used for the purpose of receiving or transmitting impulses as in radio transmission and reception. The term Aerial is actually identical with *Antenna*, but due to the general English definition of Antenna, authorities are gradually coming to distinction between transmission and reception Aerial systems by referring to a receiving device of this nature as an Antenna, and when used to transmit, as an Aerial.

There are different types and forms of Aerials, varying mainly according to purpose and facilities. The standard and perhaps more commonly used receiving Aerial consists of a single wire as in Fig. 1 or several wires as in Fig. 2. The wire used is usually of copper, as this metal combines low resistance with economy, strength, and durability. The theory of the action of the waves either received by or transmitted from an Aerial system will be found under the heading "Electromagnetic Waves."

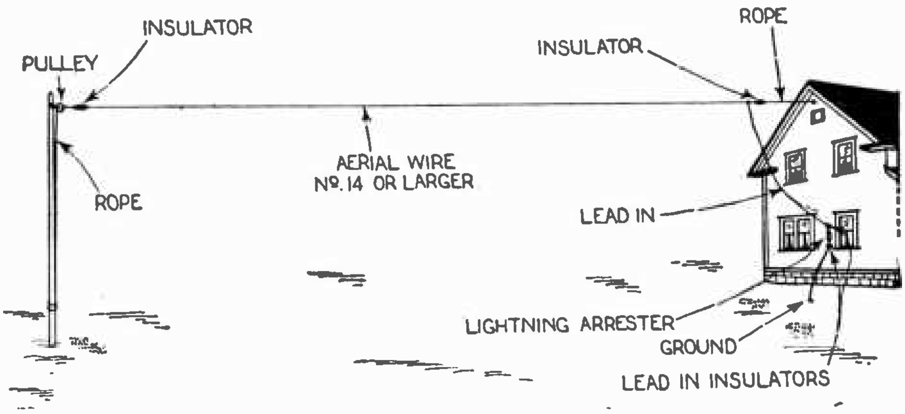

Fig. 1. A single wire aerial in the form of an inverted L. If a long wire is used, the lead-is may be connected in the center, forming a T type

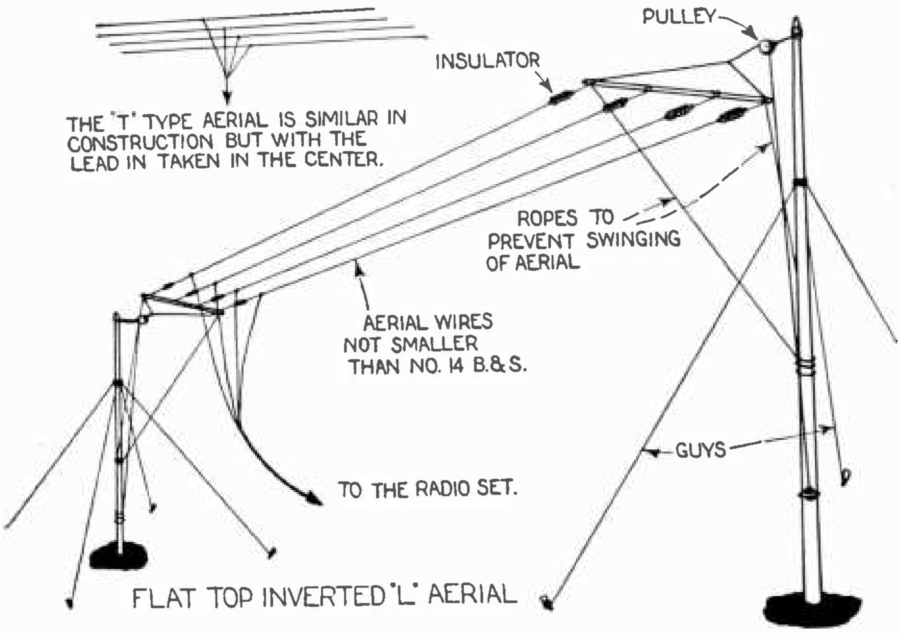

THE 'T' TYPE AERIAL IS SIMILAR IN CONSTRUCTION BUT WITH THE LEAD IN TAKEN IN THE CENTER.

GUYS
TO THE RADIO SET.
FLAT TOP INVERTED 'L' AERIAL

Fig. 2. Method of erecting a multi-wire aerial. This type of aerial may be made in either the inverted L or T form as shown

The exact type and extent of an Aerial will depend entirely on the available facilities and the particular purpose for which it is intended. These various forms will be taken up under their respective headings. In the receiving Aerials, Figs. 1 and 2, a certain definite *wavelength* (*q.v.*) is obtained by arranging a certain length to the wires of the Aerial system including the *ground* and *lead-in.* (See *Fundamental Wave-Length of Aerials.*) In the single wire Aerial, the lead-in is usually taken from the end nearest the receiving apparatus, but where a particularly long Aerial is to be used, it is customary to attach the lead-in to the centre of the suspended wire. The former is known as an *inverted L* type and the latter as a *T* type Aerial. These designations will apply as well where a number of wires are used as in Fig. 2.

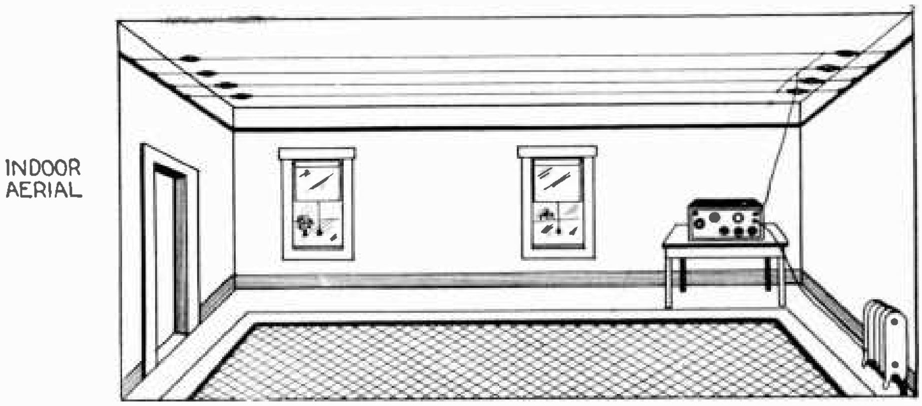

Fig. 3. Showing one method of installing an indoor aerial. While this illustrates a multi-wire type, a single wire run around the moulding of the room may give excellent results

Generally speaking, an Aerial should be as high above the ground as possible, of course within practical limits. From 25 to 100 feet is the most practical height to use. Where the Aerial is suspended at a substantial height the incoming waves will be less likely to be obstructed by surrounding trees or buildings, and in the case of transmission the same factor will apply, inasmuch as the waves may be obstructed in their transmission, if buildings or trees closely surround the Aerial.

The insulation of an Aerial is of particular importance, and especially so in the case of a transmitting Aerial. The reason for insulating an Aerial is to prevent the currents from escaping to the ground by way of trees, buildings, or the masts to which the Aerial is attached.

Fig. 3 shows a method of arranging an indoor Antenna system where it is not possible to use the out-door type. The construction may be essentially the same as the usual form of outdoor Aerial and can be arranged in a number of different ways. Very often a wire is merely suspended around two sides of a room and insulated from the moulding. One end will be connected as a lead-in to the receiving apparatus. In constructing an indoor Antenna, it is well to remember that the effective length of the Antenna is not much greater than the direct distance from the receiving set to the farthest point of the Antenna.

Fig. 4 shows a different type of Aerial known as the *Cage* type. The illustration shows an inverted L, and the T arrangement. Fig. 5 shows a *Fan Aerial* and Fig. 6 the *umbrella* type. The illustration, Fig. 7, shows one type of *loop Aerial* (*q.v.*) and Fig. 8 the same general type in somewhat different form. Owing to the fact that the theory of operation of a *loop Aerial* is somewhat different than the ordinary types, it will be described more fully under the heading "Loop Aerial." Fig. 9 illustrates a form of *Aerial Adapter* which is arranged to allow the electric light wires to be used as an Aerial. (See *Adapter Aerial.*) Fig. 10 shows an *underground Aerial* system designed by Dr. Rogers and which is not appreciably affected by atmospheric disturbances. (See *Strays.*) This form of Aerial, however, is generally impractical due to the difficulties in construction.

Aerials for transmitting may be of the same general types as receiving Antennas arranged outdoors, with the exception as explained previously, that heavy insulators must be used owing to the high voltage employed. Aerial for transmitting will depend for size on the wave-length desired.

Fig. 11 illustrates several types and arrangements of *counterpoise* (*q.v.*).

In the case of the receiving Aerial a single wire may be from 75 to 150 feet in length, or if a number of wires are used, the over-all length may be considerably less. (See *Fundamental Wave-length.*)

AERIAL CAPACITY—(See *Capacity of Antenna.*)

AERIAL CIRCUIT—Consists of *aerial* and *earth* or *ground*, including all *coils* or *inductances*, *condensers*, etc., which may be connected with the aerial and earth and forming a direct path between those points.

AERIAL SWITCH—A device to transfer the *aerial* and *ground* connections from the transmitting circuit to the receiving circuit or vice versa. Its object is to separate the high tension current of the transmitter from the low tension of the receiver. The switch is usually installed in a convenient position so that the operator may change from transmitting to receiving by one motion of the hands. A simple form of aerial switch is illustrated in Fig. 1. The circuit for same is shown in Fig. 2. A more efficient circuit is the one shown in Fig. 3. This circuit requires another blade to control the primary current to the transformer. The latter circuit is most satisfactory as it entirely disconnects the current to the transformer, doing away with the possibility of dangerous shocks to the operator. The switch commonly used in such circuits is shown in Fig. 4.

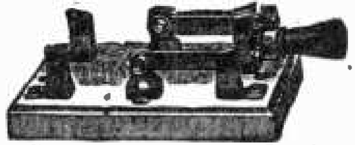

Fig. 1. A simple Aerial Switch

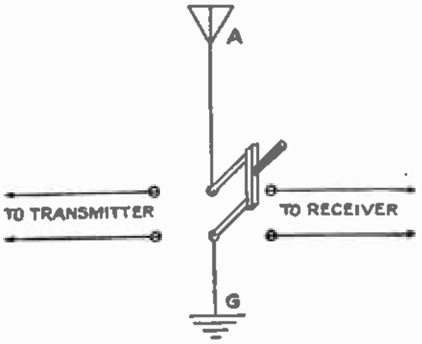

Fig. 2. Circuit for a simple Aerial Switch

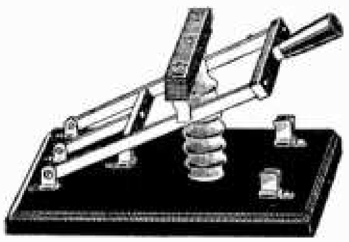

Fig. 4. An Aerial Switch with an extra blade

The switches used in the various commercial wireless stations are of course more complicated. There is a need to control many circuits with the simplest possible method. In order to do this it was found more convenient to only change the aerial connections, and allow the ground connection to both the receiver and transmitter to remain permanently. This of course necessitates a small air gap in the aerial for the transmitter. This is called an *anchor gap* (*q.v.*). This small appliance allows the transmitter to be connected continuously to the aerial as the high voltage from the transformer discharges across the small air gap, as provided for in the *anchor gap* (*q.v.*). Fig. 5 shows the circuit when this type of aerial transfer is to be used. When the switch handle is pushed down it makes connections with the receiver, when it is raised, the transmitter is ready to be used as the primary current is connected also.

AERIAL TUNING CONDENSER—A *condenser* (*q.v.*), usually variable, connected in the *aerial circuit* (*q.v.*) for the purpose of adjusting the natural period of the receiving circuit to the period of the incoming waves (see *Wavelength*) or signals coming from the *aerial*. In the illustration is shown an Aerial Tuning Condenser.

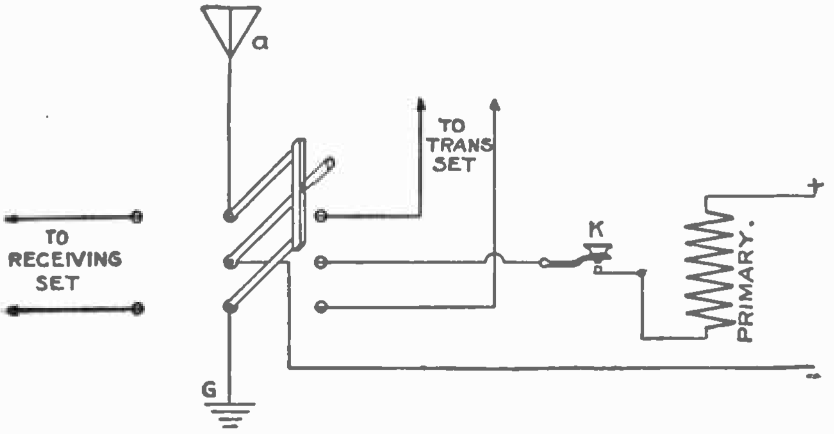

Fig. 3. Circuit for the Aerial Switch shown in Fig. 4 on page 7

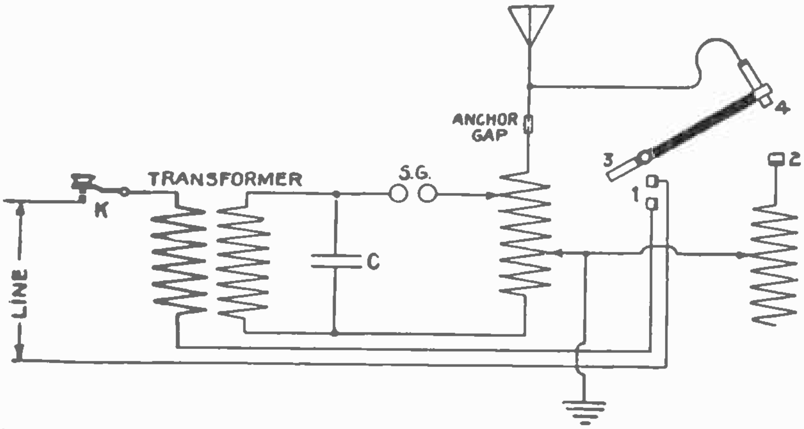

Fig. 5. An Aerial Switch employed in conjunction with an Anchor Gap as explained on page 7

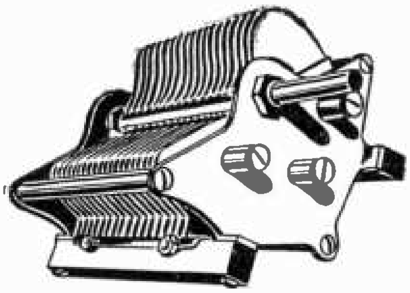
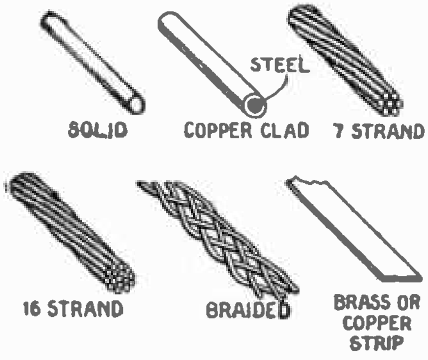
Any *capacitive* (*q.v.*) means of establishing or varying the *oscillation constant* (*q.v.*) of the receiver.



A variable condenser such as commonly used for an Aerial Tuning Condenser (see page 7).

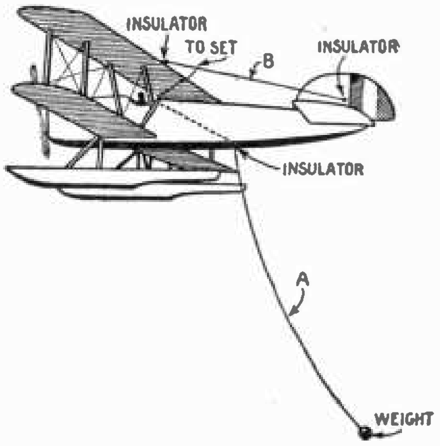
AERIAL WIRE—The wire forming the *aerial* (*q.v.*). Copper is generally used for this purpose as it offers very little *resistance* (*q.v.*) to the feeble currents in receiving.



The illustrations show various types of wire as used for aerials. Among them there are the solid copper wire, copper clad steel wire, stranded wire, braided wire and brass or copper strip.

AERO-FERRIC INDUCTANCE—The *inductance* (*q.v.*) of coils wherein the *magnetic circuit* (*q.v.*) is completed through both air and iron.

AEROPLANE ANTENNA—Receiving or transmitting *antenna* (*q.v.*) used on an aeroplane. The commonest form is a suspended wire shown as A in the illustration. The *ground* or *counterpoise* (*q.v.*) in this case may be another wire suspended on and insulated from the fuselage as indicated at B. When the plane is in flight, the hanging wire trails up and backward, depending on the speed of the plane and the size of the weight used. This type of antenna will be slightly *directional* (*q.v.*) in the direction the plane is traveling. If it is impractical to use a trailing wire antenna for any reason, a loop or coil of wire may be used, the results of course being less satisfactory. The metal frame of the plane is often used as a *counterpoise* (*q.v.*)



A. F.—Abbreviation for *Audio-Frequency* (*q.v.*)

AFTER-GLOW—Fluorescent phenomena in a *vacuum tube* after current has been withdrawn.

AGONIC LINES—Lines imagined as passing through points on the earth's surface where the magnetic inclination or dip of a magnetic needle (compass) is zero. (See *Aclinic Lines.*)

AGING, VACUUM TUBE—Gradual diminishing of the brilliancy of a tube due to the deterioration of the *filament* (*q.v.*) and the coating or deposit on the bulb. A tube is said to be Aging when it gradually loses its power to emit *electrons* (*q.v.*)

AIR CONDENSER—*Condenser* utilizing air as the *dielectric*. The majority of variable condensers used in radio work employ the air dielectric, that is, the space between plates is merely an air gap. Most *fixed condensers* (*q.v.*) use some substance such as mica, or sheets of waxed paper as a dielectric.

AIR CORE TRANSFORMER—A *transformer* used in radio, having no metal core, *the lines of force* having their path through air. (See *Amplifier, Radio Frequency.*)

ALBIZ, Count—Managing Director of the Compañia National de Telegrafia sin Hiols in 1910, of Scotch origin.

He was born in Madrid in 1858 and received a schooling at the Madrid University and London University College. He was a Tory member of Parliament.

ALEXANDERSON, Ernst Fredrick Werner (1878)—Radio engineer and inventor. Born at Upsala, Sweden, January 25th, 1878, he was educated at the High School and University of Lund, Sweden, at the Royal Institute of Technology, Stockholm, and at Berlin. In 1902 he joined the General Electric Company, and has been for some years their consulting engineer. He holds the post of chief engineer to the Radio Corporation of America, and

Photo by courtesy of General Elec. Co.

E. F. W. Alexanderson

is a member of the American Institute of Radio Engineers. Alexanderson has read many papers on electrical subjects before the chief technical societies of America.

Alexanderson is famous for his work on *high-frequency alternators* used in Radio telegraphy. The Alexanderson alternator is connected directly or *inductively* to the aerial and earth, and constitutes the simplest possible connection for producing *continuous* or *undamped waves.* It is a machine of great speed and many *field poles*, and frequencies as high as 200,000 *cycles* are obtained. For long distance work, employing very *long wavelengths*, this high-frequency alternator is largely used. Alexanderson is also responsible for the *magnetic amplifier*, patented in 1913, and has carried out successful experiments on *duplex wireless telephony.* In the Alexanderson *microphone transmitter* the *modulation* is mainly effected by variations in the tuning of the *aerial circuit.*

ALEXANDERSON ALTERNATOR—A type of *high-frequency alternator* (*q.v.*) which produces *continuous oscillations* (*q.v.*)

ALLOY—A compound of two or more metals. (See *Woods Metal.*)

ALTERNATING CURRENT—An electric current that does not flow steadily in one direction—as from *positive* to *negative*—but completely reverses its direction or *polarity* (*q.v.*) at certain definite intervals. In other words, the current flows first in one direction and then reverses and flows in the opposite direction—these changes being referred to as changes of *phase* (*q.v.*). An electric current is either *direct* (*q.v.*), alternating, or *pulsating*. The latter is an alternating current that has been rectified. (See *Rectified Current.*) Practically the only direct current that is employed or appears in a radio receiver is that supplied by the *"A"* and *"B" Batteries* (*q.v.*). In an alternating current, the change in direction or polarity takes place in a steady, even manner.

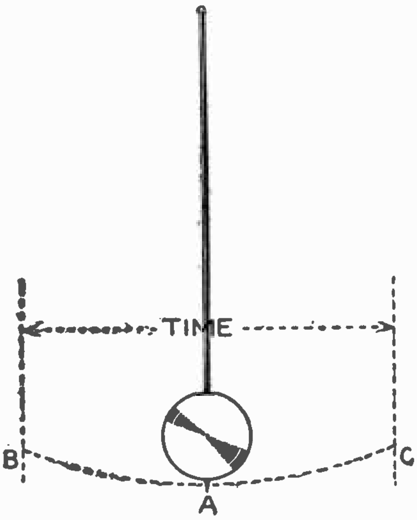


Fig. 1

An understandable analogy for alternating current is its comparison with a pendulum. In Fig. 1 the pendulum is supposed to be the alternating current or impulse. Now when the bob is swung from its natural (neutral) position A, which may be considered as zero value of voltage or current, it will move to a maximum point, either B or C. If we assume B to be the *positive* side, then the bob will move to B which will be the maximum positive *amplitude* (*q.v.*). It will then fall back to zero again, and with the power behind it, the momentum in this case, will rise on the other side to C, which is the maximum *negative* amplitude. The bob will then fall back to A once more and will have undergone a complete change of direction and values; it will have gone through a *cycle* (*q.v.*). That is to say, it will have risen from zero A to positive maximum B, then back to A, rising on the other side to negative maximum C and back to A. Now the length of time required for this complete cycle (see *Alternation*), is known as the *time period* of vibration or *phase change*. If, for example, it required one-sixtieth of a second for this change to take place, then we say that the *frequency* (*q.v.*) is sixty cycles, because obviously, a change requiring one-sixtieth of a second will occur sixty times in one second.

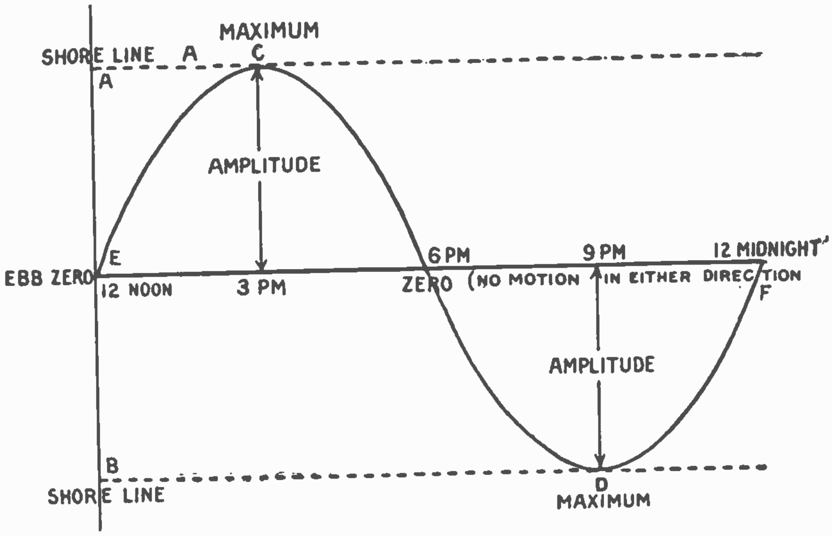

Fig. 2

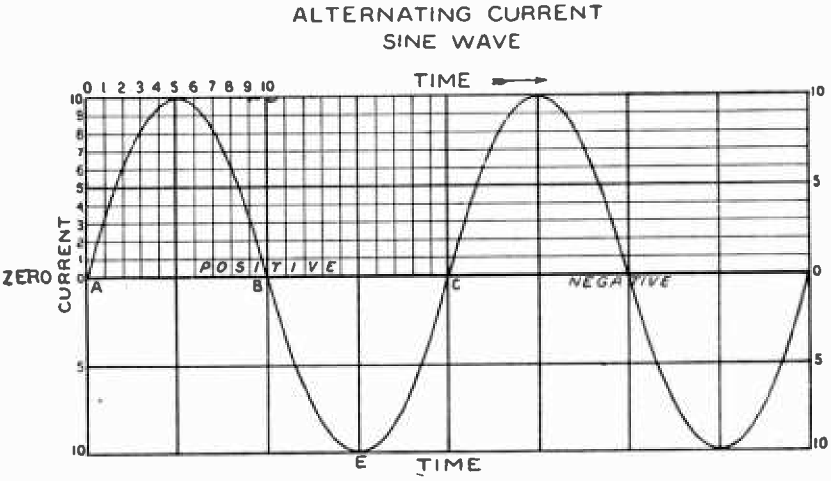

Fig. 3

The action of alternating currents may also be likened to that of ocean tides. In Fig. 2 the curved line represents the water in motion and is to be compared with current in motion in an alternating circuit. For the sake of clarity, we can assume that the tide rises and falls between two shore lines, A and B. At 12 noon the tide is at zero or "ebb" and there is no motion in either direction. Now the flow starts toward shore line A and gradually rises toward that side until at 3 P. M. it has reached its maximum height. In the case of an alternating current, we may consider that at 3 P. M. the current has reached maximum value on the positive side or in a positive direction. It then reverses and falls toward zero until at 6 P. M. it has reached the zero point. In the case of the current, it will have become zero. Motion again starts in the other direction and the tide rises once more, but in the opposite direction, toward shore line B. By 9 P. M. it will have reached maximum height in this direction, or in the case of the current it has reached maximum value or *amplitude* (*q.v.*) at D on the negative side. It then falls back again to zero, and at 12 midnight has come back to its original starting point, having gone through all stages of value or height from zero to maximum at one shore and then back to zero; then from there to maximum at the other shore and back to zero. The action of the alternating current then will have been to flow from zero to positive maximum, back to zero and reversing, from zero to maximum on the negative side, then back to zero. It will have completed one cycle. The time required for the tide to go through these changes E to F is 12 hours and is known as the *time period* or *period* (*q.v.*). Therefore, the time required for a complete change in the case of alternating current will be referred to as the period. The number of times that these changes take place within a certain time limit is known as the *frequency* (*q.v.*)

The current value in Fig. 3 is assumed to be 10 amperes, and the current values at any moment are shown as *ordinates* (*q.v.*), (vertical) while the time is shown in the *Abscissas* (*q.v.*) (horizontals). If the above curve is to be assumed as representing the Sine wave of an Alternating current having a frequency of 60 cycles per second, the total time in the chart would be one-thirtieth of a second. Thus, Time A to C would be one-sixtieth second, the Time of one complete cycle. A B is a positive Alternation and B C a negative Alternation, D and E represent maximum current values in each direction.

If the above Sine Wave is to be used as an example of a high frequency oscillation as in radio, the Time of one cycle can be assumed as about $\frac{1}{1,000,000}$ second. (See *Frequency-Oscillation - Sine - Phase - Characteristic of Alternating Current.*)

The frequency of an alternating current depends on the number of poles (field magnets) and the speed of rotation when the A.C. is generated by an alternator. (See *Alternator.*)

ALTERNATING CURRENT, THEORY OF PRODUCTION OF—Electric current in motion along a conductor always has a magnetic field (*magnetic flux*) surrounding it. If this current is passed near a number of turns of wire, the lines of flux will link with the wire turns in the circuit. The number of flux lines through a coil will depend upon the current. A change of current will change the number of linkages. If two turns of wire are used, the circuit will link twice with the same magnetic flux. Thus, a change in the current or a change in the number of turns of wire will alter the linkages.

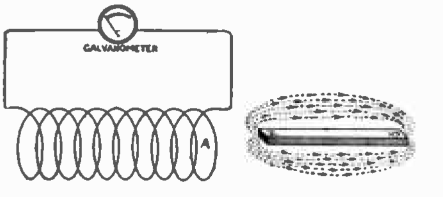

Fig. 1

Now in the case of Fig. 1, the magnet being placed near the coil causes lines of force to pass through the coil.

Each turn of wire will link the flux lines. Now any *change* in these linkages between the flux lines and wire turns will produce an E.M.F. (*electro motive force*) in the circuit of the wire turns. This is called an "induced current" because it is induced by the change in linkages. In Fig. 1, we have a coil of wire in a circuit with some sensitive measuring instrument for minute currents, in this case a *galvanometer*. Near it we have a bar magnet. When this magnet is moved toward or within the coil, a current is induced in the circuit by reason of the change in linkages. This current is *always* in a direction to *oppose* the change that causes it. (See *Lenz Law.*) "Whenever an induced current arises by reason of some change in the linkages, the magnetic field about the induced current is in such direction as to oppose the change." When the magnet is moved toward the coil, the change in linkages creates or induces a current that flows in the circuit in such manner as to make A act as a North pole. As the North pole of the magnet is toward this point A, the similar poles will oppose each other according to the simple law of magnetic attraction and repulsion. Now if we attempt to withdraw the magnet, the change will alter the linkages again, this time creating an induced current that makes A act as a South pole, thus *attracting* the magnetic North pole and opposing in the opposite manner, the change in linkages that have created the current.

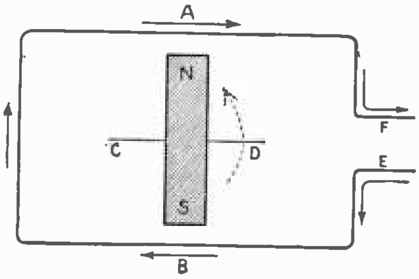

Fig. 2

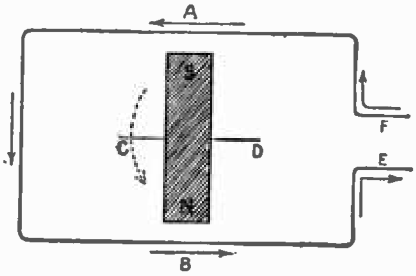

Fig. 3

We already know that if a conductor is moved across a magnetic field, an E.M.F. is induced in the conductor. The action is the same whether the conductor is moved across the magnetic field or vice versa. In Fig. 2, a magnet is shown in position on an axis—C D for rotation within the loop A B. As the magnet is rotated, the North pole passes across A, an E.M.F. is created toward F in the same direction. As the position of the magnet reverses in rotation and S passes A while N passes B, a current is induced in the *opposite* direction, both times in accordance with the law previously stated. Thus, if a meter is connected between the ends of the loop at E F and the magnet rotated, a current will be registered. With each half turn of the magnet, this current will reverse its direction. Therefore, we have produced an alternating current that changes direction with each reversal of the position of the magnets. This is the simple *AC generator* or *alternator*. The illustration, Fig. 4, shows a standard type of low frequency alternator.

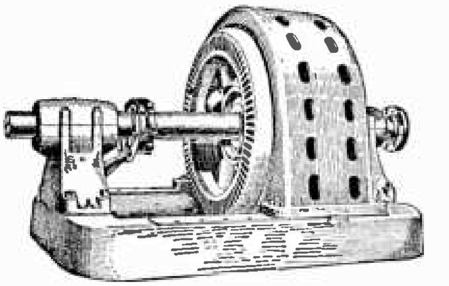

Fig. 4

ALTERNATION—In an alternating current, is the rise from zero to maximum *amplitude* and back to zero on either side, i.e., *positive* or *negative* directions. Two alternations—one positive and one negative—make a complete *cycle*. (See *Alternating Current.*)

ALTERNATOR—A machine for the purpose of changing mechanical energy into electrical energy. Fig. 1 shows an alternator in its elementary or simplest form—merely a conductor, B C moved across a *magnetic flux* (*q.v.*) (Note: For a complete explanation of the production of alternating currents, see *"Alternating Current, Theory of Production of."*) Here the conductor B C is moved to the right *across* the magnetic flux shown as dotted lines between N and S, the poles of the magnets. As the conductor moves across the flux lines of the magnet, an *electro-motive force* (*q.v.*) *or electric* current is set up or induced in the conductor, this force being in such a direction that the current produced will create a flux or magnetic field, in the same direction as the flux on the side of the conductor that comes first into contact with the flux lines N S on moving the conductor. In this case E.M.F. (electromotive force) is in the direction B to C in the conductor. In order to establish a circuit and utilize the current pro-

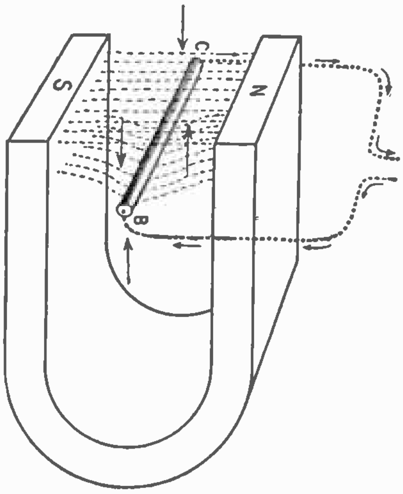

Fig. 1

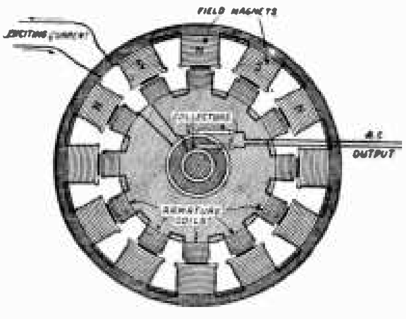

Fig. 2

duced in this manner, it is only necessary to attach wires to both ends of the conductor as shown by the dotted loop. Now at this moment the conductor is being traversed by a current having a definite polarity, that is to say, it is flowing in one direction only. When the direction of the flux lines N S are reversed, as by reversal of the magnet, or the conductor is turned so that the other end comes into contact with the flux lines, then the direction of the current in the conductor will reverse and it will flow in the opposite direction. In other words, with every reversal of the position of the conductor in its relation to the magnetic flux N S, or the reversal of the direction of the flux lines, with respect to the conductor, the E.M.F. that is created will change its direction of flow. (See *Alternating Current.*)

In an alternator it has been shown that the result is approximately the same whether the magnet is rotated or the conductor is rotated through the magnetic flux. In either case the moving member is known as the *rotor* (*q.v.*) and the stationary member is called the *stator* (*q.v.*). The magnets producing the flux lines may be stationary or they may revolve; in either case they are referred to as the *"field"* (*q.v.*).

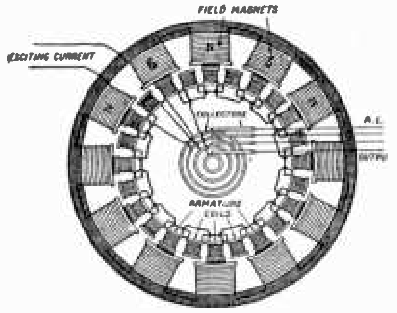

Fig. 3

It has been shown that with every change in the relative position of the field magnets and the *armature* (*q.v.*), irrespective of which member is the rotating one, a change of direction of the induced E.M.F. takes place. Then it is apparent that in order to increase the number of changes, that is, to increase the *frequency* (*q.v.*), it is only necessary to use (1) a greater number of field magnets, or (2) have the armature or conductor pass the magnets more frequently by means of greater speed in the rotating member, or by means of both. Now each of these changes is an alternation (see *Alternating current*) and two such changes will be a *cycle* (*q.v.*). Let us suppose that the moving member of a certain alternator has a rotary speed of 720 revolutions per minute and there are 10 poles or magnets. As frequency is figured by the changes per second, it will be necessary to reduce this number to the revolutions per second. Thus, there will be 12 revolutions per second. This figure multiplied by the number of *poles* (*q.v.*), which we assume as 10, indicates 120 alternations per second. As there are two alternations to each *cycle* (*q.v.*), the frequency in this case will be 60 cycles. The equation is as follows:

$$F = \frac{P}{2} \times \frac{N}{60}$$

where F is the frequency, P, the number of poles and N the speed of rotation per minute. The exact voltage or E.M.F. obtained will depend on the number of poles and the speed of rotation, and also on the distribution of the field windings and total flux from all the poles or magnets. In designing alternators the effective E.M.F. (electromotive force) is expressed by the formula:

$$E = \frac{K P \phi N Z}{10^8}$$

E is the effective electromotive force of the alternator.
K represents the E.M.F. factor of the alternator. This factor depends upon certain charcteristics of the poles and also the distribution of the windings on the armature.
P is the number of poles of the field magnates.
ϕ is the number of lines of magnetic flux that flow from one pole across the gap to the armature—known as the useful magnetic flux per pole; (see *Maxwells*).
N is the speed of rotation of the rotor in revolutions per second.
Z is the total number of conductors on the surface of the armature.
10^8 represents the number 100,000,000 —the calculation given would be determined in *abvolts* (*q.v.*), $\frac{1}{100,000,000}$ volt and it is therefore necessary to reduce it to volts by division.

In the "revolving field" alternator, as explained above, the field magnets are rotated and the conductor remains stationary. The windings in which the E.M.F. is produced, are placed in slots in the inner surface of the stator, the stator and the windings composing it being the *armature.*

In the alternators of the revolving armature type, the conductors or armatures are the rotating member and the field magnets remain stationary. Fig. 2 shows the revolving armature type of alternator in diagrammatic form. A small direct current *generator* (*q.v.*) may be used to excite or build up the field. That is to say, a current is sent through the field magnets (windings in this case) for the purpose of increasing or building up the *flux density* (*q.v.*). This is known as an *"exciter"* (*q.v.*). The exciter may be mounted directly on the end of the rotating shaft of the alternator, or mounted separately and connected to the alternator rotor shaft by means of a belt. This permits a heavy field to be built up by the electro-magnets used in place of the ordinary magnet shown in Fig. 1. If the machine is to be *single phase* (*q.v.*) there will be two *collector rings* (*q.v.*), the two phase type will have four rings, and the three phase six rings. The illustration Fig. 2 shows the general design of a single phase alternator. In this case there will be of course only two rings to collect the E.M.F. set up by the machine. Fig. 3 illustrates the general scheme of armature winding for a two phase machine. Here there are actually two separate E.M.F.'s set up by the separate windings and the ends of each of these windings are connected to collector rings as shown. In the three phase arrangement there may be three separate windings and six collector rings.

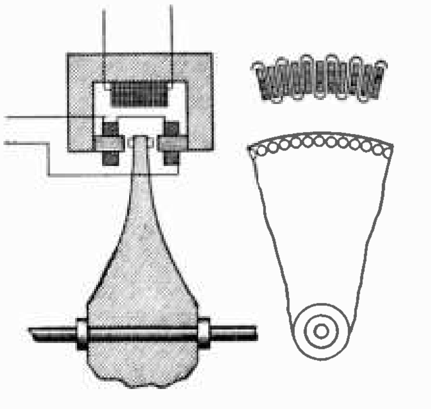

Fig. 4

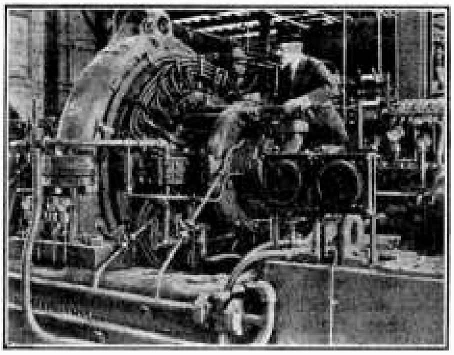

Fig. 5

The use of the revolving armature type for comparatively small voltages is due, as mentioned previously, to the fact that they are easily constructed, and also the advantage that the exciter need not be an external source, but may be a separate winding with a *commutator* (*q.v.*) mounted on the main shaft. The revolving field type of course allows much greater space for the armature winding, inasmuch as the stationary member is not limited to any particular space, whereas the moving member must be arranged as small as possible to do away with mechanical troubles. Thus, the stationary armature can be wound and properly insulated for great voltages. For this reason the revolving field is generally used in high power work. Another point of importance is that where the armature revolves, the windings must be made very carefully as the centrifugal force due to rapid rotation of the members places a great strain on them.

One of the widely used forms of alternator for extremely high frequencies, is the Alexanderson, named after its originator, *Ernst Alexanderson* (*q.v.*), a noted engineer. This machine is of the inductor type. It is a well-known fact that magnetism is more readily established through iron than through air, and therefore when iron is placed in the air gap of a magnetic circuit, the lines of force or flux lines are greatly increased. Then when the iron is withdrawn, the flux lines fall to their original value. We have seen that as changes of flux take place throughout a magnetic circuit an electromotive force is induced in a coil or conductor (armature) surrounding the magnetic circuit. Now, if iron is periodically inserted into and withdrawn from the magnetic field, an alternating current will be set up in the coil surrounding the field. This principle is made use of in the inductor alternator and the field and armature thus remain stationary, contrary to the usual form of an alternator. Now if we arrange to have pieces of iron moved rapidly in the gap between field and armature, changes of flux will take place. Obviously, it is easy in this manner to create many changes of flux within a certain time, and therefore the alternating current set up (E.M.F.) will have a high frequency as seen by the explanation of this phenomena given previously. These moving pieces are so arranged that they practically close the gap between field and armature with only enough clearance to prevent the rotating member striking the stationary members. This is briefly the principle of the Alexanderson alternator. Fig. 4 shows the general plan of an inductor alternator. On the right shows the scheme of winding in slots around the entire form, and as there are necessarily many windings in order to obtain the high frequency, they are generally single turns of wire, each turn having a separate slot. On the left is given a general idea of the arrangement of the rotor, which in this case, as explained previously, is neither field nor armature, but iron teeth arranged on the periphery of the moving disk. The field is increased or excited in the usual manner by means of a source of direct current. In the assembly, the relation of the moving disk to the field and armature is shown. Fig. 5 is a commercial type of Alexanderson Alternator having a frequency (*q.v.*) of 100,000 cycles used for high power radio transmission (*q.v.*).

ALTERNATOR, SINGLE PHASE—(See *Alternator.*)

ALTERNATOR, POLYPHASE—(See *Alternator.*)

AMMETER OR AMPERE METER—An instrument for measuring current in amperes in a circuit. Is connected in series with a circuit. Exists in a variety of forms. The operation of the most commonly used type depends upon the fact that the force a magnet exerts depends upon the number of *ampere turns* (*q.v.*). Therefore, the greater the current sent through its coils, the greater will be its attraction for a balanced armature. Fig. 1 shows a common form of ammeter.

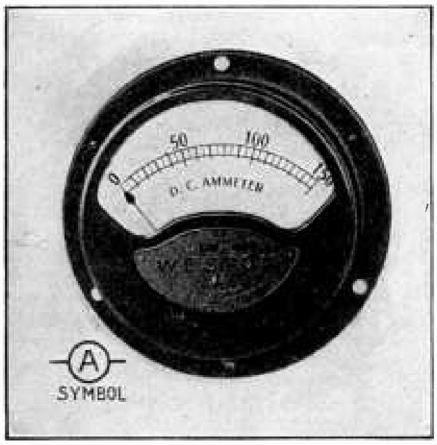

Photo by courtesy of Weston Elec. Inst. Co.

Fig. 1

AMMETER, THERMAL — Commonly known as "*Hotwire Meter.*" Also called "Aerial Ammeter" and "Radio Frequency Ammeter." Operates on the principle of thermal expansion, i.e., the tendency of a wire to expand with heat of current passing through it. Is used to measure current in amperes at extremely high voltages as in radio transmission. Figure 2 shows a Thermal Ammeter which is generally employed in radio work.

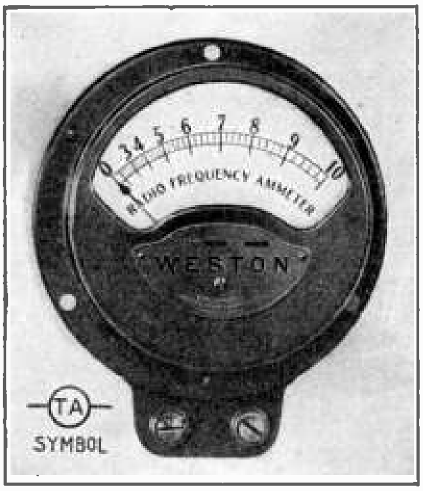

Photo by courtesy of Weston Elec. Inst. Co.

Fig. 2

AMP.—Abbreviation for *Ampere.*

AMPERE—The practical unit of the rate of flow of electricity. It is the unit current, or the rate of flow when one *coulomb* (*q.v.*) flows each second. The value or strength of electric current is almost invariably given in amperes. This unit is used to express the flow of a definite quantity of electricity in a second. If, for example, ten coulombs pass a given point in a circuit in one second, then we say that the current in that circuit is ten amperes. (See *Coulomb, Milli-ampere, Micro-ampere.*)

AMPERE, Andre Marie—A distinguished French physicist, born 1775, died 1836. Noted for his researches in the field of *electro-dynamics.*

AMPERE-HOUR—Commercial unit of quantity. Is that quantity which flows in one hour through a circuit carrying a current of one *ampere.* It is equal to 3,600 coulombs.

AMPERE, INTERNATIONAL—Symbol a—is defined as the unvarying electric current which deposits silver at the rate of 0.00111800 gram per second from a specified solution of nitrate of silver in water.

AMPERE'S RULE FOR DEFLECTION OF NEEDLE—"If one swims with the current and looks at the plus (+) or *north seeking pole* of a magnetic needle it will be deflected to the left, while the negative (—) or *south seeking pole* will be urged to the right."

AMPERE'S THEORY OF MAGNETISM—The theory advanced by *Ampere* that an *electric current continually circulates around each molecule of a magnetic substance and that the process of magnetization is one of arranging these currents in such manner that they all take the same direction.*

AMPERE TURNS—Expressed by the product of number of turns of, and the number of amperes flowing through, the coils of an electro-magnet. Thus, one ampere turn would be one ampere flowing through one turn. The ampere turn is very frequently used as a unit of *magneto-motive force* (*q.v.*) due to the ease with which it can be obtained.

AMPERE VOLT OR VOLT AMPERE—The expression sometimes used to denote *watts* (*q.v.*). For example 1 volt ampere will be one watt, as watts are equal to the product of the volts and amperes in D.C. circuits. (See *Efficiency,* also *Watts.*)

AMPLIFICATION CONSTANT — The factor expressing the maximum voltage *amplification* (*q.v.*) that it is possible to obtain with a given vacuum tube. Thus, if a certain tube will permit amplification of eight times the original voltage, the amplification constant is said to be 8. (See *Vacuum Tube.*)

AMPLIFICATION FACTOR—The ratio of the change of instantaneous voltage, between filament and plate of a *vacuum tube* to a small change of instantaneous voltage between filament and grid for a given constant plate current:

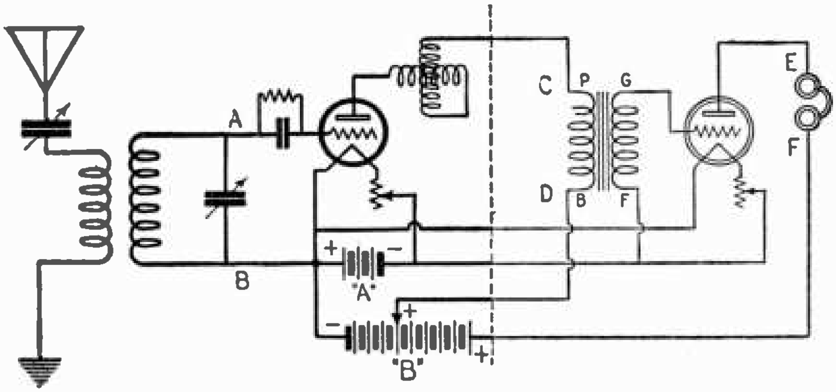
$$y = \frac{\delta V_p}{\delta V_g}$$

The ratio of power (radio signals), voltage or current output of an amplifying device to the power, voltage or current delivered to the input terminals. Generally speaking the degree of increase in amplitude or volume by insertion of an amplifying device in the circuit. (See *Amplification Voltage.*)

AMPLIFICATION, VOLTAGE — In a *vacuum tube* the ratio of the voltage apparent between the terminals of an impedance in series with the *plate,* to the voltage impressed on the *grid.* (See *Amplifier.*)

AMPLIFIER—One of the most important features of the *vacuum tube* (*q.v.*) is its ability under certain conditions to amplify or increase the intensity of electric currents. Such tubes are generally referred to as amplifier tubes and an amplifier is understood to be one or more such tubes with the necessary associated circuits to accomplish amplification.

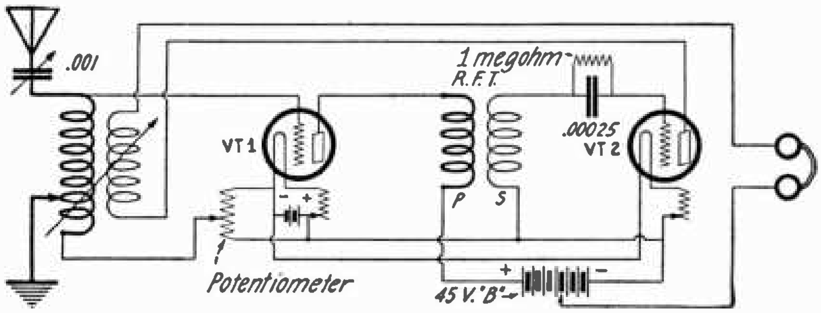
X—In the accompanying diagram a circuit of a typical one stage *audio frequency* (*q.v.*) amplifier is shown in conjunction with the *detector circuit* (*q.v.*). In this case the *radio frequency signals* (*q.v.*) are impressed at the points A-B from the aerial and ground circuit. The resulting signals at points C-D are audio frequency or voice frequency because they have undergone a change or *rectification* (*q.v.*). Now, if we consider only the solid lines, the circuit will be an ordinary detector circuit and the signals at C-D can be heard by merely connecting the phones at that point in place of the primary of the transformer—P-B. However, by sending these currents through the transformer and impressing them on the second tube it is possible to obtain signals at points E-F of much greater volume and yet having the same general characteristics or sound. The signals or currents will have undergone amplification—the effect of the amplified tube on a local source of power increase the amplitude, but the form or nature of the signals or waves will be the same. (This statement is not entirely true as amplification is generally accomplished only at the expense of some slight changes in the nature of the waves). They will, however, sound about the same in the phones at E-F as they will when the phones are placed at C-D, the volume at E-F being greater due to the amplification. (See *Distortion*). Now it must not be assumed that an amplifier in itself actually has the ability to increase power without some assistance. It is no more possible to obtain something for nothing in electricity than it is in mechanics. What actually takes place is that the amplifier tube and associated circuits control local power—in this case the voltage of "B" battery—in such a manner as to boost or amplify the power of the signals without materially changing their nature. Therefore, an amplifier may be considered as a device which modifies the effect of a local source of power in accordance with the variations of input power, and produces an increased output power or a means of stepping-up or increasing the amplitude or volume of a signal or series of signals. (See *Amplifier Action or Vacuum Tube.*) (See *Amplifier, Audio Frequency, Amplifier Radio Frequency,* also *Transformer.*)



A single stage radio frequency amplifier as used in conjunction with a tuner and detector
Showing the method of amplifying rectified signals at audio frequency

AMPLIFIER ACTION OF VACUUM TUBE—The tendency of a vacuum tube to increase the power or voltage of incoming signals under proper conditions. In the illustration is shown a simple vacuum tube circuit. The incoming signals are impressed on the tube at points A and B. Now it has been noted that small changes of voltage at the *grid* (*q.v.*) will produce much greater changes at the *plate* (*q.v.*). (See *Vacuum Tube, Theory of Operation.*) In other words, the constant changes in value of the incoming signals that are impressed at A-B will produce comparatively larger changes in the current at the plate and therefore larger changes of voltage in the output circuit at C-D. These changes will of course manifest themselves in the form of signals in the phones placed at C-D. Now if these voltages are impressed on a *resistance* (*q.v.*) of suitable value—such as the primary of an amplifying transformer—they can be sent to another tube and again amplified. (See *Amplifier, Audio Frequency.*) In other words the amplifying action of a vacuum tube means the ability of that tube to use input power—the power of the signals delivered to the tube—to control a local source of power such as the "B" battery voltage used on the plate of the tube, and deliver increased power. The signals to be increased or amplified in this manner may be *Radio Frequency* (*q.v.*) or *Audio Frequency* (*q.v.*), each instance requiring a different type of *amplifier* (*q.v.*). The radio frequency signals are amplified by means of a tube and suitable apparatus (transformer or resistance) before they have been changed to audio frequency. The signals that have been *rectified* (*q.v.*) or changed to audio frequency may be amplified by means of a similar arrangement of somewhat different type. The latter would be known as audio frequencv amplification. The increase in power is accomplished without any material change in the nature of the signals or wave form (*q.v.*)

AMPLIFIER, INTERMEDIATE FREQUENCY—An arrangment of a *radio frequency amplifier* to increase the strength of signals at the *intermediate frequency* (*q.v.*) as used in a *Super-Heterodyne receiver.* This is usually a radio frequency amplifier using *transformer coupling* (*q.v.*) the transformers being designed to cover extremely high wave-lengths. (See *Super-Heterodyne,* also *Transformer.*)



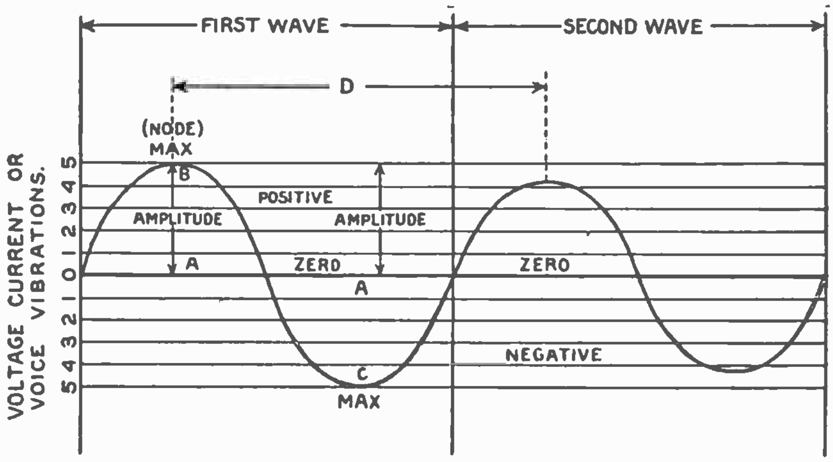
A single stage radio frequency amplifier as used in conjunction with a tuner and detector

AMPLIFIER, RADIO FREQUENCY — An amplifier used to increase the volume of the incoming signals at *radio frequency* (*q.v.*) before they have been *rectified* by the detector. In the illustration is shown a single stage of radio frequency amplification. This is the transformer coupled type. In this case the incoming signals of radio frequency are increased in strength and then passed on to the detector tube VT2. If further amplification is desired, more stages may be used, the number being held within certain limits due to *distortion* (*q.v.*). If more than three stages are used, it is often difficult to control the *feed-back effect* (q.v.) and efficiency is cut down.

AMPLITUDE—The current or voltage on an A.C. or H.F. circuit at any instant.

The greatest vertical distance above or below zero of the crest or trough of a wave is the maximum amplitude of the wave. In the accompanying illustration the numerals at the left (*ordinates q.v.*) may be assumed to be volts, current (amperes), or voice vibrations. A is the zero point; B the maximum *positive,* C the maximum *negative,* and D the length of the wave. Thus, A. B will be the maximum *positive* amplitude, A C the maximum *negative* amplitude, and D the wave length. B is known as the crest or Node—C is the trough or antinode.

X—Now if in a certain train or group of waves, the amplitude of one wave is less than the one immediately preceding it, there is said to be *damping* (*q.v.*), the degree of this damping or diminishing in amplitude being referred to as *decrement* (*q.v.*). Thus, if we assume that in Fig. 1 the current or amplitude of the first wave is 10 amperes, and the next wave has an amplitude of only 5 amperes, then the damping or decrement is 50 per cent, because the amplitude has decreased that much. Similarly, if the first wave amplitude were 10, and the second were 9 amperes, then the decrease



Line wave showing two cycles of an alternating current, indicating the amplitude and damping

Super Regenerative and *Super Heterodyne*. The principle of regeneration is one that has revolutionized the art of radio reception and broadcasting. The vast majority of present day receivers use regeneration in one form or another. Basically, regeneration is the process of returning a certain portion of the unrectified or radio frequency (*q.v.*) current from the plate circuit. of the detector tube to the grid circuit. This has the effect of reducing the resistance of the grid circuit and thus permitting more ready passage of the weak impulses. The result is not only to greatly increase the sensitivity of the detector to weak signals, but actually to step up or amplify the volume of the received signals. In Fig. 1, coils L1 and L2 are the aerial tuning units in conjunction with the variable condenser, C1; C2 and C3 are variable condensers of low capacity; L3 is the plate control for regenerative action; T is the telephone receiver, G, P and F are respectively the grid, plate and filament elements of the tube; R the filament rheostat, and A and B the batteries for filament and plate. In the illustration Fig. 2, C1 is the aerial tuning condenser, L1 the primary coil of a standard vario coupler; V1 the grid variometer and V2 the plate or regeneration variometer. L2 is the secondary of the vario coupler, and the balance of the elements are as in Fig. 1, GL being the customary grid leak and condenser. Regenerative receivers have come into some disfavor owing to their tendency to radiate annoying signals into the antenna, and also the howling within the set when not properly adjusted. While regeneration in some form or other is used in the majority of receivers, it is not widely used now in its original state. (See *Neutrodyne*, *Tuned Radio Frequency*, etc.)

There are many types of regenerative set, some extremely simple and others more complicated. The original Armstrong regenerative circuit is shown in Fig. 1. Fig. 2 shows a more modern application of the regenerative principle and at the same time a more complicated one. (See *Regeneration*, *Super Regeneration* and *Super Heterodyne*.)

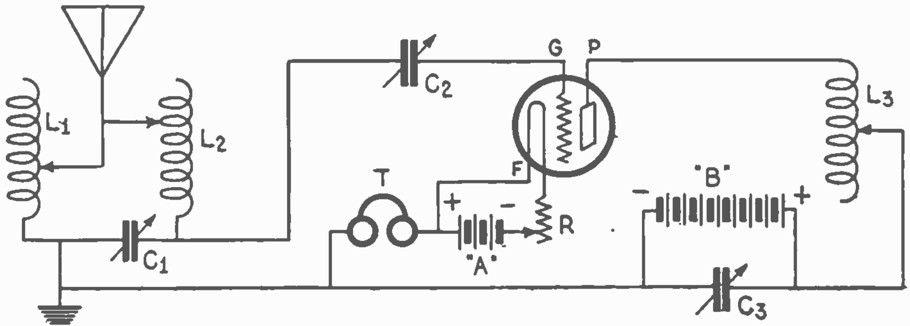


Fig. 1. The Original Armstrong Circuit.

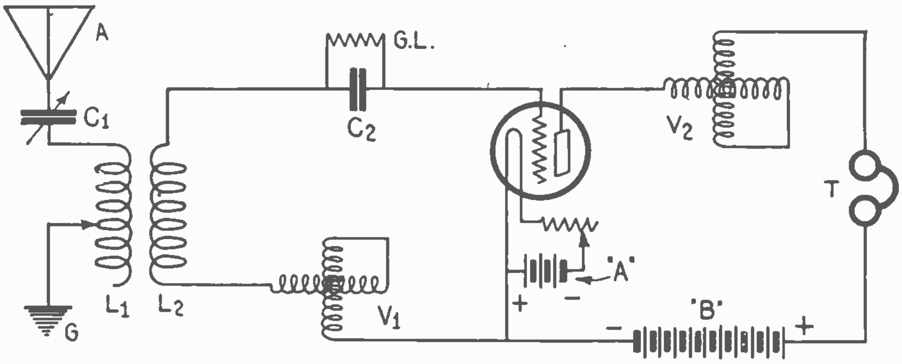

Fig. 2. The Armstrong 3-Circuit Regenerative Receiver.

ARRESTER—A device used for by-passing heavy electrical discharges in the atmosphere in the vicinity of the antenna when they strike the antenna. It ordinarily consists of a small gap between two metallic points connected in series with the antenna and ground in order to protect the apparatus and property against danger. (See *Lightning Arrester*.)

A. R. R. L.—Abbreviation for American Radio Relay League.

ARTIFICIAL ANTENNA—See *Mute Antenna*.

ARTIFICIAL MAGNET—A magnet produced by magnetizing a piece of steel that previously had no magnetic attraction. May be produced by rubbing a *natural magnet* or another artificial magnet across a piece of hard steel in the same direction a number of times. (See *Electro-magnet*.)

ASSUMED DIRECTION OF CURRENT FLOW—The direction which an electric current is assumed to take in its flow. Current is generally considered as leaving the *positive* terminal of its source, flowing through the circuits external to the source, and thence to the *negative* terminal of the source. The direction of flow within the source itself is from the negative to the positive terminal. (See *Theory of Current Flow*.)

ASTATIC COILS—Coils wound in such a manner that, when connected together, they neutralize each other's effect and produce no external *magnetic field*. They are used in the measurement of *inductance*.

ASYMMETRIC CONDUCTOR — One that permits the flow of greater current in one direction than in another. Non-symmetrical as to conductivity.

ASYMMETRICAL EFFECT—The lack of symmetry in the directional effect in a loop or frame aerial due to lack of symmetry in construction. (See *Loop Aerial*.)

ASYNCHRONOUS—A term used in referring to AC (Alternating Current) motors or generators and also to *dischargers* used in radio transmission. As applied to alternating current machines it is signified that the speed of rotation of the machine does not have any definite relation to the *frequency* of the currents produced—thus, out of *synchronism*. (See *Synchronous*.)

An asynchronous radio circuit is one which is not tuned to, or in syntony with, the frequency of the *oscillations* impressed on it. (See *Aperiodic*.)

ASYNCHRONOUS ROTARY DISCHARGE—A spark discharge produced at electrodes of a *rotary discharger* (*q. v.*) for transmitting radio signals, in which the spark rate or number of sparks per second has no relation to the *frequency* of the *alternating current*. (See *Spark Discharge*.)

ASYNCHRONOUS SPARK GAP—See *Spark Gap*.

ATMOSPHERIC ABSORPTION — The portion of the total reduction of radiated power due to atmospheric conductivity, reflection and refraction. The amount of energy loss in radio transmission due to atmospheric factors. This applies only to *electromagnetic waves* (*q.v.*) in *motion in the ether* and should not be confused with the reception losses due to atmospheric disturbances.

ATMOSPHERICS — See *X's*, *Strays*, *Static*.

ATTENUATION—of the electric or magnetic intensity or of the average energy density in electric waves refers to the reduction in strength with increase of distance traversed due to absorption or equivalent losses, as distinguished from the reduction in strength due to geometrical divergence. In free space, the geometrical divergence of waves from a small source involves a diminution of the average energy density in accordance with the inverse square law; plane waves (e. g., along wires) suffer no reduction by divergence, but undergo attenuation due to resistance and other line faults. (See *Attenuation, Geometrical Divergence*).

ATTENUATION, GEOMETRICAL DIVERGENCE—The gradual decrease in strength of electromagnetic waves (radio signals) as the distance which they have traversed increases. The effect on the waves as they travel through the air is essentially the same as in the case of light waves. Now if a beam of light is viewed one mile from its source it will have a certain intensity, but if it is viewed again from a distance of two miles the intensity will be much less. In the case of radio waves, the intensity is said to decrease as the square of the increased distance traveled; that is to say, if they have a certain power at a distance of five miles from the transmitter, the same waves at twice the distance or ten miles will be found to have a strength only one-quarter as great. Similarly, if the waves travel fifteen miles or three times the distance, the signal strength will be only one-ninth that of the same waves at a distance of five miles from the transmitter.

AUDIBILITY—The measure of strength of received radio signals as heard in a telephone receiver connected to the radio receiving apparatus. A radio telegraph signal which is at all audible can be read, i.e., the dots and dashes distinguished from one another; radio broadcast programs heard with at least some degree of clarity.

AUDIBILITY (Radio Telegraph)—A measure of the ratio of the telephone current producing a signal in a telephone receiver to that producing a barely audible signal. (A barely audible signal is one which just permits the differentiation of the dot and dash elements of the letters sent in code.) In the simple shunted telephone method of measuring signals the audibility is defined as:

$$\frac{s+t}{s}$$

where s and t are the *impedances* of shunt and telephone respectively.

AUDIBILITY FACTOR—A measure of signal strength obtained by observing the *resistance* to be placed in shunt with the telephones of a receiving station to reduce the signals to unit audibility. Approximately, the audibility factor is proportional to the power absorbed from the signal waves by the receiving apparatus. Unit audibility is the strength of signal at which dots and dashes can just be discriminated.

AUDIBILITY METER—A device for comparison of the strength of received signals, either from different stations or with different circuits by means of a variable *resistance* shunted (placed) across the phones. This resistance is decreased until the signals are just audible in the phones. Now, if another station is tuned in, or the circuit changed in some manner, the signals may either be entirely inaudible or they may be much louder, this giving an idea of the *comparative* strength without actual measurement. A popular type of Audibility Meter is shown in the above illustration.

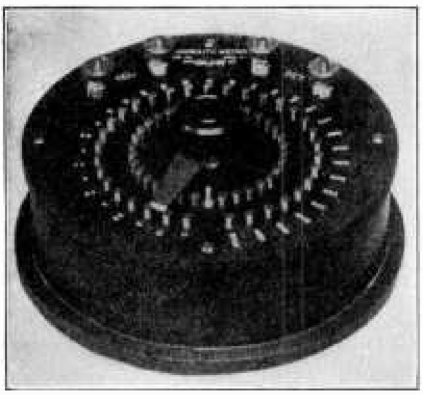

Photo by courtesy of General Radio Co.

An Audibility Meter.

For measurements with an audibility meter, the following shunt formula is used:

$$K = \frac{s+t}{s}$$

Where s is the *impedance* of the *shunt* resistance and t the impedance of the phones, then K is the audibility constant. In general practice a *series* resistance is devised to compensate for the reduction in resistance of the shunt circuit, this keeping the impedance of the plate circuit constant.

AUDIO AMPLIFIER—An *amplifier* used to increase the volume of signals of *audio frequency* (*q. v.*). Audio amplifiers are connected in the circuit of the detector in place of the phones (input) as shown in Fig. 1. This is the standard two stage audio amplifier. The separate stages each consist of a *vacuum tube, a transformer, socket* for the tube and a control *rheostat*. If desired one rheostat may be used for both amplifier tubes as the *filament* current (*q. v.*) can be the same if the tubes are of a similar design. This is known as "transformer coupled amplification." Another much used method is known as "resistance coupled amplification."

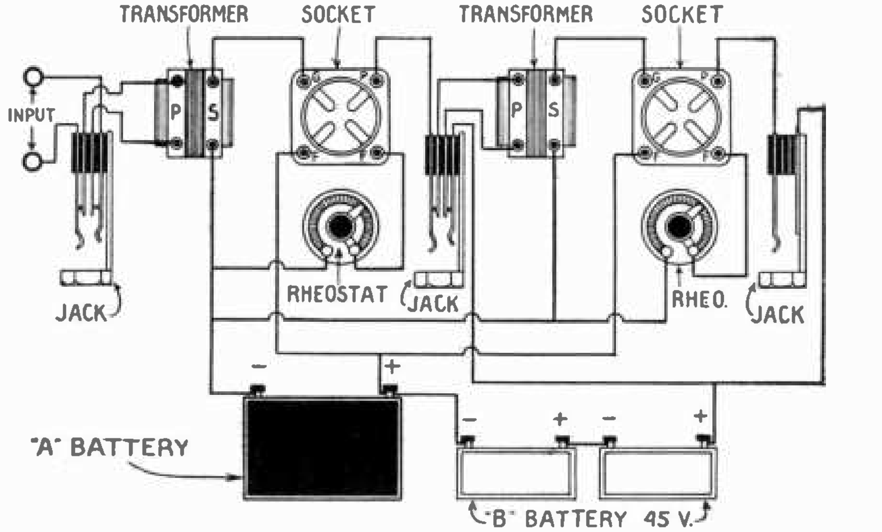

Fig. 1. A standard two stage Audio Amplifier employing phone jacks for detector, first stage, and second stage Audio Amplifiers.

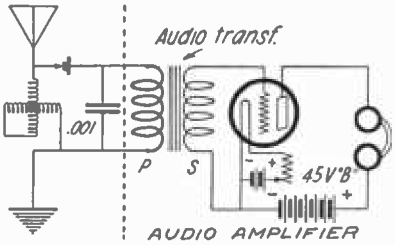

Fig. 2. A one stage Audio Amplifier connected to a crystal receiving set.

Fig. 2 shows one stage of audio frequency amplification connected to a crystal receiving set. There are numerous variations of audio amplification. (See *Push-Pull Amplification*, also *Resistance Coupled Amplifier*, and *Power Amplifier*.)

AUDIO FREQUENCY—A frequency corresponding to normally audible sound waves, i.e., between 40 and 10,000 per second. The limits of audibility are given variously from 16 to 20,000 cycles, but for ordinary usage may be taken as from 40 to 10,000 cycles per second. In audio frequency amplification as used in conjunction with the tuning and detector apparatus of the radio receiving set, the volume of the received sound is amplified or increased over that of the originally rectified sound waves. (See *Radio Frequency*; also *Amplifier*.)

AUDION—The name given by Dr. L. De Forest to a *vacuum tube detector* which possesses a glowing *cathode* and has a steady E. M. F. (*Electromotive force*) permanently applied between *anode* and hot *cathode* and two cold *anodes*. (See *Vacuum Tube*.)

AUSTIN, Louis Winslo, Ph.D.—Born in Ordwell, October 30th, 1867. Graduated at Middlebury College and studied at Clarke University and the Universities of Strasburg and Berlin. Noted for the fact that he is head of the U. S. Naval Telegraphic Laboratory, Washington, D. C., and for his work in measuring high frequency currents.

AUTO-COHERER—A coherer having automatic action to release the particles that cohere when circuit is established. Now obsolete. (See *Coherer*.)

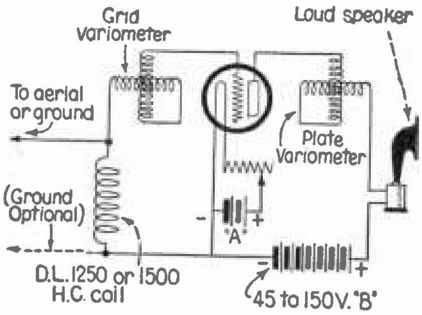
AUTODYNE RECEPTION—See *Self-Heterodyne Reception*.

AUTO INDUCTIVE COUPLING—See *Coupling*.

AUTOMATIC INTERRUPTER—A vibrating electro-mechanical device to make and break an electric circuit by using the energy passing through it. The most common example is that of a *spark coil*. An interrupter may be used for several purposes. In the case of a spark coil it is used to produce sparks for transmission of signals. In another form it may appear in a mechanical battery *charger*, in this instance being used to interrupt the *alternating current* and permit passage of the current in one direction only. A *buzzer* uses a type of interrupter—a vibrating device producing a buzzing sound having a pitch dependent on the rapidity with which the vibrations take place.

AUTOMATIC TRANSMITTER—An apparatus for operating a sending *key* mechanically. (See *Wheatstone Transmitter*.)

AUTOPLEX—A type of radio receiver employing one vacuum tube, operating along the lines of the *Super-regenerative* principle and designed to operate a Loud-speaker. The circuit comprises two standard variometers, a 1500 turn duo-lateral coil, and the usual vacuum



Circuit of the Autoplex radio receiver.

tube, socket, batteries, etc. It is extremely critical in operation, but if carefully assembled will give excellent volume under good conditions. Illustration shows the circuit diagram of the Autoplex receiver.

AUTO-RECEIVER—A device for the automatic reception and recording of radio signals. It is essential in the reception of signals transmitted by an Automatic transmitter (see *Wheatstone Transmitter*) as the speed is too high to permit reception by ear. There are three general classes of automatic receiver: a *resonance intensifier* in conjunction with an inking arrangement; a *phonographic recorder* and a recorder using *photographic means*. In the latter method, a powerful beam of light is projected on to a mirror which is arranged to respond to the signals in approximately the same manner as a mirror *galvanometer*. In the phonographic type, the signals are reproduced on a drum. (See *Resonance Intensifier, Photographic Recorder,* also *Phonographic Recorder.*)

AUTO TRANSFORMER—A device for changing voltage in a circuit carrying alternating currents. A form of *transformer* having but one winding, any part of which may be used as the *primary* and any part as the *secondary*. In Fig. 1 the two windings P and S are continuous, although different sizes of wire may be used according to the purpose for which intended. In this case the voltage taken from the secondary D E will be less than the voltage impressed at A B, because the secondary has fewer turns of wire than the primary. Now in Fig. 2, this conditions is reversed, and as the primary has only a few turns of wire and the secondary has a comparatively large number, the voltage obtained from D E will be greater than that impressed at A B. The voltage ratio is approximately proportional to the ratio of wire turns. Thus, if the primary has 100 turns of wire and a pressure of 100 volts is placed at A B, then the voltage at D E would be within certain limits about equal to the number of turns of the secondary. In other words, if the number of turns on the secondary is one-third the number of turns on the primary, then the voltage at D E will be approximately one-third that impressed at A B. The main advantage of the autotransformer is that a saving is accomplished by having the primary and secondary windings combined. The chief disadvantage is that where extremely high voltages are used there is always danger of the two windings becoming crossed or shorted. (See *Short.*) For this reason they are used mainly for comparatively low voltages. One of the most common forms is the step-down type, known as a "bell-ringing transformer." These are used to cut down the voltage of an electric light line to suitable value for use with small toys or bells. If the transformer is used to increase the voltage, it is known as a "step-up" transformer. (See *Transformer—Radio, Audio.*)

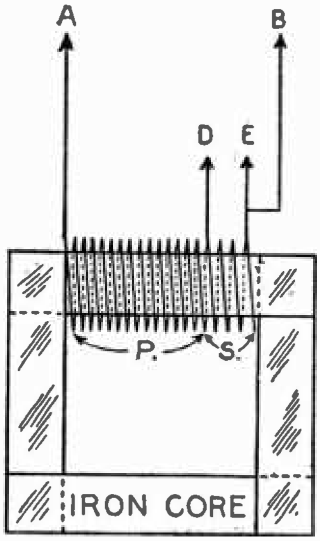


Fig. 1.

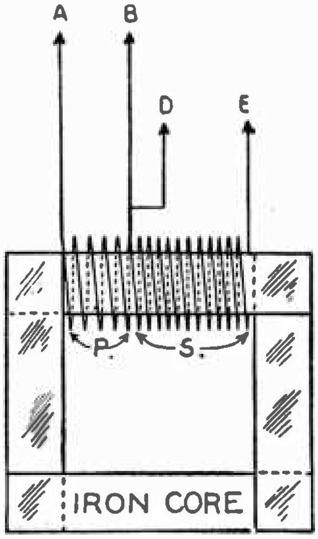

Fig. 2.

AUTO TRANSFORMER COUPLING—See *Coupling.*

B

B—Abbreviation for Baumé, the scale used in a *hydrometer* (*q.v.*)

B. A. AMPERE—The standard ampere fixed by the British Association for the Advancement of Science.

BACK COUPLING—See *Reactance Coils.*

BACK ELECTRO-MOTIVE FORCE—An *Electromotive force* (E.M.F.) which opposes the original electromotive force. The more common term is "*Counter E. M. F.*" In many arrangements of electrical circuits there will be an electromotive force set up in such manner as to oppose the impressed voltage or force. This will be true in the case of a *choke coil* in which any variation in the pressure or electromotive force applied to the coil will result, under proper conditions, in the production of a back or counter-electromotive force that will oppose the change in the original force.

This phenomena is frequently found in electrical circuits; at times introduced for a purpose and at others self-introduced, and therefore demanding consideration in design of apparatus. The rotation of the *armature* of a motor creates a counter E. M. F. opposed to the impressed E. M. F. and upon which the driving power of the motor depends. When an external E. M. F. is impressed on a circuit in which there exists a local E. M. F., the flow of the current through that portion of the circuit containing the local E. M. F. will result in an increase or decrease of energy depending on whether the local E. M. F. is opposed to, or in the same direction as, the external E. M. F. (See *Counter Electromotive force.*)

BACK OSCILLATION—When the *condenser* of a transmitting circuit of the spark type discharges across the *spark gap* some of the *high frequency* current may flow back through the secondary of the transformer instead of taking its normal path across the gap. This back flow is usually referred to as *Back oscillation* or kick back, and is apt to break down (see *Breaking Down of Insulation*) the insulation of the transformer if not prevented or controlled. Back oscillation is retarded ordinarily by means of coils of wire having a certain arbitrary *inductance* value. When the high frequency discharge from the condenser has any tendency to break through, the *reactance* of these coils becomes so great that they act in effect as insulators. As the capacity and inductance of these coils might create an *oscillatory circuit* of the same *natural period* as the primary oscillator, they are shunted with non-inductive carbon resistances. These coils are termed "*choke*" coils.

BAKELITE—An insulating material having widespread use in radio. It possesses great strength and has a high *dielectric* (insulating) value together with the ability to withstand high temperatures. This material is furnished in many forms and under a variety of trade names, being considered one of the best of the insulating compounds.

Chemically known as *Oxybenzylmethylenglycol anhydride.* It is produced by the union under heat and pressure of phenol and formaldehyde together with a small percentage of some alkaline agent. Is heat resisting up to about 500 degrees Fahrenheit—disintegration setting in somewhere above that point.

BALANCED CIRCUIT—An electric circuit arranged in such manner with relation to adjacent or neighboring circuits as to do away with the effect of *mutual induction* (*q.v.*).

BALANCED DETECTORS—A term applied to an arrangement of opposed rectifying *detectors* for reducing the effects of strong *strays* in receiving apparatus. The detectors must be balanced for violent *electro-motive forces,* but not balanced for the moderate E. M. F.'s due to the signals. Actually, a method of eliminating stray impulses in reception.

BALANCED METALLIC CIRCUIT—A circuit through conductors (wire or any metal) in which the total resistance is the same on each side of the circuit. (See *Circuit.*)

BALANCED ROTARY CONDENSER—A variable condenser having some arrangement for keeping the plates accurately balanced in rotation at all points. Fig. 1 shows a form known as the "balanced plate" type. In this case the plates are so arranged that half the movable plates are on one side and half on the other side of the shaft.

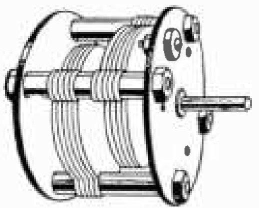

Fig. 1. A "Balanced-Plate" type Rotary Condenser.

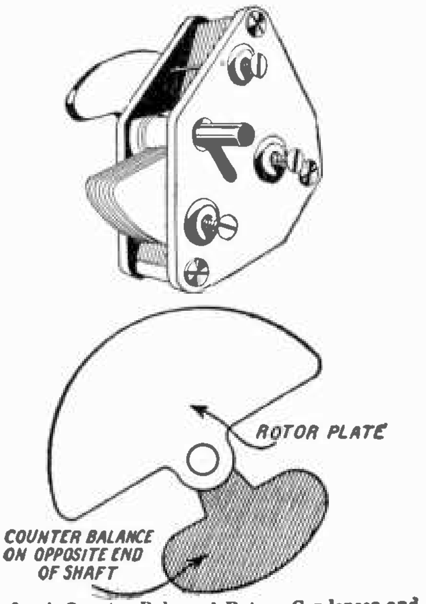

Fig. 2. A Counter-Balanced Rotary Condenser and illustration showing how the counter balance is attached to shaft.

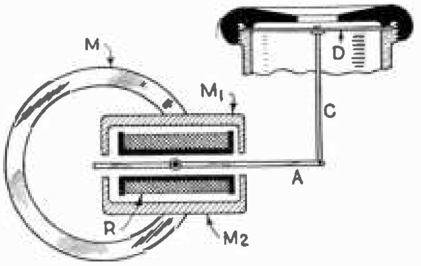
This maintains the balance of the part. Fig. 2 shows another method known as "counter-balanced." The weight of the balance is the same as that of the movable plates and its position on the other side of the shaft serves to maintain balance. The idea is to prevent the plates slipping due to lack of balance and thus keep the setting at the desired point after adjustment.

BALANCING—Any method of eliminating interference by reducing the *amplification* of the undesired signals while permitting full amplification of the desired signals. (See *Interference Eliminator.*)

BALANCING AERIAL—An aerial system designed to permit reception of signals from distant points without interference from a powerful nearby transmitter. The system involves the use of two aerials, one for balancing, the other for receiving. The receiving aerial is tuned to the wavelength of the desired signals, while the balancing aerial is tuned to the wavelength of the nearby station (the interfering signals).

In operation the receiving circuit is coupled to each aerial *electro-magnetically,* and is acted on by both series of *oscillations* (distant and nearby waves). By careful adjustment of *coupling* and phase relation of the *induced currents,* the interfering wave may be balanced out in effect and the desired oscillations received.

BALDWIN RECEIVER—Perhaps the most sensitive type of telephone receiver thus far developed. It employs what is known as a "balanced armature," the signals being produced by the vibrations of a *diaphragm* which is not acted on directly by the magnets. The illustration shows the general plan of a receiver of this type. The *armature* (A) is of soft iron and is pivoted between two U-shaped soft iron pieces (M1, M2) mounted on the ring-shaped horseshoe magnet (M) as indicated. The armature is acted on by the magnets in response to incoming signals and the movement of this element in turn acts on the mica diaphragm (D) by means of a fine brass wire (C). The usual windings (R) are placed between the two pole pieces, the armature being mounted in a central slot. These receivers are much used both for headphones and for loud-speaker units. In the latter case the mica diaphragm is generally made heavier to handle the more powerful vibrations due to the *amplification* of the signals.



Principle plan of the Baldwin Receiver unit.

When no fluctuating impulses (signals) flow through the windings (R), there is no *magnetic stress* on the armature (A), because this member is suspended centrally between the pieces (M1) and (M2), the magnetic attraction of which are equal. Now when a fluctuating impulse flows through the windings (R) it produces a magnetic flux which combines with the flux of the permanent magnet (M) and the total flux is distributed asymmetrically or unevenly on both sides of the armature. The result is a rocking vibratory movement to this member which is in turn communicated by the juncture wire (C) to the diaphragm (D), producing the audible signals. (For a comparison of this action with the conventional telephone receiver action, see *Telephone Receiver.*)

BALKITE BATTERY CHARGER—An electrolytic battery charger which makes use of a sulphuric acid solution and tantalum as the valve metal. Used for charging *storage batteries* from *alternating current.* See illustration.

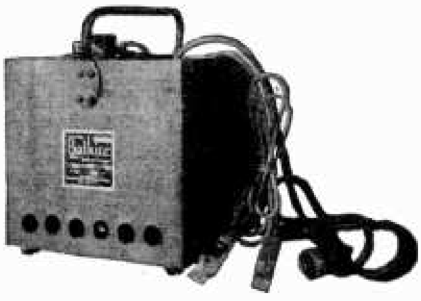


Photo by courtesy of Fansteel Products Co.

A Balkite Battery Charger.

Note: The name Balkite is derived from the name of the man who perfected the process of extraction of tantalum from its ores.

BALLAST TUBE—An automatic means of regulating the *filament current* of vacuum tubes. The device is enclosed in a glass tube and is arranged to permit passage of a certain fixed amount of current. The ballast element is a wire whose *resistance* changes with the current through it, due to the change of resistance with the temperature of the wire. When the *electromotive force* increases beyond normal, the increased current raises the temperature and hence the resistance, so that the current is held to the normal value.

B. and S.—Abbreviation for Brown and Sharpe Gauge (*q.v.*).

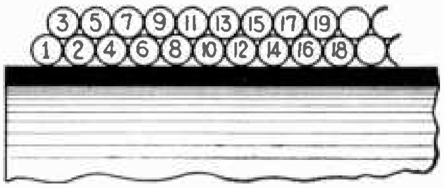
BAND OF FREQUENCIES—A continuous range of *frequencies* extending between two frequencies. (See *Band of Wavelengths;* also *Band Pass Filter.*)

BAND PASS FILTER—A *filter* arrangement designed to permit passage of all *frequencies* extending between two definite frequencies but excluding all other frequencies. (See *Band of Frequencies.*)

BAND OF WAVE-LENGTHS—A continuous range of *wave-lengths* extending between two definite wave-lengths. For example, the usual broadcast band of wave-lengths is approximately 250 meters to 550 meters.

BANKED BATTERY—A *battery* that has its *cells* connected in *parallel.*

BANK WINDING—A form of winding for coils in which the turns are staggered so that two or more layers may be used without having large distributed capacity losses. The illustration shows method of bank winding for two layers. Note that in this form the *electrostatic capacity* between any two turns is only that between adjacent turns, representing only a small part of the total winding, whereas on the usual form of winding the adjacent turns would represent a good portion of the total *inductance* and hence the effect of distributed capacity would then be much greater. (See *Distributed Capacity.*)



Method of bank winding wire on a coil form.

BARRETER—A receiving instrument consisting essentially of a small mass of conducting material that is heated by the passage of an *oscillatory* current, and arranged so that the consequent alteration of electrical *conductivity* affects an indicating instrument, such as a telephone receiver or *galvanometer.*

BASKET COIL—Variometers—couplers, etc. (See *Basket Wound.*)

BASKET WOUND—A method of winding coils, such as variometers or variocouplers. The winding is a latticework of wires in skeleton form, the object being to save weight and eliminate large losses such as occur in the types using a great deal of solid insulating material. The illustration shows a popular form of basket variometer.

A Basket Wound Variometer.

BATTERY — In the electrical field, a group of *primary or storage cells, dynamos*, or *condensers* grouped together to form a single unit. The term is often used incorrectly to refer to a single cell—as "dry battery," the correct name for which is "dry cell." Thus a group of condensers joined together as one unit is termed a battery, also a number of dynamos arranged as a single unit for the production of electrical energy. (See *Dry Cell*, also *Battery of Alternators, Storage Battery, "A," "B" Battery*, etc.)

"B" BATTERY—An appliance for obtaining electricity of sufficient voltage to supply the plate of a *vacuum tube*. There are two types of "B" batteries, viz., the *dry cell* type and the storage types. In order to obtain the high voltage required for vacuum tube plates, many small cells are connected in series. The usual method is to connect them together and seal in a square package. Often taps are brought out so that various voltages may be obtained for *critical* vacuum tubes. The most popular voltages which dry cell "B" batteries give are 22½ and 45 volts. The storage "B" battery is similar to the ordinary storage battery with the exception that the cells are much smaller, but contain more cells in series. These can be charged in the same manner as the "A" or *storage battery*. In Fig. 1, we have a popular type of "B" battery. This is tapped in order that different voltages may be obtained.

"B" BATTERY 22½ VOLTS

Fig. 4. How a common "B" Battery may be used both for detector and amplifier.

If separate batteries for each tube are desired, the circuit should be connected as in Fig. 5. This lengthens the life of the "B" battery as the drain on the battery is much less, i.e., only one vacuum tube is operated on each battery.

Fig. 5. Method of employing separate "B" Batteries for the detector and amplifier.

BATTERY OF ALTERNATORS — In ordinary electrical work such as house lighting, several *alternators* for the production of alternating current may be used together as one source of power. Also in high-power radio transmission, several *high-frequency alternators* may be used together to produce added power. (See *High-Frequency Alternator.*)

BATTERY TESTING INSTRUMENTS —The various devices used for determining the condition of batteries used as radio apparatus. (See *Ammeter, Voltmeter*, also *Hydrometer.*)

BEAT FREQUENCY—The *frequency* or number of vibrations per second of a series of *oscillations* representing the difference between two other series having different frequencies. It is numerically equal to the difference between the original two series of oscillations. Thus, if we have a series of oscillations having a frequency of 100,000 *cycles* per second, and combine it with another series having a frequency of 90,000 or 110,000 cycles, the *beat frequency* will be 10,000 cycles or the difference between the other two frequencies.

X. The frequency of recurrence per second of either maxima of addition or minima of opposition of two superposed periodic phenomena having the same nature but of different frequencies. The time measure of vibration of a beat or heterodyne. (See *Heterodyne*, also *Beats.*)

BEATS—When two sets of *oscillations* of different *frequencies* occur in the same system, the difference in the frequency or rapidity of vibration causes a new set of oscillations having a frequency equal to the difference between the original two sets. This may be accidental as in the case of certain types of receivers such as the *regenerative* type, in which case the beat oscillations are undesired and cause interference or disturbances in the set. Then again a beat frequency may be purposely introduced as in the case of the *Super-Heterodyne receiver*. Here we have the natural incoming oscillations from the antenna combined with a series of oscillations produced locally in the system. The result is a new set of oscillations where the incoming series and the locally produced series are not of the same frequency. (For more complete explanation see *Super-Heterodyne Receiver.*)

X. Where two *periodic phenomena* are *super-posed* or run together and the frequencies differ, the gradual change in *phase difference* produces a condition wherein the *amplitudes* are in opposition at one instant and in concurrence at a later instant with the various intermediate stages during the interval. (See *Heterodyne*, also *Beat Frequency*.)

BEG OHM—A *resistance* of one billion *ohms*. (See *Megohm*.)

BELIN, EDOUARD—French scientist, the inventor of what is considered the first practical system of radio transmission of photographs. The device can be used for sending photos by cable or telephone lines as well as radio. (See *Transmission of Photographs by Radio*.)

Brown photo.

Edouard Belin.

BELL, Alexander Graham (1847-1922)—Scottish scientist. Born in Edinburgh, March 3rd, 1847, he was educated at the High School and University and graduated as a doctor of medicine. In 1870 he went to Canada, and in 1872 became professor of vocal physiology in the University of Boston. In 1876 he exhibited his apparatus for the transmission of sound, afterwards developed into the telephone. Bell was experimenting with an electric invention by means of which he hoped to make speech visible to the deaf. A delicate metal reed was caused to vibrate by spoken speech and to transmit an electric current to the opposite end of a wire, where the vibrations of the first reed were reproduced in a second reed by a magnet. He found that it was possible to transmit not merely vibrations of the original reed, but to reproduce the sound itself in the vibrations of the second reed. In 1878 he invented the photophone, to enable sound to be transmitted by variations on a beam of light, and later a phonograph. Bell was the author of many scientific papers, was awarded the Albert Medal of the Royal Society of Arts in 1902 and the Hughes Medal of the Royal Society in 1918. He died Aug. 2nd, 1922.

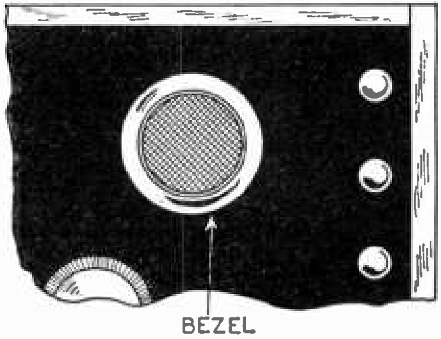
Alexander Graham Bell.

BELLINI, Dr. Ettore—Born in Foligno, Italy, April 13th, 1876. Educated at the University of Naples. Noted as Electrical Engineer to the Royal Italian Navy, and chief of the Naval Electrical Laboratory at Venice. Joint inventor with Captain Tosi of the "Radiogoniometer" (*q. v.*), a device for finding the direction of transmitted radio signals.

BELLINI-TOSI AERIAL — See *Goniometer*.

BELLINI-TOSI DIRECTION FINDER —See *Goniometer*.

BEZEL — In mechanics, generally a groove and flange made to receive a beveled edge. In its adaptation to radio some liberty was taken with its real meaning. Its significance in this sense is a small metal ring having a wire mesh or glass center. It is fitted into a circular hole in the panel of a radio receiver and used as a peep hole to enable the operator to know at all times the conditions of the tubes, whether or not they are properly lighted.



A Bezel on the panel of a radio receiving set.

BILLI CONDENSER—A variable *condenser* of low *capacity*, consisting of two brass tubes, one of which is arranged to slide in and out of the other for the purpose of varying the capacity. Such condensers were much used before the days of broadcasting, in conjunction with any circuit using a crystal and battery for detector. This type of condenser has long been obsolete in the United States.

BINDING POST—A screw and nut arrangement used on electrical units and radio apparatus to make convenient connections from an external source to the desired point within the apparatus. Binding posts are provided, for instance, to make handy connections from batteries to the set and from the aerial and ground leads. The illustration shows a popular type of binding post.

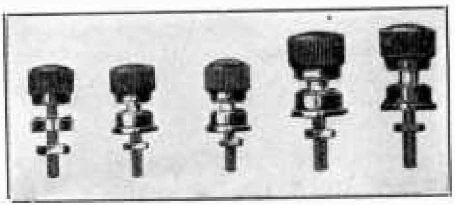


Photo by courtesy of The H. H. Eby Mfg. Co.

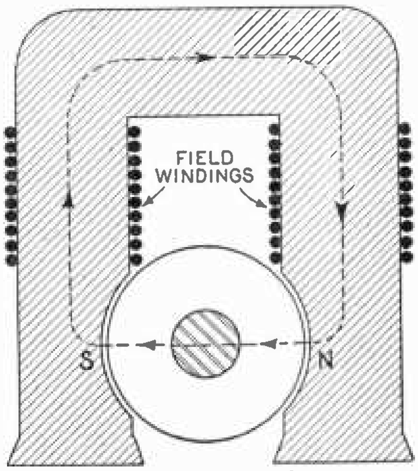
A group of Binding Posts as used on electrical and radio apparatus.

BI-POLAR—Having two *poles*. Usually a *dynamo* or motor whose *armature* rotates between a *field magnet* having only two poles. The most modern types are of the Multi-polar variety. (See *Bi-polar Magnetic Field*.)

BI-POLAR ARMATURE WINDING—An *armature* wound in a manner to permit its use with a dynamo having a bi-polar magnetic field.

BI-POLAR MAGNETIC FIELD — The magnetic field (*q.v.*) created between two magnetic poles. The illustration shows a common form of bi-polar magnet for a dynamo. Bi-polar magnetic fields are now used as a rule only for direct current machines of low power, such as those under 5 *Kilowatts*. (See *Dynamo*, also *Generator*.)



A Bi-Polar Magnet of a dynamo.

BI-TELEPHONE RECEIVER—A headset with two receivers or phones as generally used in radio. In the early days of radio transmission it was the custom to use only one phone.

BLONDEL, Andree—French electrical expert. Born at Chaumont, France, in 1863, he graduated at Paris University, and studied electric waves, on which subject he early contributed a number of papers to various scientific journals. In 1893 he invented the *oscillograph*, an instrument somewhat similar to a mirror *galvanometer*, for showing curves of *oscillating* or *alternating currents*. This invention opened up a fresh field in the study of alternating currents. In the same year Blondel explained for the first time mathematically the effect of inertia in the shunting of *alternators*. He is responsible for a system of acoustically syntonic wireless telegraphy, and for directed waves produced by a double aerial. In 1902 he patented a method for producing electric oscillations for wireless telephony, and has written many papers on microphonic control for transmitters, wireless telephony, the singing arc, etc.

BLONDLOT, Professor Prosper Rene—French wireless expert. Born at Nancy, France, in 1849, studied at

Paris, and became professor at the faculty of sciences, Nancy, and afterwards Honorary Professor and Correspondent of the Institute of France. Professor Blondlot is famous for his studies of electro-magnetic waves, particularly with regard to their speed, and the laws of *propagation* of wireless waves in various media.

BLOWER MOTOR—A motordriven fan used to deliver a high pressure blast at the *spark gap* to prevent *arcing*. (See *Spark Gap*, also *Spark Discharger*.)

BLOWOUT—See *Magnetic Blowout*.

BLUE GLOW—A condition within a *vacuum tube* when the vacuum has become poor. After continued use a tube will often hold a small percentage of gas, which causes a blue glow when current is passed through it. A tube in this condition is a poor *detector* or *amplifier* and should be replaced. The condition should not be confused with the glow often caused by an excessive voltage. In this latter case decreasing the voltage to the normal value will generally permit the tube to be operated efficiently. The blue glow in this case is due to *ionization* of the residual gas by the excessively high *potential* impressed across the elements of the tube.

BOARD OF TRADE UNIT—B.O.T. 1,000 Watt Hours. One and a third Horse Power.

BODY CAPACITY—The effect of the human body when tuning a radio receiving set. The hand when placed on or near the controls very often throws the receiver out of balance with the incoming signals. In the case of very *sharp tuning* this effect is more in evidence and is likely to cause howls due to *self-oscillation*. The howling is due to the production of an audible *beat frequency* in the system, caused by the combination of the local *oscillations* with the incoming signal oscillations. The remedy may be to shield the panel with metal foil or in some cases to merely alter the direction of the leads from the *tuning condenser*. The experienced operator seldom pays much attention to the phenomena, as a little practice enables the listener-in to compensate for the effect. To make this more clear, if, when tuning the set, the withdrawal of the hand from the dial *detunes* the set or throws it out of balance, it is due to the fact that the hand has acted as a certain amount of *capacity* in the circuit, and naturally its withdrawal is equivalent to a change in the condenser setting. A simple system is to turn the control beyond the point of maximum volume, then when the hand is withdrawn the capacity will drop to its proper value. This can be mastered very readily. If the tuning condenser is connected across the secondary, i.e., one side to the grid, and the other to the grid return, the stator plates of the condenser should be connected to the grid of the tube. If metal foil or thin copper sheeting is used for shielding it should be connected to the ground post of the set.

The tendency of the human body to insert an arbitrary capacity in the circuit. The phenomena is especially noted where maximum volume is obtained only by very critical control close to the oscillating point, in which case the circuit may be thrown out of resonance.

BOLITHO CIRCUIT—A *super-regenerative circuit* patented in England in 1919 by Captain J. B. Bolitho. The circuit was originally intended to operate a relay device. The circuit has been adapted to use as an *amplifier* for radio reception.

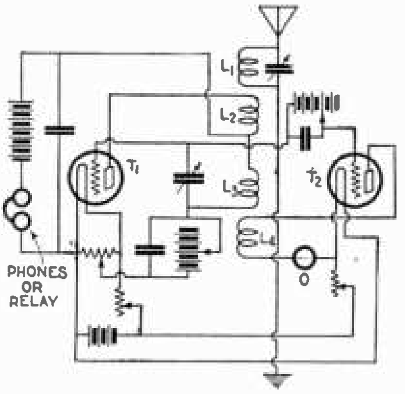


Diagram of the Bolitho Circuit.

In the illustration the phones may be replaced by a loud speaker or relay. In operation, T1 is held at a point just below that where *oscillation* sets in by means of T2 which is excited by an oscillator O in the plate circuit and coupled by means of coil L4 to the tuned grid circuit through L2 and L3, the coupling, as explained, being so arranged that the tube is always just below the oscillating point. A *reaction coil* L4 is placed in the plate circuit of T2 in such manner as to oppose the magnetic linkage between coils L2 and L3. The *frequency* of the generator O is lower than that of the received signals. As indicated, the grids of both tubes T1 and T2 are joined together and the tube T2 maintains the circuit in a receptive condition when tube T1 is tuned just below the oscillating point.

The oscillator O makes the *plate* of T2 alternately *positive* and *negative* with the following effect: When the plate of T2 is negatively charged there is no current in coil L4, this coil therefore not affecting coils L2 and L3, and permitting tube T1 to build up self oscillation. When the plate is made positive by the action of the oscillator, current flows through coil L4, and as it is coupled in opposition to coils L2 and L3 it neutralizes the coupling between L2 and L3 and prevents transfer of energy between the grid and plate circuits of the tube T1. This tends to stop the self oscillation and makes the circuit receptive to the energy (signal) produced by outside signals in the aerial coil L1. The frequency, of course, is determined by the frequency of the oscillator O. The system is especially adapted to the reception of continuous wave signals. (See *Super-regenerative circuit*, also *Feed-back* and *Regenerative circuits*.)

BOLOMETER—Type of *Wheatstone Bridge* having an easily heated *resistance*, such as a very fine wire in one arm. (See *Wheatstone Bridge*.)

BOOSTER—An expression signifying a small *dynamo* used in conjunction with main dynamo to temporarily raise, when necessary, its normal *pressure*. It is generally driven by a motor supplied with energy from the main generator and thus becomes in effect a *continuous current transformer*. Frequently used for charging *accumulators* of a generating plant. The term "Boost" is also used to denote increase or a stepping-up of any electrical quantity. (See *Amplification*.)

BORNITE—A *crystal rectifier* much used in radio reception. It is a natural sulphide of iron and copper, having a metallic blue lustre. This mineral is used in combination with zincite or copper pyrites as a crystal detector. Such combinations are generally known as "crystal to crystal" detectors to distinguish them from the ordinary variety using one mineral and a wire contact.

BORON—A non-metallic chemical element used in radio as one of the electrodes for the *T. Y. K. Arc*. Chemical symbol B, atomic weight 11.0, specific gravity 2.6.

B. O. T.—The customary abbreviation for *Board of Trade Unit*. The unit represents 1,000 *watt hours*. (See *Board of Trade Unit*.)

BOX AERIAL—A term occasionally applied to loop aerials. (See *Loop aerial*, also *Frame Aerial*.)

BRADFIELD INSULATOR—A particular form of *Lead-in Insulator*, consisting of an ebonite tube provided with zinc cone and ebonite spark discs, for breaking up continuous streams of rain running down outside which might cause the aerial to become grounded. The whole is held in position, half way through roof of operating room, by means of a stuffing box. The aerial is led in by means of a conducting rod through center of tube. (See *Petticoat insulator*.)

BRANLY COHERER—Early form of *Marconi Coherer*. (See *Coherer*.)

BRANLY, EDOUARD—French radio expert. Born at Amiens, France, Oct. 23rd, 1844. He was educated at Paris and afterwards became Fellow of the University, doctor of physical science, and doctor of medicine. Branley early made a study of electro-magnetic waves, and in 1890 and 1891 patented methods of operating a local relay circuit from a distance by means of wireless waves. In 1900 he was awarded the Grand Prix by the International Jury of Superior Precept Instruction for his exhibition of radio-conductors.

In 1890 Branly published an account of his very extensive series of observations on the electrical conductivity of loosely packed metal filings, and he made the extremely important observation that an electric spark at a dis-

Edouard Branly.

tance had the power of suddenly changing the electric *conductivity* of loose masses of powdered *conductors*. To Branley is due the *coherer* named after him.

BRAUN, FERDINAND—Professor at the University of Strasburg, and one of the leading world authorities on Radio transmission. As early as 1899 Braun was granted a patent for *closed oscillating* systems with an *inductively coupled* antenna. The system was claimed by Braun to possess a much greater efficiency than the directly coupled systems. The Braun transmitting set, as manufactured by Siemens and Halske, consisted of a large coil worked into an *electrolytic interrupter*, a set of *Leyden jars*, enclosed *spark gap*, *oscillation transformer* wound with insulated wire placed in oil, and for the receiving set the standard type of *coherer relay* and Morse register. In 1899 Braun established communication between Cuxhaven and Heligoland, using aerial wires 90 feet high, and the inductive coupled aerial connection for transmitting. In 1903 Braun joined with Slaby, von Arco, and Siemens to form the Telefunken system of transmission. Professor Braun was awarded the Nobel prize with Marconi in 1900, for his work in wireless. Braun has devised a method of directional wireless which depends upon the interference of *electric waves* travelling in the same direction but different in *phase*. Three simple vertical wire aerials are set up in positions corresponding to the angular points of an equilateral triangle, and *oscillations* are created in these which differ from one another in phase. In 1897 Professon Braun published a description of his cathode ray tube, and afterwards pointed out, in 1902, how such a tube could be used to trace the forms of alternating current waves.

BRITISH STANDARD WIRE GAUGE—The standard wire gauge of Great Britain. The table shows the various diameters in thousandths of an inch (mils.).

BREAK or BREAKER—See *Circuit Breaker.*

BREAKDOWN POTENTIAL or BREAKDOWN VOLTAGE—The voltage necessary to *break down* or puncture a *dielectric*. The ability of any *insulating* material to resist breakdown is an important matter. An insulator or dielectric material is usually given a certain rating or point above which it is likely to fracture. Thus, a condenser may have a breakdown rating of 500 volts. That is to say that voltages up to 500 and slightly over may be handled with safety, but any large increase above that figure may result in puncture of the material by the excessive potential or voltage. The relation between dielectric strength and breakdown voltage is shown in the following formula:

$$V = cd\ \tfrac{2}{3}$$

Where d is the thickness of dielectric in millimeters
V the potential difference in volts
c-a constant representing the potential difference required to cause a dielectric breakdown of a sample of the material 1 mm. thick. (See *Dielectric Strength.*)

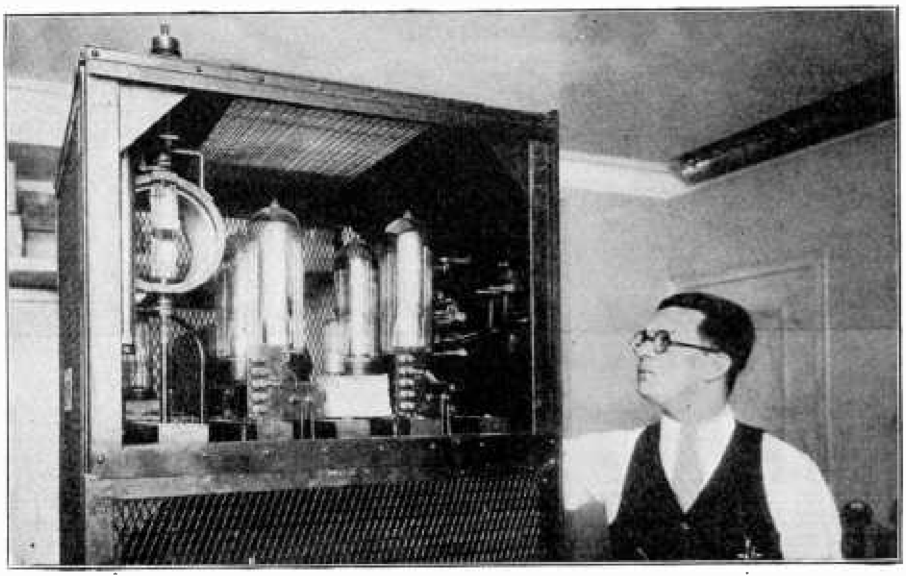

Fig. 1. A bank of 250-watt transmitting tubes in a Radio Broadcast Station. Note the small receiving tube for comparison of size.

BREAKING DOWN OF DIELECTRIC—In a *condenser*, the gradual weakening of the *dielectric* or insulating sheets which eventually causes them to permit direct passage of the current. For example, if a force of 1000 volts is applied for a considerable period to a condenser that has been designed for a maximum of 500 volts, the insulating material between the plates would probably be punctured by the current. (See *Break-down Potential.*)

BREAKING DOWN OF INSULATION—The same effect as referred to under *Breaking Down of Dielectric*. The insulation weakens and permits the ready passage of electric currents. (See *Break-down Potential.*)

BRIDGES—See *Capacity Bridge*, also *Wheatstone Bridge.*

BRIDGING—A term occasionally used for *shunt* (q.v.) connections. Thus, a grid condenser is generally shunted or bridged by a *grid leak.*

BROADCAST—Transmission of music, news and other matters of general interest and entertainment by means of *radio telephony*. (See *Broadcasting, General Treatise on Methods.*)

BROADCASTING, GENERAL TREATISE ON METHODS—The application of radio telephony to the transmission through the ether of musical programs, speech or any form of news or entertainment, in such manner that it can be readily received by anyone possessing a radio receiver sufficiently sensitive and capable of being tuned to resonance with the particular waves being sent out. While broadcasting in its present world-wide scope is a comparatively new enterprise, it has actually been used to a more or less degree since the practical development of the wireless telephone. As near as records can be determined, the first actual broadcasting was done in 1912. It was, however, not until after the world war that it began to develop into an industry of prominence. Now it occupies a place of very definite importance in everday life; carrying news and entertainment into the remote corners of the earth, far removed from telephone or telegraph communication.

The fundamental principles of broadcasting are essentially those of radio transmission, with the addition of means of combining the speech or music vibrations with the regular radio waves. First we have to consider the radio waves of high-frequency—alternating current that changes in direction many thousands of times each second. These high frequency waves are known as the carrier waves. The frequency of these waves varies according to the length of the waves (wavelength), in the case of American broadcasting stations, being between 250 and 550 meters in most cases, which means a frequency range of approximately 550,000 to 1,200,000 cycles.

Now by means of a microphone, a device similar in principle to the mouthpiece of an ordinary telephone, but designed to handle large currents, the air pressure waves, i.e., speech or music, are converted into variations of electric current. By use of suitable amplifying apparatus, the strength of the electric waves radiated from the antenna is varied to correspond electrically to the acoustic or sound variations due to the speech or music being impressed on the microphone. The speech or music waves are low frequency waves, generally ranging between 100 and 4000 per second. Thus, while the carrier wave oscillations are of high frequency, the variations in it are low frequency, corresponding to the ordinary speech or music vibrations.

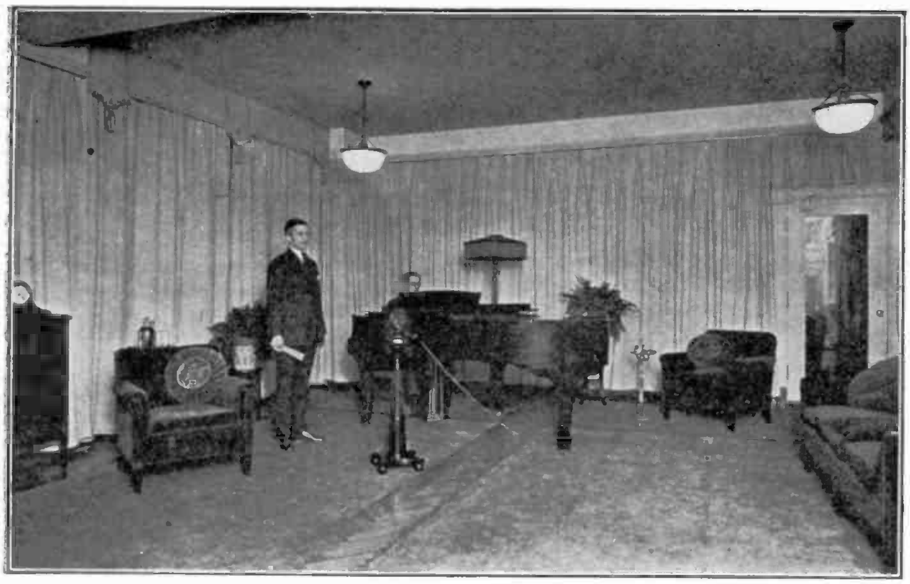

Fig. 2. Studio of a modern Radio Broadcast Station.

The process of varying the radiated wave in accordance with the sound waves is known as *modulation*. This adjustment is of the utmost importance, as defects here result in distorted or improperly modulated sound waves and the reproduction cannot be perfect. The reception of broadcast programs is essentially the same as that of ordinary radio signals, with the exception that care must be used at the receiving end to preserve the form of the original vibrations. When dot and dash signals are received, the tone is of comparatively little importance, whereas with voice or music it is essential that the tone quality be retained.

In broadcasting the high frequency oscillations are produced by means of a tube or group of tubes, practically identical with those used for reception, but designed to handle large currents and voltages. The majority of American stations use vacuum tubes of 250 watts power rating, one or more of them being used to obtain the total power required. These tubes are shown in the illustration, Fig. 1.

When a program is being broadcast, the action is somewhat as follows: The artists are disposed before the microphone with due regard to the effect of certain instruments. That is to say, one type of instrument may be placed near the microphone, while another must be placed farther away, owing to the differences in tone and volume. This is done to prevent any one tone or range of tones from predominating. These speech or music currents are converted into electrical variations by the microphone and then increased many times in power or amplitude by means of a speech amplifier system, comprising vacuum tubes and the necessary associated circuits.

These amplified currents are applied to the grid of a control tube or bank of tubes and result in large variations in the plate current of the tubes. (See *Theory of Vacuum Tube.*) The control tubes are supplied with filament current from storage batteries or special low voltage D. C. generators, and the high voltage applied to the plates of the tubes is furnished by generators. This power will vary in most cases from about 1,000 to 5,000 volts. In some broadcasting stations, the power is obtained through high voltage direct current generators, while in others, the alternating current supply is stepped up or transformed through high voltage transformers and then rectified by means of special vacuum tubes.

The high frequency waves are applied to the antenna system tuned circuits and carefully modulated in accordance with the variations of the speech or music being transmitted. The action of the transmitter and the effect of the modulation must be carefully observed at all times during the transmission of programs. (See *Harmonic Suppressor*, also *Oscillograph.*) Fig. 2 shows the studio of a modern broadcasting station. It is interesting to note that these studios are very carefully arranged and the walls cushioned to prevent troublesome acoustic effects. There must be no reverberation—echoes—or the transmitted program would be distorted by the additional or repeated tones. Fig. 3 shows the main control panels. Fig. 4 illustrates the power generating system of a typical broadcasting station.

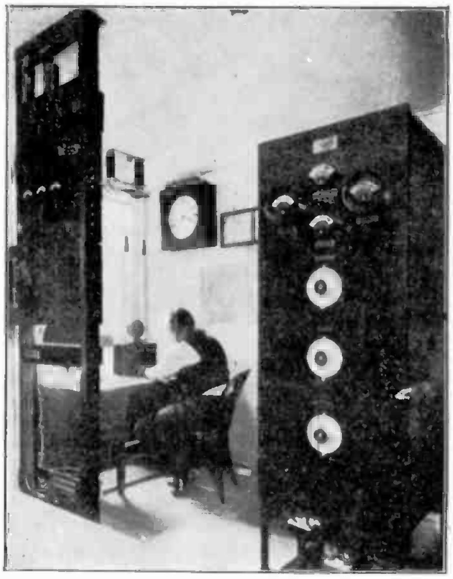

Fig. 3. Main control panels of a Radio Broadcast Station.

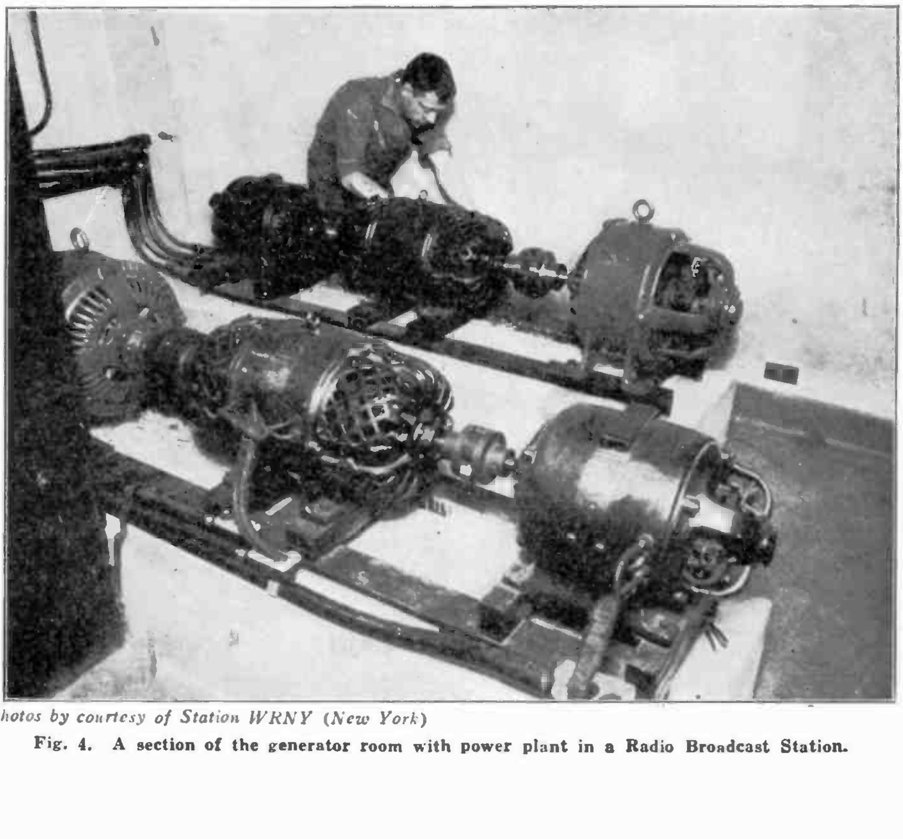
The radio waves generated and radiated from the broadcasting station travel away from the antenna at tremendous speed—that of light waves, or about 186,000 miles per second. These waves radiate off into space in



Photos by courtesy of Station WRNY (New York)

Fig. 4. A section of the generator room with power plant in a Radio Broadcast Station.

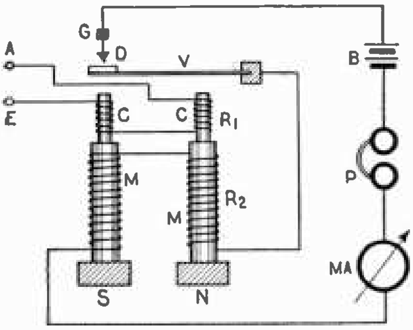
much the same manner as light waves, but a certain portion apparently follow the curvature of the earth. When these waves impinge on a receiving aerial they follow the path of least resistance, and being then in the nature of electrical impulses, they follow the aerial and lead-in wire to the receiving set, and thence to the ground. The receiver is arranged in such fashion that it corresponds electrically to the antenna circuit of the transmitting station. That is to say, the receiver is placed in resonance with the particular signals desired. The usual system of detecting, either with a simple crystal or by means of vacuum tubes, may be followed by special amplification which will make the signals audible on a loud speaker. In many cases the signals are amplified in their original form (radio frequency amplification), then rectified by the detector and further increased in volume at audio frequency. (See *Modulation*, *Speech Amplifier*, *Electromagnetic Waves, etc.*)

BROAD TUNING—A term used to designate the lack of *selectivity* in reception or in transmission, the use of several *waves* rather than a sharp, pure wave. If a receiving set is of such a nature that it is difficult or impossible to receive the desired signals without hearing any other, the set is said to be "broadly tuned." (See *Tuning*, also *Selective Tuning.*)

BROKEN CIRCUIT—See *Open Circuit.*

BROWN AMPLIFYING RELAY—An arrangement whereby the comparatively weak signals received by a *crystal detector*, usually of the *carborundum type*, may be *amplified* or increased in intensity, either to allow a recording machine to be used or merely to make the signals more readily audible in the ear phones. The device consists essentially of an arrangement for controlling and stepping up the vibrations in conjunction with a small *battery* or *dry cell.*

One example of such a relay is shown in the illustration. In this case the soft iron *cores* cc are *magnetized* by the *permanent magnets* mm, the poles of which are marked n and s. R1 is a fine wire winding such as is ordinarily used in ear phones and R2 is a larger winding placed over the main magnets mm. Directly above the soft core cc with the windings R1 is placed a steel vibrating tongue V having a contact D which touches lightly contact G. Contact G is of a special alloy of osmium and iridium and the contact D is a carbon button, which in contact with G forms a *microphone.* The winding R2 is joined with the telephone P and the battery B, all in series with the microphonic contact. When current (signal current) enters the leads A—E through the windings R1 the result is a change of *flux* in the core of the magnet which vibrates the tongue V. This in turn varies the current of the battery B and causes correspondingly greater sounds in the ear phones P. Several of these relays may be connected together to permit a much greater *amplification* of the original signals.



The Brown Amplifying Relay Circuit.

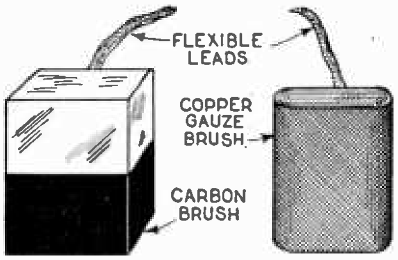
BROWN & SHARPE GAUGE—The American wire gauge adopted as standard for wires for electrical purposes. Commonly known as B. & S. The various sizes run from 40 to 0000, 40 having a diameter of .00314 inch, and 0000 being .46 inches in diameter. We refer to wire having a diameter of .00314 inch as being 40 B. & S. gauge. (*See page 26 for table.*)

BROWN, Sidney George—Born in Chicago, U. S. A., in 1873, of English parents, he was educated at Harrogate and London University. An early study was made by him of the subject of submarine telegraphy. During these investigations he invented the magnifying relay for cables. Another important invention was the cable drum relay. In the year 1898 he invented the magnetic shunt. Since that time many of his activities have been directed to the solution of problems in telephone and wireless telegraphy.

In particular the radio experimenter will know the telephone receivers bearing his name and the important developments of the *microphone relay.* In the field of land telegraphy and telephony, his activities have resulted in the invention of such items as the carbon telephone relay system, which is largely used on land trunk lines for the transmission and reception of telephony.

He is a Fellow of the Royal Society and Vice-President of the Radio Society of Great Britain. His writings on technical subjects are extensive, and numerous valuable patents have been taken out by him, including the vacuum tube *oscillation generator* in 1916 and ionic electric relays in 1918.

BRUSH—A device for collecting current from the *commutator* (*q.v.*) of a *dynamo* or supplying current to the commutator of a motor. Brushes are made in a great variety of forms, the most common being carbon blocks or brass or copper gauze. The illustration shows two different types.



Two different types of Brushes. At the left is shown a carbon brush, and at the right a copper gauze brush.

BRUSH ANGLE—The angle formed by a brush in its contact with the *commutator.* The angle is usually 45°. If the brushes do not bed properly, sparking is apt to occur.

BRUSH DISCHARGE—A faintly luminous discharge which takes place on the surface of *conductors* charged to *high potential*, due to *ionization.* This effect can be noted at times on the *antenna* of a powerful transmitting station. (See *Corona.*)

BRUSH HOLDER—Metal clamp capable of adjustment which holds the *brush* in position on the *commutator* of a dynamo or motor. (See *Brush.*)

BRUSH LOSS—The loss in *watts* or power due to the friction of the brushes against the *commutator.* This loss is at a minimum when the brushes make perfect contact at the proper angle.

BRUSH PRESSURE—A term used to designate the pressure with which the brushes bear on the *commutator* of a dynamo machine and also referring to the voltage or *electrical pressure* delivered at the brushes.

B. S. G.—Abbreviation for British Standard Gauge of Wire, commonly known as B. S. (See *British Standard Wire Gauge.*)

B. T. U.—Abbreviation for "British Thermal Unit," being the commonly used heat unit. The amount of heat required to raise the temperature of a pound of water one degree Fahrenheit at ordinary atmospheric pressure.

BUCHER, Elmer E.—Born Akron, Ohio, Nov. 11, 1885. Educated at high school and private tutors. An American pioneer, Experimental Engineer with De-Forest Wireless Telegraph Company in 1903; constructed several high power stations in Middle West and Gulf Coast and later for United Wireless, which absorbed the Deforest Company. Organized training school for United Wireless and instituted first radio schools for Y. M. C. A. in New York City. Supervised commercial operations and conducted research work for United Wireless; later instructing engineer Marconi Wireless Tel. Co. Technical Editor "Wireless Age" 1913 to 1917. Appointed Commercial Engineer for newly formed Radio Corporation of America in 1920, and since 1922 has been in charge of general sales for that corporation. Author of numerous standard works on radio, including "Practical Wireless Telegraphy," "Wireless Experimenters' Manual," "Vacuum Tubes in Wireless Communication," and many others. Holds numerous U. S. patents on radio systems and devices.

BUCKLED DIAPHRAGM—Warping of the *diaphragm* of a phone as used in radio. Excessive voltages if applied direct to the head-phones will often bend the diaphragms. Any such defect may seriously impair the operation of the part and when it is noted that a diaphragm is bent or warped through rough usage or the application of too great voltages, it is best to replace it immediately.

BUCKLING OF PLATES—During discharge of a *storage battery* the plates gradually expand, owing to the fact that lead sulphate has about twice the volume of the same quantity of lead peroxide. Should this expansion or discharge take place too quickly, the plates will bend or buckle. (See *Storage Battery.*)

BUNSEN BURNER—A form of gas burner frequently used in radio construction for heating the soldering iron where electricity is not available. By special arrangement of the parts, the gas is combined with the proper amount of air before it reaches the burning part. This is done by driving the gas through a tube with small holes drilled to allow the air to be sucked in. This method promotes complete combustion and gives a non-luminous flame that heats the soldering iron without

THE BROWN & SHARPE (B. & S.) COPPER WIRE GAUGE—Below is a comprehensive copper wire table, which is the standard one in use in the United States. The resistance and cross-sectional areas of various sizes of conductors are given, so that considerable calculating can be done with the data at hand. A mil means 1-1000 (one thousandth) of an inch. Hence a wire with a diameter of 9 thousandths of an inch could also be stated as having a diameter of 9 mils. The area of cross-section of the wire in circular mils is found by squaring the diameter in mils; thus the 9 mil conductor would have 9 times 9, or 81 circular mils area. This is the end area of the wire, of course, and is used in all electrical figuring. If the resistance per 1,000 feet of a certain size wire is, say, 50 ohms, then 500 feet of the same size wire would have a proportionately less amount of resistance, or ½ of 50 ohms, that is, 25 ohms. The resistance per foot is found by dividing the resistance in ohms per 1,000 feet by 1,000. This wire table is for bare copper wire. Conductors, according to the B. & S. standard gauge, halve their sectional area in circular mils (Cir. Mils) for every 3 gauge sizes smaller wire; and double their sectional area in Cir. Mils for every 3 gauge sizes increase.

Gauge Number.	Size.		Weight and Length.			Resistance.			Carrying Capacity, 2,000 Amperes p. sq. in. section.
	Diameter in Mils.	Square of Diameter or circular Mils.	Grains per Foot.	Pounds per 1000 Feet.	Feet per Pound.	Ohms per 1000~~0~~ Feet.	Feet per Ohm.	Ohms per Pound.	Amperes.

depositing soot as in the case of an ordinary luminous flame.

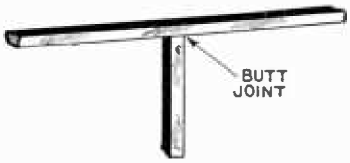
BURSTYN, Dr. W.—Born in Austria, 1877. Educated at Vienna University. Noted as: Developer of the *quenched spark system* in radio transmission, upon which he worked in conjunction with Baron Lepel in 1907 to 1912.

BUS BAR—A single bar, usually copper, which serves as a common connector for a number of pieces of apparatus. Also referred to as Omnibus Bar.

BUS BAR WIRE—Square copper wire, usually tinned, much used in making radio connections. This wire is generally furnished in lengths of two or two and a half feet and is particularly efficient for radio work, as it offers a low *resistance* connection, makes a neat appearance, and is suitable for soldering at joints.

BUSHING—Pieces of insulating material, usually fibre or rubber composition, used to *insulate* parts of radio apparatus or in mounting machine screws or shafts of *condensers* and other devices. The term is also applied to brass or other metal bearings through which the shaft of a piece of apparatus is run.

BUTT JOINT—A method joining two lengths of wire together by placing them end to end or at right angles and soldering the joint. The illustration shows a common butt joint.



Showing how a Butt Joint is made.

BUZZER—An electric call signal device that makes a buzzing noise caused by the rapid vibrations of a contact breaker in a circuit using a small *battery* or *cell*. (See *Testing Circuit.*)

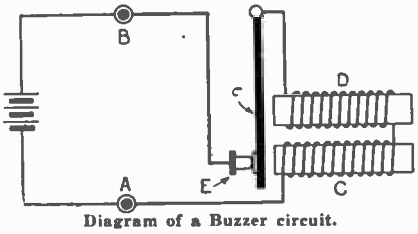


Diagram of a Buzzer circuit.

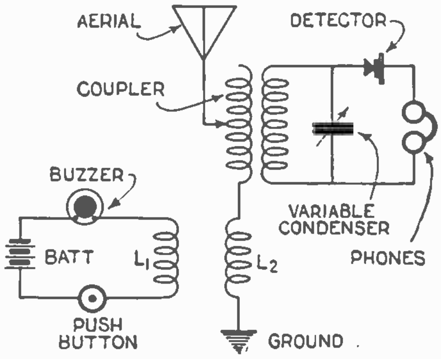
As the *current* flows from the posts A B the *electro-magnets* C and D are energized and draw down the vibrator spring F. This breaks the contact between E and F and as the current no longer flows the magnets release the spring F, which returns to its normal position and establishes the circuit once more. This making and breaking of the circuit takes place so rapidly that the vibrator makes a buzzing or humming sound, the speed with which it vibrates determining the pitch of the note. (See *Frequency*, also *vibration.*)

BUZZER EXCITER—A method of using a *buzzer* to produce local signals in a crystal receiving circuit to permit sensitive adjustment of the *detector*. The illustration shows a common method of producing signals to test the receiving set in this manner. In this case a small coil having a few turns of wire is placed in the buzzer circuit as indicated and a similar one is placed in the ground lead of the receiving set. When the button is depressed the buzzer is set in vibration and a transfer of energy takes place between L1 and L2. This causes an *oscillating* impulse (*q.v.*) to flow through the receiver circuit. The detector can then be adjusted to the most sensitive point at which it can be left until outside signals are heard. Another but less efficient method of exciting the circuit is to connect a short length of wire from the contact point of the buzzer to the ground connection of the receiving set. The former system is much more practical and furnishes better test signals.



Buzzer Exciter.

Coil L1 being placed in *inductive relation* to coil L2, which is in the antenna circuit, undergoes a change of *flux* when the buzzer is *excited.* This sets up a *difference of potential* across coil L2 which charges the antenna ground system and produces oscillation at a definite *frequency* according to the adjustment. Now if the secondary circuit is tuned to resonance with the primary circuit, the signals will be audible in the phones when the detector is properly adjusted. Also called *Buzzer Wave Generator.*

BUZZER MODULATION—See *Modulation.*

BUZZER PRACTICE SET—A combination of a *buzzer* and signalling key arranged on a baseboard used for the purpose of practicing signalling.

B. W. G.—The abbreviation for Birmingham Wire Gauge—a system of gauging wire used in England. (See *B & S Gauge*, also *British Standard Wire Gauge.*)

BY-PASS CONDENSER — See *Condenser*, also *Filter.*

C

C—The chemical symbol for carbon. When printed in *italics*, it is also the symbol for *coulomb* in electrical practice. It is the international symbol for *capacity.*

CABLE—A number of wires stranded together, used to carry electrical currents, heavily insulated and often covered by a sheath or outer coating of lead, rubber, gutta percha, or braided silk or cotton. The term is used very often in a broad sense to signify any heavy wire or strand of wires that may be insulated more thoroughly than is ordinarily the case. (See *Conductor*, *Stranded Wire*, etc.)

CADMIUM—A chemical metallic element somewhat resembling zinc. In color, white with a bluish tinge. It is useful in fusible alloys because of its property for uniting readily with other metals, having a low melting point. Its electrical conductivity is about 25% of that of silver. It is very useful in the construction of a crystal detector, the molten metal holding the crystal firmly and as it melts at a low temperature the heat will not affect the sensitivity of the crystal. Cadmium is also used in making cells, notably the *Weston Cell.* (See *Weston Cell.*)

CAGE ANTENNA—An aerial having a number of wires arranged in cylindrical form, suspended either vertically or as a horizontal top. So named because of its resemblance to a cage. (See *Aerial.*)

CALCULATION OF CAPACITY—The mathematical or comparative determination of *capacity.* There are various formulas in use for calculating capacity under various conditions, such as for capacity of various types of condensers, or the capacity of a circuit. Rough approximations of capacity of condensers might be obtained by direct comparison with a known value. Other formulas are used for the calculation of antenna capacity. For determining the capacity of flat condensers, such as fixed condensers used for transmitting or receiving circuits, the following formula is generally used:

$$C = 0.0885\,K\,\frac{S}{r}$$

In this case, C is the capacity in micro-micro farads; to obtain result in the usual units of micro-farads, divide the result by one million. S is the surface area of one plate in square centimeters; r is the thickness of the dielectric in centimeters and K a constant depending on the material between the plates of the condenser. (See *Dielectric Constants.*)

CAL-ELECTRICITY — Electricity produced in the secondary of a transformer due to changes in temperature of the core. This current is in addition to the current normally induced in the secondary. (See *Transformer*, *Core*, also *Core Losses.*)

CALIBRATION—A process whereby instruments such as *galvanometers* ammeters, *wavemeters*, etc., are made to indicate certain values. Before such

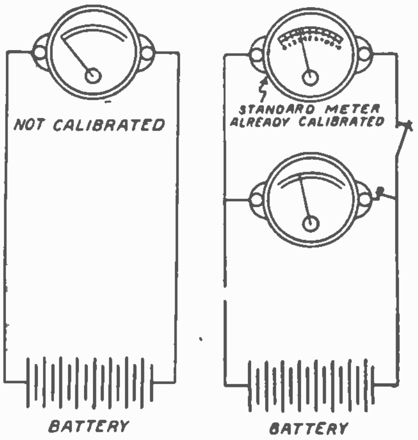


Fig. 1. Fig. 2.

Calibrating a Meter

instruments can be made use of, it is necessary to mark the dials in such a manner that the indicator showing on the dial or scale will have a definite meaning in terms of electrical values. Thus, a voltmeter before calibration is shown in Fig. 1. When it is placed across a battery, the pointer will move to some position on the white space, but without indicating any definite value. Now by testing with another meter which is already marked or calibrated in volts, we find, for example, that when the pointer is at the middle point in its swing, it indicates 10 volts. Similarly various other positions are found to indicate more or less voltage by comparison with the standard. This is shown in Fig. 2. It will be understood that one of the small switches must be open at all times. The reading of the calibrated meter is taken with the other meter out of the circuit (switch open), then the reading is marked on the other meter at the point indicated with the calibrated meter out of the circuit. Such a method would, of course, be inefficient and it is shown only to give a rough idea of the purpose and meaning of calibration. Another example of calibration is in the case of a dial on a receiver. Fig. 3 shows the usual form of dial used in tuning a receiving set. The dial is marked off to scale, from 1 to 100, the numbers having no particular significance. Now if we find that when the tuning dial is set at 20 it is adjusted for a wavelength of 260 meters, we can put that figure in place of the 20. The same procedure can be followed throughout the entire range of the dial, and when thus marked in terms of a definite quantity—wavelength in meters in this case—the dial is said to be calibrated.

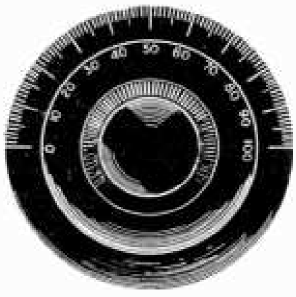

Fig. 3.

A dial as used on radio receiving sets may be Calibrated according to different wavelengths.

The actual method to be followed out in calibrating will depend on the equipment available and the accuracy desired. If a standard of comparison is available, it saves a great deal of work. Thus, a voltmeter can easily be calibrated by means of a standard meter, already calibrated, and a source of steady voltage controlled by a rheostat. An ammeter can be calibrated in the same manner by using a standard ammeter, and a wavemeter can be calibrated from another wavemeter of known values.

Calibration may be done in such a manner that the readings require mathematical solution to determine their value in terms of actual volts, amperes, meters and so on, or it may be *absolute*, in which case the readings are directly in terms of the quantity and require no solution. (See *Voltmeter Calibration, Wavemeter Calibration*, also *Rough Calibration.*)

CALIDO—An alloy containing nickel and chromium with a small percentage of iron. The melting point is very high, about 1550 degrees centigrade. Calido wire is much used as a *resistance*, particularly for heating devices. The chief characteristics are as follows: maximum working temperature 1100 degrees centigrade; microhms per cubic centimeter at 20 degrees centigrade, 100; temperature coefficient per degree centigrade, 0.00034; specific gravity, 8.2.

CALLAND CELL—A primary cell used in French telegraph work. It is a form of gravity cell having a negative electrode of copper and a positive electrode of amalgamated zinc, the electrolyte being zinc sulphate. Crystals of copper sulphate are used as a depolarizer. (See *Gravity Battery.*)

CALORIE—The unit of heat in the C. G. S. (Centimeter-Gram-Second) (q.v.) system. It is equivalent to the amount of heat necessary to raise the temperature of one gram of water from 0° to 1° centigrade. (See *Thermal*, also *C. G. S.*)

CALORIMETER—In electrical practice, an instrument used to measure the heat generated in a conductor carrying an electric current.

CAMBRIC, VARNISHED—Varnished muslin used as an insulating material. Also known as Empire Cloth. (See *Spaghetti.*)

CANAL RAYS—When an electric discharge takes place between the *anode* and a perforated *cathode* in a vacuum tube, fine pencils of light are seen to pass through the perforations in the cathode. These rays are called *canal rays*, and consist of positively charged particles. They produce phosphorescence on the wall of the tube.

Canal rays travel at a lesser velocity and in the opposite direction to the cathode rays. This fact and also the fact that the rays are deflected by powerful electric or magnetic fields in the opposite direction to cathode rays, is taken as proof that they consist of positively charged particles. (See *Cathode Rays.*)

CAPACITANCE—A term very often used as synonymous with *capacity*. Due to the fact that capacity may refer to the current carrying ability of a conductor and also to electrostatic capacity, it has been suggested that capacitance be used to refer only to *electrostatic capacity* of a body or device. Capacity would then refer to *current carrying ability*. (See *Capacity*, also *Electrostatic.*)

CAPACITATIVE REACTANCE—That part of the *reactance* of a circuit carrying alternating current which is due to the *capacity* in the circuit. (See *Reactance* also *Impedance.*)

CAPACITATIVE COUPLING — See *Coupling*.

CAPACITY—Generally speaking, the quantity of electricity in any form which a body is able to store or contain. The term is usually qualified to denote the particular case, such as *electrostatic capacity*, which is a measure of the ability of a condenser to store up energy in the form of electrostatic charges; also *current-carrying capacity* of a conductor, which is considered as the ability of a wire to carry a certain amount of electric current without overheating. The tendency in electrical literature is to use the term capacitance as applying to the electrostatic capacity of a condenser. Thus, a certain condenser may have a capacitance of 2 micro-farads. The unit of electrostatic capacity is the *farad*. This is understood as the capacity of a condenser that will store one *coulomb* of electricty under an electromotive force of one *volt*. When V is expressed in volts, C in farads, and Q in coulombs, $C = Q/V$.

CAPACITY CIRCUIT—An electrical circuit in which the *capacity* is very large compared with the *inductance*. The inductance may be considered negligible.

CAPACITY CONVERSION FACTORS—In the calculation of *capacity*, as the capacity of a condenser, there are several different units. For instance, a *farad* is a large unit of capacity and is equal to one million *microfarads*, or conversely, a microfarad is equal to one millionth of a farad. In the same way a farad is equal to one billionth of an *abfarad*. The four units used in capacity measurement are the *farad*, *micro-farad*, *micromicrofarad*, *statfarad* and *abfarad*. The following table gives the conversion factors for these various units:

$$1 \text{ abfarad} = \begin{cases} 10^{9} \text{ farads} \\ 10^{15} \text{ mfds.} \\ 9 \times 10^{20} \text{ stfds.} \end{cases}$$

$$1 \text{ farad} = \begin{cases} 10^{-9} \text{ abfd.} \\ 10^{6} \text{ mfds.} \\ 9 \times 10^{11} \text{ stfds.} \end{cases}$$

$$1 \text{ mfd.} = \begin{cases} 10^{-15} \text{ abfd.} \\ 10^{-6} \text{ farads} \\ 9 \times 10^{5} \text{ stfds.} \end{cases}$$

$$1 \text{ stfd.} = \begin{cases} 1/9 \times 10^{-20} \text{ abfd.} \\ 1/9 \times 10^{-11} \text{ farad} \\ 1/9 \times 10^{-5} \text{ mfd.} \end{cases}$$

$$1 \text{ mmfd.} = 10^{-6} \text{ mfd.}$$

In the table above, farad is abbreviated Fd.; abfarad is shown as abfd.; microfarad is mfd., micromicrofarad is mmfd. and statfarad is stfd. In dealing with large figures containing many ciphers the amount is shown as 1,000,000 is 10^6 and $\frac{1}{1{,}000{,}000}$ is 10^{-6}, etc. (See *Capacity, Farad*, also *Unit.*)

CAPACITY EARTH or CAPACITY GROUND—A substitute for the usual ground connection where the wires or plates are buried beneath the ground or attached to a water or steam pipe. It is in effect a second aerial, and is placed either under the regular aerial or to one side. It is more used in radio transmission than in reception. (See *Counterpoise.*)

CAPACITY ELECTROSTATIC — See *Capacity* also *Electrostatic Capacity.*

CAPACITY FREQUENCY FACTOR—The relation between the apparent capacity of a condenser and the *electrostatic capacity*. (See *Capacity, Condenser* also *Electrostatic.*)

CAPACITY OF CONDENSERS IN PARALLEL—When several condensers are connected in parallel the resultant capacity is the sum of the individual capacities. It is written:

$$\text{Capacity} = C_1 + C_2 + C_3, \text{etc.}$$

It will be evident that the resultant capacity of condensers connected in parallel is just the reverse of case for resistances, where the total resistance is less than that of the smallest individual resistance in the parallel connection. (See *Resistance Measurement* also *Capacity of Condenser in Series*, also *Condensers in Series* and *Condensers in Parallel.*)

CAPACITY OF CONDENSERS IN SERIES—When several condensers are connected in series with each other the resultant capacity is always less than the capacity of the smallest condenser in the group. The capacity of condensers in series is given as follows:

$$\text{Capacity} = \cfrac{1}{\cfrac{1}{C_1} + \cfrac{1}{C_2} + \cfrac{1}{C_3}, \text{ etc.}}$$

The resultant capacity is thus the reciprocal of the sum of the reciprocals of the several capacities. (See *Condenser, In Series.*)

CAPACITY MEASUREMENT OF ANTENNA—A simple method for the measurement of the capacity of an antenna as given by Austin follows: The illustrations show the general arrangement. The inductance L in Fig. A is a coil that will increase the wavelength (natural) of the antenna system 4 or 5 times; C is a calibrated variable condenser and W a standard wavemeter. In operation the coil L is connected in the antenna circuit, the buzzer is used to excite the antenna circuit and the wavelength is measured by w. The coil L is then taken out of the antenna circuit and shunted by the condenser C. The condenser C is then varied until the wavelength of the combined coil L and condenser C is the same as that obtained before with the coil in the antenna circuit but without the variable condenser. The capacity of the condenser now will be approximately that of the antenna, ignoring the distributed inductance of the antenna system. Fig. A shows the first operation, the measurement of the antenna with the coil in the circuit, and Fig. B shows the measurement of the wavelength of the coil and condenser. (See *Mutual Capacity, Wavemeter, Natural Wavelength,* also *Distributed Capacity.*)

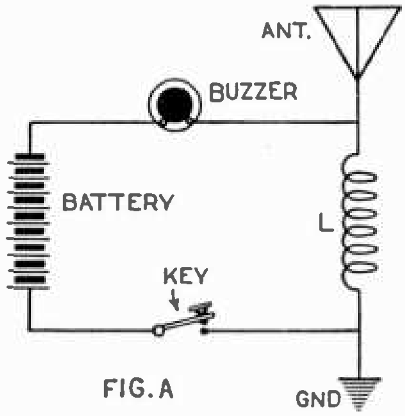

FIG. A

The first operation in the measurement of the antenna. The wavemeter is shown below.

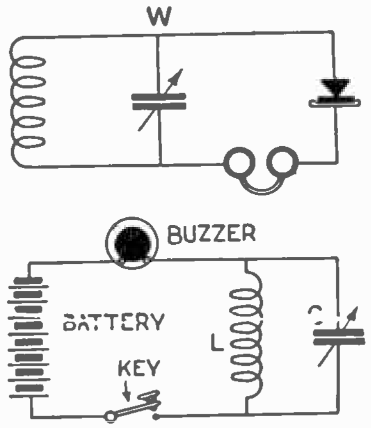

FIG. B

Circuit for the measurement of wavelength of coil and condenser.

CAPACITY MUTUAL—See *Mutual Capacity.*

CAPACITY RESISTANCE—The resistance to alternating currents offered by a body possessing electric capacity. (See *Capacity,* also *Resistance.*)

CAPACITY SWITCH—Any switch used in a circuit to introduce or cut out capacity (condenser).

CAPACITY (UNIT OF)—The unit of capacity is the farad. A condenser has a capacity of 1 farad when 1 coulomb is required to raise its potential from zero to 1 volt. Since the farad is very large, its millionth part, or the microfarad is generally used.

CARBON—A non-metallic chemical element used for many purposes in electricity and radio. It exists in three forms, two crystalline and one non-crystalline. The first two are diamond and graphite, the third charcoal. Carbon is used as an electrode in electric arcs, as one of the poles in certain types of primary cells, as a material in place of wire for various forms of resistance, and as brushes in motors and generators. (See *Diaphragm, Carbon.*)

CARBON RHEOSTAT—A rheostat or variable resistance using carbon in place of the customary wire. In its simplest form a carbon rheostat may be merely a piece of carbon having a sliding contact. This is shown in Fig. 1. Owing to the relatively high resistance of carbon used in this manner, such a controlling resistance will generally be termed a *potentiometer* (q.v.) and used as such.

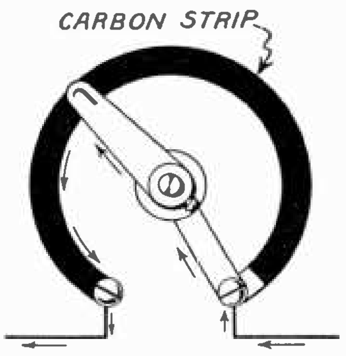

Fig. 1.—A carbon rheostat with a rotary sliding contact.

The most practical form of a carbon rheostat is known as a carbon pile rheostat. This type uses a number of flat pieces of carbon of relatively low resistance placed together and arranged with a knob and screw in such manner that the pressure can be varied. This change in pressure alters the resistance of the mass and allows control of the current for vacuum tubes. The same principle is used for very high resistances as well as for low values. The principle will be seen from the illustration Fig. 2.

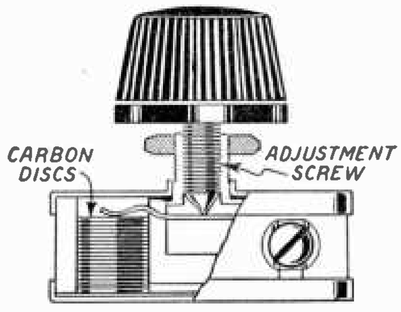

Fig. 2.—A carbon pressure type rheostat.

CARBORUNDUM—An abrasive material, a product of the electric furnace, composed of silica and carbon. It is used in radio as a crystal rectifier, although the strides of radio have practically rendered it obsolete, many other better crystals being in use. The chief difficulty with its use as a rectifier or crystal detector was the fact that for efficient operation it required a cell or battery and potentiometer to regulate the current flowing through it. The simple crystal circuit using a carborundum detector is shown in the illustration. C is a tuning coil, D the carborundum crystal and contact, P a potentiometer and T the head phones. (See *Rectifier,* also *Detector.*)

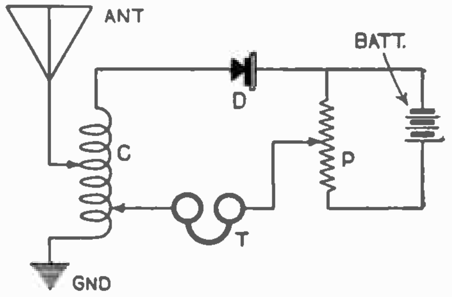

Diagram of a radio circuit employing a carborundum crystal detector.

CARDBOARD TUBING—Tubing made of laminations of paper pasted together. They are used for home made coils of all descriptions, and while not as efficient as the composition tubing, can be used for many purposes without any great loss. As a general rule it is better to use some of the numerous compositions, such as bakelite or rubber compounds.

CARPENTIER, JULES—French radio expert. Born in Paris, in 1854, he joined the Ecole Polytechnique in 1871, and in 1876 was appointed principal stores engineer of the Lyons Railway Company, making a special study of electricity. For his work in electricity he obtained in 1881 the cross of Chevalier of the Legion of Honor. One of the early pioneers of radio in France, he founded the Compagnie Generale Radiotelegraphique, afterwards absorbed in the Compagnie Generale de Telegraphie sans Fil. Carpentier is a member of the Academie des Sciences, Commander of the Legion of Honor, and President of many scientific societies.

CARRIER WAVE—The *continuous wave* (q.v.) of radio frequency generally thought of as carrying the voice or music waves from the radio broadcasting station. Actually it is a radio wave of high frequency, which is altered in amplitude by the music or speech transmitted. In action, this continuous wave has another wave super-imposed on it. This other wave having wave form and amplitudes determined by the voice or other sounds being transmitted. The illustration shows the carrier wave, the waves representing speech or music and the combination of the two. This effect of varying the amplitude or strength of a continuous wave by means of some sort of program is known as *modulation.* (q.v.) The wave representing the speech or music is imposed on the carrier wave resulting in the combined wave which reaches the listener and is translated by suitable apparatus into approximately the same sounds that are transmitted. (See *Modulation, Broadcasting*, also *Speech Vibrations.*)

CARRYING CAPACITY—See *Current Carrying Capacity.*

CARTRIDGE FUSE—A fuse in which the fuse wire is surrounded by some non-inflammable substance, enclosed in a cartridge-like tube and having brass lugs soldered to caps at ends. Used to prevent the hot wire from "flying" when fused. (See *Fuse.*)

CASCADE—A term applied to pieces of apparatus connected together in series, particularly vacuum tubes. In this case, the arrangement would be such that each vacuum tube would amplify the signal output of the preceding tube. The tubes will be so connected that the output of one is introduced as input to the next and so on the total result being greatly increased signal strength from the output of the last tube. This term may apply to either radio frequency or audio frequency amplification. (See *Amplifier, Radio Frequency*, also *Audio Frequency.*) A simple cascade arrangement is shown in the illustration. Fig. 1 is a circuit with two stages of cascade radio frequency amplification, and Fig. 2 a circuit using two stages of audio frequency amplification with the usual detector tube in each case. A combination of both radio frequency and audio frequency stages of amplification might also be used, the term cascade amplification also applying here.

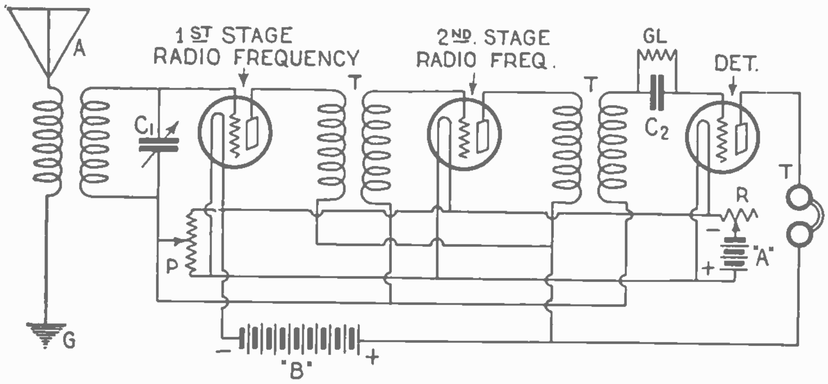

Fig. 1.—Circuit diagram showing two stages of cascade radio frequency amplification and detector.

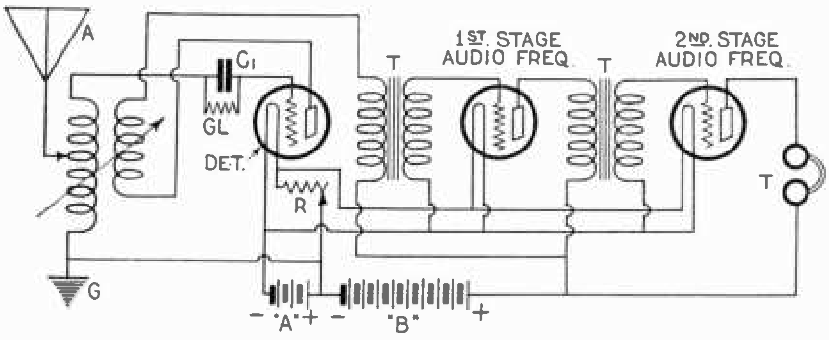

Fig. 2.—Diagram of detector and two stage cascade audio frequency amplifier.

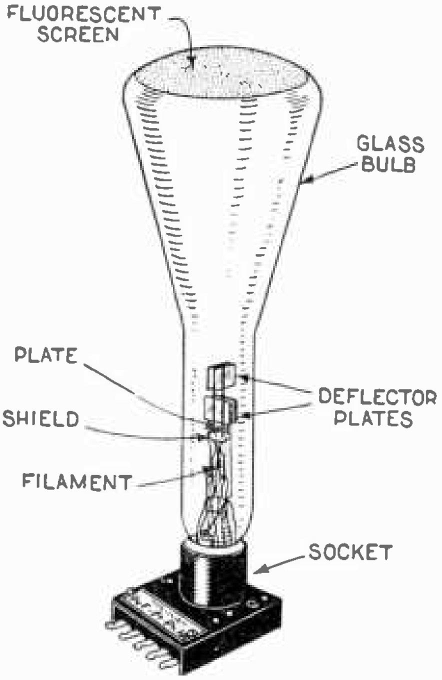
CATHION or CATION—The charged particles which appear at the cathode or move toward it through the electrolyte of an electrolytic cell. (See *Anode.*)

CATHODE or KATHODE—A *negative electrode*. The term is often applied to the filament of a vacuum tube to distinguish it from the anode or plate. (See *Cell, Electrolysis*, also *Anode.*)

CATHODE RAY TUBE—A vacuum tube having a high vacuum, that is from which practically all air has been exhausted, used in the production of cathode rays. These tubes in their modern form are used for many purposes in studying the nature and form of electric waves. The illustration shows one of the latest types of tube, known as the *Cathode Ray Oscillograph*. This tube is used for the following purposes: examination of the wave forms of various rectifiers, study of wave forms of different types of generators, study of vacuum tube characteristics, examination of the characteristics of X-ray and other types of tubes, examination of radio frequency waves modulated as in broadcasting, measurement of hysteresis and dielectric loss in various materials, study of phenomena in arcs and sparks, together with numerous other associated effects. The development of this tube is one of the marvels of science, enabling the research engineer to virtually see the electric wave, and to study exhaustively, electric phenomena otherwise invisible.



A cathode ray tube with socket.

The Western Electric modification of the Braun Cathode ray tube or oscillograph, is a three electrode glass tube about 30 centimeters (about twelve inches) long, in the form of a cylinder an inch and three-quarters wide, spreading out in conical shape, the tube being about three and a half inches wide at the top. The *cathode* is a filament coated with active oxides and arranged to emit the number of electrons required for the cathode rays, at a dull red heat. The *anode* or plate is a small platinum tube set very near the filament. Between the filament and the anodes is a small circular screen having a hole just a little smaller than the circular filament. A battery of several hundred volts is connected between the filament and plates with the positive terminal connected to the plate. The electrons emitted from the hot filament are controlled by this field in the same manner as in an ordinary vacuum tube. A small portion of these electrons pass completely through the tubular anode and constitute the *cathode* rays. These rays are passed between two pairs of deflecting plates set at right angles to each other, and fly against the large end of the tube. This end is covered with a fluorescent mixture which renders the rays visible. These rays are deflected in various ways. For example, if an alternating current is applied the visible spot on the screen will be drawn out into a line. (See *Electron, Vacuum Tube*, also *Wave Analysis.*)

CATHODE RAYS—The stream of electrons or electrical particles sent out from the *cathode* or filament of a vacuum tube. These rays are negatively charged. (See *Cathode, Electrons, Vacuum Tube* also *Oscillograph.*)

CAT-WHISKER—The fine wire used with certain crystal detectors to make contact with the crystal. Usually a springy metal such as phosphor bronze wire.

"C" BATTERY—One or more small cells having a voltage generally between 2 and 10 volts, used in the grid

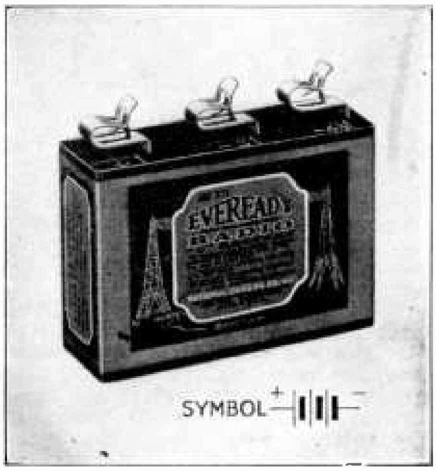


Fig. 1.—A 4½ volt "C" battery. This type of battery has a common positive terminal and is tapped at negative terminals for 3 and 4½ volts.

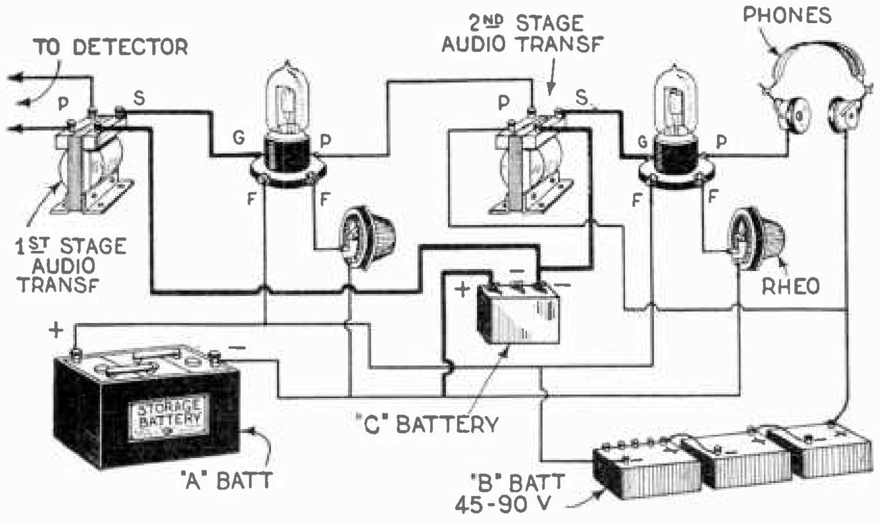

Fig. 2.—A diagram showing how the "C" battery is connected in the audio frequency amplifier.

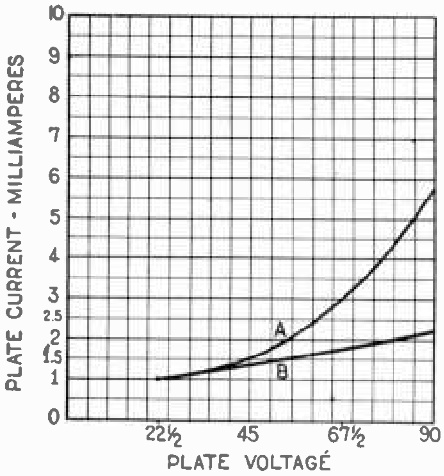
circuit of an amplifier tube for the purpose of impressing a negative potential on the grid of the tube. The method of connecting it in the circuit is shown in Fig. 2. Fig. 1 shows a typical 4½ volt "C" battery. (See also *Grid Bias* and *"C" Battery Curve.*)

"C" BATTERY CURVE—In order to show the effect of a "C" battery on the consumption of current from the "B" battery in an audio amplifier, a *curve* (q.v.) may be drawn as in the illustration. In this case the test was made with a type UV 201A tube used as a one stage *audio frequency amplifier* in a conventional circuit. It is readily apparent on referring to the lines A and B that when the "C" battery is in use the consumption of current by the plate is much less than without it.



Test conducted on UV201A tube using single stage audio amplifier with conventional circuit.
Plate Voltage—Abscissae.
Plate Current in milliamperes—ordinates.
A—Consumption curve without "C" Battery.
B—Consumption curve with "C" Battery.
(Note: 1.5 ma. at 45v plate rising to 5.75 ma. at 90v plate without "C". With "C" Battery consumption maximum is 2¼ ma. at 90v.)

CELL—A cell is one of the four chief sources of electric energy. In a cell the energy is created by an *electro-chemical* process, using in its simple form two unlike metals immersed in a dilute acid or alkaline solution. In the illustration Fig. 1 the common form of electric cell is shown. C is a strip of *carbon* and Z a strip of *zinc*. These are placed in the jar in a conducting solution of sal ammoniac. If the exposed terminals from the carbon and zinc strips are connected together by a piece of wire, current will flow from one side of the cell to the other through the wire. The current flows from the carbon or *positive* pole to the *negative* or zinc pole through the wire, completing the circuit through the solution from zinc to carbon. (See *Current, Direction of Flow.*) The cell described is known as a *primary cell.*

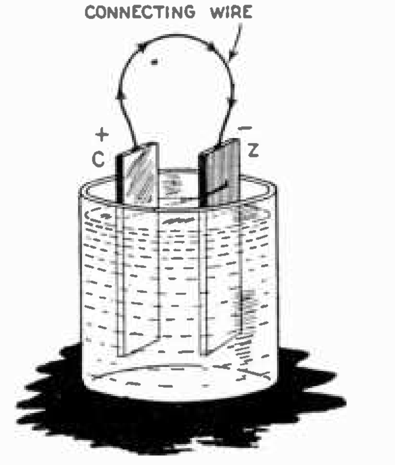


Fig. 1.—Common form of electric cell.

In Fig. 2 a simple *storage cell* or *secondary cell* is shown. In this case there are two lead plates immersed in a dilute solution of sulphuric acid. A source of primary current (primary cell) may be connected to the secondary cell in the manner shown in Fig. 3 and after being connected for a certain length of time it will be found that the energy of the primary cell has been transferred to the secondary cell and stored in it. This process of placing electric charges in a secondary cell is known as *charging*, and the current stored up in it is known as the *charge*. Now, if the wire is connected from one terminal to the other it will be found that electric energy can be withdrawn in a similar manner to that of the primary cell. A secondary cell may contain several plates and several of these cells may be connected together to form a storage battery. (See *Storage Battery, Current, Production of,* also *Anode* and *Cathode.*)

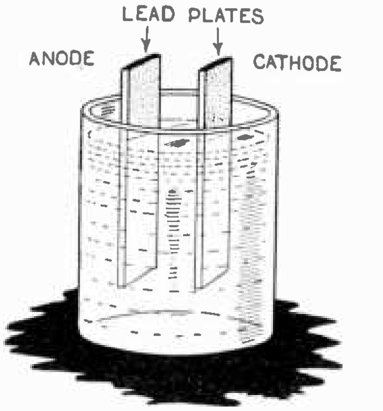

Fig. 2.—Storage or secondary cell.

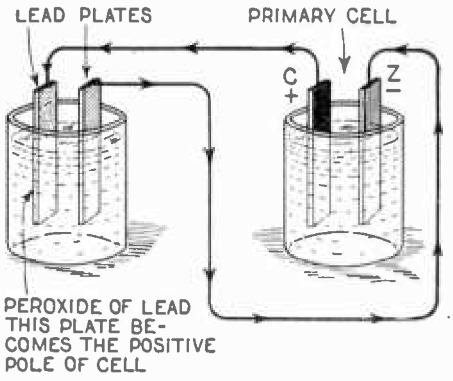


LEAD PLATES
PRIMARY CELL
C
+
Z
−
PEROXIDE OF LEAD THIS PLATE BECOMES THE POSITIVE POLE OF CELL

Fig. 3.—Primary cell connected to secondary or storage cell.

CELL, SECONDARY—When a *primary cell* is connected to a *storage* or *secondary cell*, the current from the primary cell flows into the secondary cell and in effect deposits energy in that cell. Then when the charging source (the primary cell) is withdrawn, the secondary cell can be used in practically the same manner as the primary cell. A wire connected from one terminal to the other will permit passage of current. The action of storing up energy in a storage cell is approximately as follows: When the charging current flows from plate to plate through the solution in the secondary or storage cell, the plate connected to the *positive* (+) *pole* (carbon or copper) of the primary cell, receives a brown coating of *peroxide of lead.* At the same time the other plate becomes spongy or porous. Now as one plate has received a coating while the other remains unchanged as far as its surface is concerned—it acts as a primary cell if the charging source is taken away and the two terminals connected. It now has all the essentials of an ordinary chemical cell. As long as the coating of peroxide of lead remains on the surface of one of the plates, the cell will be capable of delivering current.

When the coating has been worn off or eaten away the cell is said to be in a discharged condition. It will then be necessary to go through the same process of connecting a primary source to the terminals in order to again deposit peroxide of lead on one plate. It will therefore be evident that when the *storage cell* is charged, *current* is not actually stored in it, although in effect it has received potential energy. What has actually occurred is that the current supplied to the cell during the charging process has produced electro-chemical changes, making the plates dissimilar and thus producing a difference of potential. (See *Current, Production of*). The *voltage* or *electromotive force* of primary cells varies from .06 to 1.5 volts according to the nature of the elements used and the grade of the *electrolyte* (q.v.). Secondary or *storage cells* of the lead plate type produce from 2.1 to 2.6 volts. (For more complete explanation of the theory and action of a secondary cell, see *Storage Battery.* See also *Electro Motive Force, Current* and *Voltage.*)

CELL, THEORY OF PRIMARY—It has been explained under the heading *Cell,* that a primary cell produces electrical energy by chemical action. More specifically the action of a simple cell is as follows: When the copper and zinc, or carbon and zinc placed in a cell are connected together by a conductor, (wire or other conducting object) the acid in the case of a sulphuric acid solution, attacks the surface of the zinc plate and forms a compound known as zinc sulphate. While this sulphate is being formed some of the hydrogen contained in the sulphuric acid is liberated in the form of bubbles which appear on the copper plate. Some of these bubbles escape into the surrounding air by rising to the surface of the solution, but others cling to the surface of the copper plate and gradually cover it with a film of hydrogen. It may be said here that the decomposition of the zinc plate in the acid solution furnishes the *electro-motive force* required to cause the flow of current between the plates, through the solution and through the conductor. Now, hydrogen is a non-conductor, and as the hydrogen gradually covers the copper plate, the surface of the plate in contact with the solution gradually decreases. The flow of *current* from zinc plate to copper plate in the solution is thus gradually diminished, until eventally we can imagine the copper plate as being entirely covered with hydrogen and no longer in contact with the solution. In addition to this insulating action of the hydrogen, it tends to set up a current within the cell in the opposite direction to the normal flow of current produced by the chemical action. A cell in this condition is said to be "polarized," and various means have been used to cut down or eliminate the *polarization effect.* The purpose of these various means is to prevent the hydrogen bubbles clinging to the surface of the copper plate, thus allowing them to escape to the top of the solution and thence into the surrounding air. (*See Polarization, Current, Voltage, also Storage Cells.*)

CENTIMETER—A measure of length in the metric system. It is one hundredth part of a meter, or approximately .3937 inch. It is used as the unit of length in the Centimeter Gram Second System (q.v.).

CENTIMETER GRAM SECOND or C. G. S. A system of units of measure employed in practically every branch of engineering, particularly in electrical practice. It is a decimal system, the centimeter being the unit of length, the gram the unit of weight and the second the unit of time. All other units are derived from these three. When the magnitude of a quantity is spoken of, it refers to the relative magnitude of the quantity when compared with some other quantity of the same nature. The magnitude used as a standard of comparison is termed a unit. Thus, if the length of a body is measured in feet, as for example, ten feet, it means that the magnitude of the body is ten times unity or ten times one foot. Similarly a *current* of ten *amperes,* is a current of magnitude ten times as great as the unit quantity—one ampere. Now an ampere is the practical unit of rate of flow of electric current. The unit has a certain definite value. (See Ampere.) The magnitude of any other similar quantity measured in amperes will mean a value equal to a certain number of units. In addition to the C. G. S. system of units, there is a practical system. This is commonly used for ordinary calculations. Under this system, the following are the main units: The *volt* is the practical unit of *electro-motive force;*—the force required to maintain a flow of current of one ampere through a resistance of one ohm. The unit of *current strength* or rate of flow of current is the *ampere;*—the strength of current maintained by a force of one volt through a resistance of one *ohm.* The unit of *resistance* is one *ohm,* and is the resistance of a *conductor* or *circuit* that will permit the passage of a current of one ampere under the force of one volt. The unit of *quantity* is the *coulomb,* which is the quantity of current flowing in a circuit when one ampere passes a given point during one second of time. The *watt* is the practical unit of *electrical power,* being the power of a current of one ampere flowing in a circuit under the pressure of one volt.

It will thus appear that the practical system is actually based on the C. G. S. system. Calculations of an involved nature necessarily make use of the C. G. S. system, and when multiples or sub-multiples are used they are expressed in Greek and Latin prefixes. For example, a million ohms is 10^6 ohms and is expressed as a *meg-ohm.* "Meg" being derived from *mega millian.* Similarly a millionth of an ampere is expressed as a *micro-ampere* or 10^{-6} AMPERE. The various units under the C. G. S. and practical systems are taken up in detail under the respective headings, as *JOULE. ERG, DYNE* and so forth. (See also *Inductance (Unit of); Capacity (Unit of); Electrostatic Units and Electromagnetic Units.*)

C. E. M. F.—The abbreviation for *counter electromotive force* (q.v.).

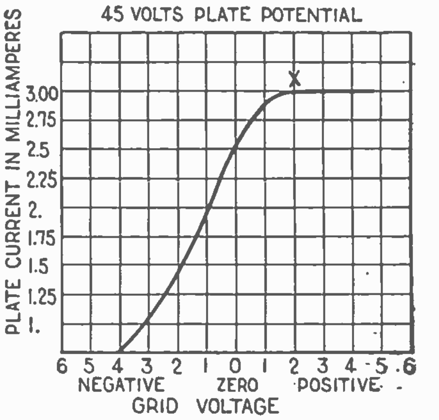
C. G. S. UNIT OF CURRENT—The absolute *electromagnetic unit of current.* It is the current which when passed through a conductor bent into a circle of one centimeter radius will attract or repel a unit magnetic pole placed at its center, with a force of one *dyne* (q.v.).

CERUSITE—A kind of mineral used as a rectifier in some types of *crystal detectors.* It is a carbonate of lead having a whitish-grey color. This mineral is not as good a rectifier as some of the others, but has the advantage of more uniform sensitivity over practically its entire surface. (See *Crystal Detectors.*)

CHALCOPYRITE—A crystal used in a *pericon detector,* which is composed of zincite and chalcopyrite in contact with each other. It is a combination detector suitable for use where it is subject to jarring, since it has nearly uniform characteristics over its entire surface. It works without the aid of an electric battery.

CHARACTERISTICS—A term broadly applied in electricity to refer to any distinguishing feature in electrical apparatus. In radio usage the term is generally applied to *vacuum tubes.* The characteristic of a tube is understood as the relation between the potential (voltage) at the *grid* (q.v.) and the resulting current obtained from the *plate.* (q.v.) It may also occasionally refer to other features of a tube, such as its current requirements or amplifying quality as distinct from the ratio of *grid voltage* to *plate current.* (See *Characteristic Curve, Vacuum Tube Characteristics;* also *Plate Current.*)

CHARACTERISTIC CURVE—A diagram showing graphically in the form of a curved line the relation of changing values. Thus, in the case of a *vacuum tube,* a change in the *grid* voltage produces certain changes in the *plate* current (q.v.) and these changes may be plotted as curves. The temperature of a wire carrying current increases with increase in the *current* passing through it, and this increase may be shown by a curve. (See *Vacuum Tube Characteristics.*)



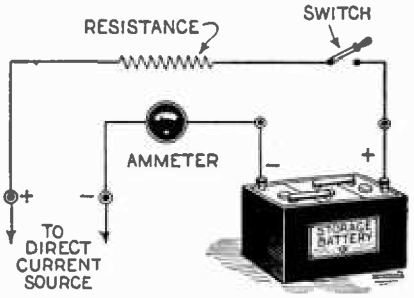
Characteristic chart of vacuum tube grid and plate voltage.

CHARGE—The presence of electricity in a body. Is usually defined as an excess or deficit of *electrons* (q.v.) on an insulated body. In the case of a *condenser* (q.v.) after it has accumulated electrical energy it is said to be in a charged condition, or to have an *electro-static charge.* The charge in a *condenser* is measured in *coulombs.* (q.v.) A *storage battery* is said to contain a charge when it has been connected to a source of direct current for a length of time, and the hydrometer test shows the electrolyte at proper specific gravity.

CHARGE, SPACE—See *Vacuum Tubes,* also *Space Charge.*

CHARGED BODY—Any body that has accumulated electrical energy. (See *Charge.*)

CHARGER, STORAGE BATTERY—Any means of controlling the current delivered from a primary source for the purpose of charging *storage batteries* or other *secondary cells.* Chargers are made in many forms and are designed for either direct or alternating current. Direct current chargers consist of certain resistances, with the necessary meters and switches. A simple form of direct current charger is shown in the illustration. In constructing a direct current charger there are several important details that must be



Charging storage battery from direct current source.

taken into consideration. The plates of a storage battery require certain charging rates in amperes, depending on the size and number of the plates. That is to say, the manufacturer specifies that when charging, a certain number of amperes must be passed to the battery from the charging source for a definite number of hours. This figure may be decreased but not increased. As an example, some storage batteries will take a charge of five amperes without injury to the plates, which rate would be ruinous for other batteries. Now the question of obtaining the proper amount of charging current arises. The majority of house lighting systems have a voltage of from 110 to 125 volts. (Reference is now made only to direct current systems, alternating current chargers being taken up later on.) According to *Ohm's Law* (q.v.) the current flowing in a circuit is directly proportional to the *voltage* and inversely proportional to the *resistance*. Voltage is the product of resistance times the current, the resistance in ohms and the current in amperes. Therefore if we desire a current of five amperes from a source of 110 volts, it is necessary to have a resistance of a value in ohms which, when multiplied by the current in amperes,—five in this case—will produce 110. Conversely, we can divide the voltage—110 by the current—5 to obtain the correct resistance. This would indicate a resistance of 22 ohms. There is another factor which enters into the problem however, the back pressure, or Counter Electromotive Force exerted on the charging source by the battery. In the case of a six volt storage battery, this will be six volts. This must be subtracted from the voltage of the charging source to obtain the effective value. Thus, the effective value in this case would be 110 — 6 or 104 volts. Then as explained before, dividing the voltage by the current required, we find that it is 104 ÷ 5 or approximately 21 ohms. Then by placing a resistance of 21 ohms in the circuit, as shown in the illustration, and connecting the battery as indicated, a charge of five amperes can be applied to the battery. The same result can be obtained by placing an ordinary electric lamp in series in place of the resistance. (See *Lamp Bank.*) The *internal resistance* of the battery is very small compared to that of the line resistance, and can be ignored. A point to remember is that the voltage of the charging source must always be higher than that of the storage battery, because, as explained above, the back or *counter electromotive force* of the battery, must be subtracted from the voltage of the charging source to indicate the effective voltage. Thus, if the battery exerts a counter electromotive force of six volts and the charging source is only six volts the counter force would be equal to the charging force and there would be no charging current. When *direct current* is not available and *alternating current* is used to charge the battery, it will be necessary to change it to direct current. For this purpose it is essential that some form of *rectifier* be used. This rectifier may be of a chemical, mechanical or electrical type. These various forms will be taken up under their separate headings. (See *Rectifier, Balkite, Tungar, Rectigon, Electrolytic Rectifier, Tube Rectifier.*)

CHARGING—The act of expending electrical energy to place a charge in or on a battery or body. The term is used generally to indicate the process of impressing electrical energy on the *storage battery* elements for the purpose of making the battery a secondary source of electricty. (See *Charger, Chemical Rectifier* also *Tube Rectifier.*)

CHARGING BOARD—A term used synonymously with *charging panel* to denote an arrangement for controlling the current used for charging *storage batteries.* It generally consists of an insulated panel with various *switches, fuses* and *resistances* thereon to limit the amount of current delivered, and at the same time furnish a ready means of connecting and disconnecting the various circuits connected through it. The fuses act as safety devices and break the circuit when too great a current is delivered. (See *Fuse, Switch, Charger.*)

CHEMICAL RECTIFIER—Device for changing alternating current to direct current. (*See Electrolytic Rectifier.*)

CHLORIDE BATTERY A type of storage battery for heavy duty operation. The positive plate is made of lead with a number of holes pierced in it and each filled with a coil of pure lead. This coil is forced into the holes during manufacture and is said to enable the battery to withstand heavy discharge without damage to the plates. (See *Storage Battery.*)

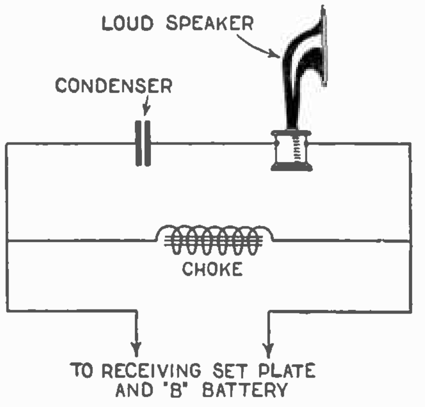
CHLORIDE CELL—A cell (q.v.) which uses in most cases, a positive plate having lead as the active material, the negative plate being made of metallic zinc. A solution of chloride of zinc is used, from which the name is derived. (See *Chloride Battery.*)

CHOKE OR CHOKING—The action of a device in a circuit wherein it tends to choke, or hold back, certain forms of current or certain *frequencies* while permitting others to pass freely, or to oppose fluctuations in the strength of the current passing through it in the circuit.

CHOKE COIL—A coil of wire possessing considerable *self-inductance* and relatively little *resistance.* These coils are used in various ways and for a variety of purposes. When connected in a direct current circuit, and possessing the proper value, they have a tendency to prevent any fluctuations in the current and thus keep the current smooth. An example of its use is with a *loudspeaker.* A *condenser* will permit passage of *high frequency (alternating) currents* such as we find in radio reception, but will effectively block direct currents. On the other hand a choke coil will pass direct current without offering any appreciable resistance, but will retard the *modulated currents* (q.v.) It will be apparent then that by a proper combination of the two (Choke Coil and Condenser) as in the illustration, the direct currents can be shunted around the loud speaker and thus prevent injury to it, while the necessary modulated currents are allowed to pass through without difficulty. Another use for the Choke is in a circuit carrying alternating currents. In this case the choke will limit the current in the circuit without loss, whereas an ordinary resistance, while it would limit the current, would dissipate a certain amount of energy. Chokes may be made with iron cores of the open or closed type, for *low frequency currents*, or may only have air for the core when used in *high frequency* circuits. The closed core type is the more common form. The formula most commonly used in determining the inductance of a choke coil in *henries* is as follows:

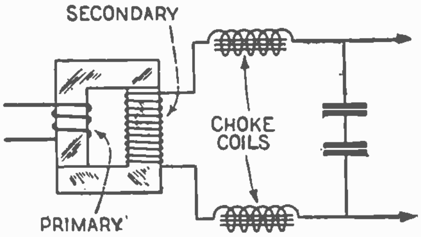
$$L = \frac{1.257 \times \mu \times A \times N^2 \times 10^{-8}}{l}$$

Where L is the inductance in henries.
μ is the permeability. (This varies from about 1000 to 2000 in most cases).
A is the effective area of iron cross section (square centimeters).
N is the number of turns of wire.
l is the length of iron path (in centimeters).



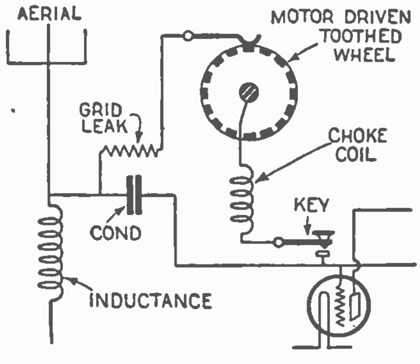
Method of using choke coil in connection with loud speaker.

CHOKE, HIGH FREQUENCY — A choke coil of high *self-inductance* (q.v.) used in transmitting circuits to prevent puncture of the secondary windings of the *transformer* (q.v.). When the condensers in a transmitting circuit are charged or discharged, a back pressure is exerted on the windings of the transformer supplying the high voltage. The illustration shows the position of these choke coils in the transmitting circuit. (See *Back Oscillation.*)



Position of choke coils in transmitting circuit.

CHOPPER—A device used in the aerial circuit of a *continuous wave* (q.v.) transmitter to break up the continuous trains of waves into separate groups and thus permit them to become audible. In the case of reception of ordinary *damped waves* (q.v.) the head phone produces signals that have a frequency of vibration equal to the number of wave trains per second. When the transmitted waves are con-



Showing how chopper is used to interrupt signals from continuous wave transmitter.

tinuous there is obviously no interval, that is, there are no groups of waves and they are therefore inaudible in the usual receiving apparatus. The *chopper* is only necessary when *crystal detectors* are used for reception. (See *Ticker, Beat Reception and Continuous Wave Transmission.*)

CIRCUIT—The path followed by an electric current passing from its source through a wire conductor or series of such *conductors*, and back again to its starting point. A *closed circuit* is one that is continuous and will permit the passage of current. An *open circuit* is one that is not continuous and, being broken or open at some point, will not permit passage of the current. The term is used very commonly, and broadly covers any system for the conducting of electric current from its source, through some electrical instrument or appliance and back to the starting point.

CIRCUIT BREAKER—Generally speaking, any device for automatically breaking or opening a circuit and thus preventing flow of current through the circuit. More specifically, it may be a device similar to a *switch*, used to automatically open the circuit when the current falls below a certain point, or rises above a certain fixed value. Thus an *overload circuit breaker* is an arrangement which will automatically open the circuit if the current becomes too great. This is shown in Fig. 1. It is a simple form and consists of an *electro magnet* which requires a certain force to operate it. When the current in the circuit reaches a certain point, the magnet operates, pulling down the bar "A" against the action of the spring "P," and thus breaking the circuit. As long as the current is not more than that fixed by the requirements of the circuit—the magnet being arranged in accordance with the particular requirements — the current flows, the breaker operating to open the circuit only when more than the desired current is introduced into the circuit. In the illustration we can consider "S1" and "S2" as the source of current, "M" as an electro-magnet in series with the motor "D," and "A-B" a switch, in which "A" has attached to it a piece of soft iron. Now if the current required for the motor is ten amperes, the magnet can be so designed that it will not act on the bar "A" until 15 amperes flow through it. Thus, as long as the current is less than this, the circuit is continuous, but if the current is increased to 15 amperes, the magnet operates and attracts the bar "A," breaking its contact with "B" and thus opening the circuit. In Fig. 2 a simple *underload breaker* is shown. In this case the operation is the reverse of that of the *overload breaker*. Here the bar "A" is held down in contact with "B" by the magnet "M" thus keeping the circuit closed through the motor "D". Now assume that the motor requires ten amperes and the magnet requires the same amount to hold the bar "A" in place against "B". If then the current in the circuit falls below ten amperes, the magnet can no longer hold the bar "A" against the action of the spring "P" and it rises, breaking the contact between "A" and "B" and thus opening the circuit. These circuits are of course only assumed for the purpose of illustrating the theory of circuit breakers. Actually the system is generally much more elaborate. Circuit breakers are used for many purposes—chiefly to prevent any sudden increase or decrease of current in a circuit, and to control the flow of current for charging batteries. (See *Charger-Storage Battery.*)

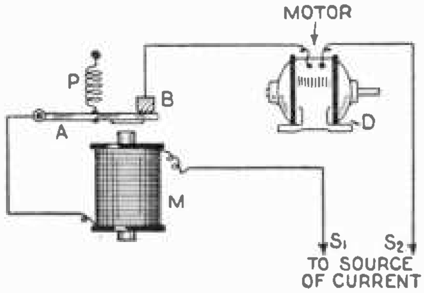


Fig. 1. Overload Circuit Breaker.

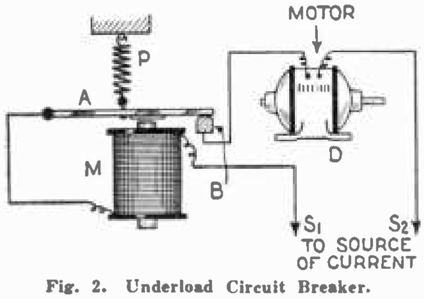

Fig. 2. Underload Circuit Breaker.

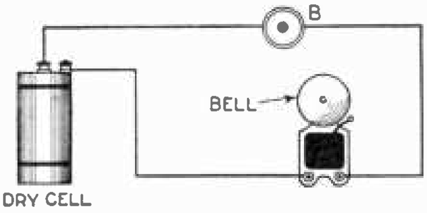
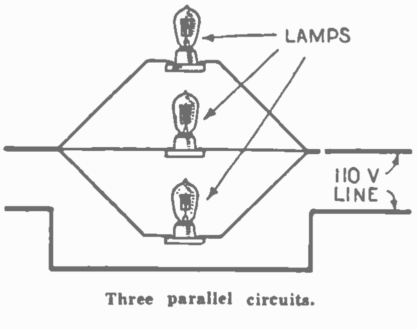
CIRCUIT, BROKEN—A circuit that is not continuous, having been opened either purposely, or due to some defect in the circuit. The term is usually applied where the circuit is opened by the breaking of a wire, or through a faulty contact.

CIRCUIT, OPEN — A circuit which is open and through which current cannot flow, or a circuit which is normally open but which can be closed at will by pressing a key or button. A common example of open circuit is in the case of an electric bell circuit. The illustration shows such a circuit. Normally it is open and current does not flow to the bell, but on pressing the button B, the circuit is closed and current passes to the bell. (See *Circuit*, also *Closed Circuit.*)



Open circuit which can be closed by pressing button "B".

CIRCUITS, PARALLEL — Circuits starting at a common point and ending at a common point. The illustration shows three *parallel circuits*. Actually each one is a part of the whole circuit. (See *Parallel Resistances.*)



Three parallel circuits.

CIRCULAR MIL—The cross-sectional area of conductors (wires) is usually designated in terms of circular mils. A circular mil is the area of a circle having a diameter of one thousandth of an inch. Thus a wire having a diameter of one quarter of an inch is said to have an area of 250 circular mils. (See *Square Mil.*)

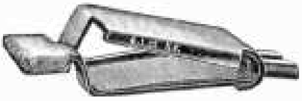
CLEAT—A form of porcelain *insulator* used in house wiring. They are generally arranged in two parts, with corresponding grooves in which the wire is held, and are nailed or otherwise fastened to the wall. Cleats are about the cheapest form of insulator and where the voltages used are low, are quite as effective as the more elaborate types. Cleats are much used in radio work, both for insulating lead in wires coming from the aerial, and for insulating the aerial itself.

CLERK-MAXWELL, JAMES—Born at Edinburgh, Scotland, in 1831, and educated at Edinburgh and Cambridge University, he became Professor of Natural Philosophy at Aberdeen, 1856-69, and Professor of Physics and Astronomy at King's College, London, 1860-65. In 1871 he became the first holder of the new chair of experimental physics at Cambridge, where he died, November 15, 1879. Clerk-Maxwell was recognized in his later years as one of the greatest authorities on physics of his time, and his fame has been steadily increasing since his death. Radio owes Clerk-Maxwell a deep debt. Electricity was the chief study of his lifetime, and his first important paper on the theory of *electromagnetism* was communicated to the Royal Society in 1867. In 1873 he published his "Electricity and Magnetism," a work on the subject which has never been surpassed. In it he formulated his famous *electro-magnetic theory* of light and his theories on electric waves, which developed into the modern system of wireless telegraphy and telephony through the experiments of Hertz.

James Clerk-Maxwell.

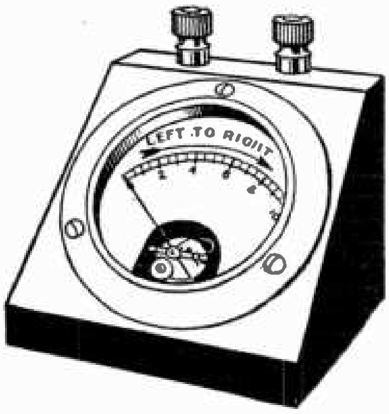
CLIMAX—A high resistance nickel steel alloy, used extensively in *rheostats* (q.v.). It is one of the cheapest and most practical alloys for low-temperature resistance wire. Its chief properties are as follows: Maximum working temperature 540 degrees centigrade, resistance in microhms per cubic centimeter at 20 degrees centigrade, 87.2; temperature coefficient per degree centigrade, .00054, and having a specific gravity of 8.14.

CLIPS—A clamp connector used for various purposes in radio receiving and transmitting circuits. (See *illustration.*) In a receiving set a clip may be used at the end of a flexible wire for the purpose of varying the connection to the various "B" battery taps; clips are very frequently used in making the connections to the storage "A" battery, and for many other purposes about the receiving set. One of their principal uses in the transmitter is in connection with the leads to the oscillation transformer. Flexible leads with clips attached come from the other units of the transmitter and are clamped at will along the various turns of the oscillation transformer until the point giving the desired wave length or highest radiation reading is found.



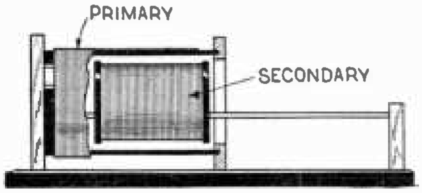
Type of clip in general use.

CLOCKWISE—A term used to indicate that the rotating part of an electrical machine or instrument moves from left to right (when facing it), or as the hands of a clock. In the illustration the needle or pointer of the meter moves in a clock-wise direction. In an electrical measuring instrument this is always true where the zero point is at the left part of the dial. The opposite is known as *counter-clockwise.* When looking at the *armature* of a motor or generator, if the rotating part moves from left to right it is said to have a clock-wise motion.



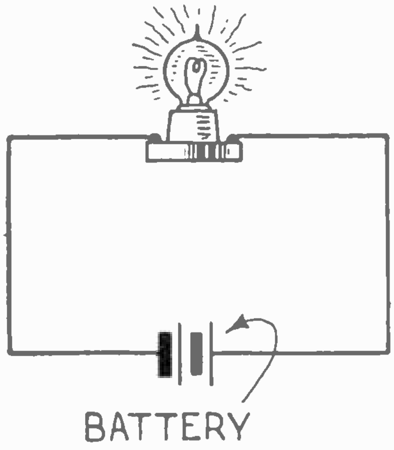
Indicator needle moves from left to right in clockwise motion.

CLOSE COUPLING The arrangement of two coils acting as *primary* and *secondary,* placed close together in such manner that the coupling or electrical relation between them is close. In the illustration the secondary coil is shown entirely within the primary. In other words the transfer of energy will be large in this case as the coupling is close. If the secondary is withdrawn a certain distance from the primary, the effect is referred to as loosening the coupling, and the coils are then said to be *loose coupled,* the transfer of energy from one to the other being considerably less than in the case of close or *tight coupling.* (See *Coupling.*)



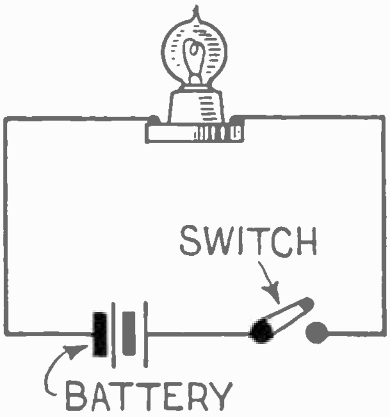
Loose coupler with secondary placed to produce close coupling.

CLOSED CIRCUIT—A circuit which permits the continuous flow of electricity. The illustration shows an ordinary dry cell connected in circuit with a small lamp. In Fig. 1A the circuit is closed and current is permitted to flow to the lamp. In Fig. 1B the circuit is open and no current can flow. A closed circuit is therefore an electrical circuit that is continuous. (See *Circuit,* also *Open Circuit.*)



-1A-

Circuit closed.

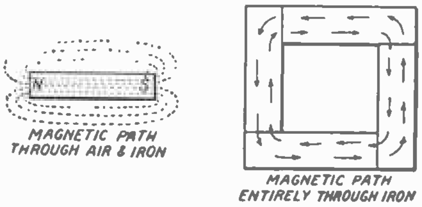


-1B-

Circuit open by means of switch.

CLOSED CIRCUIT CELL—A cell that can be used in a closed circuit for a considerable length of time without the impairing effects of *polarization* (q.v.) An *open circuit* cell is one that can only be used intermittently, as for example, with an electric bell where the circuit is only closed for a brief period. If an open circuit cell is used in a circuit that remains closed for some time, polarization sets in and ruins the cell in a very short time. An open circuit cell might be used with the *test buzzer* (q.v.) because in this case the circuit is closed intermittently as the key is depressed. (See *Cell.*)

CLOSED CORE—A core (q.v.) used in *transformers, chokes,* etc., which is continuous, forming a *closed magnetic path.* The illustration shows the difference between a closed core and an open core. In the open core type, one end is the north pole, the other the south pole, whereas in the closed core, there are obviously no poles. The closed core type is occasionally referred to as a *non-polar* core. (See *Core, Transformer,* also *Choke.*)



N
S

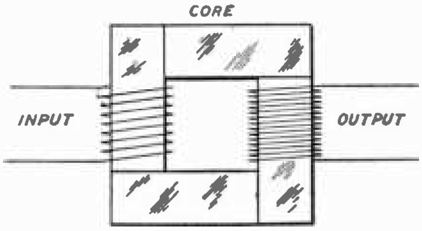
MAGNETIC PATH ENTIRELY THROUGH IRON

Open core above on left. closed on right.

CLOSED CORE TRANSFORMER—A *transformer* (q.v.) having a *closed core.* In the illustration the magnetic path, or core, is continuous, being made of strips of uniform size. This form of core is known as *"laminated."* An efficient transformer is generally made with a closed core. A transformer may be for a variety of purposes, such as *step-up, step-down, audio frequency* or *radio frequency.* (See *Transformer.*)



Closed core transformer.

C. M.—Abbreviation for circular mil. (q.v.)

Cm.—The abbreviation for *centimeter,* the unit of length in the C. G. S. system (q.v.).

COCKADAY CIRCUIT—A popular radio receiving circuit devised by the American experimenter, Lawrence M.

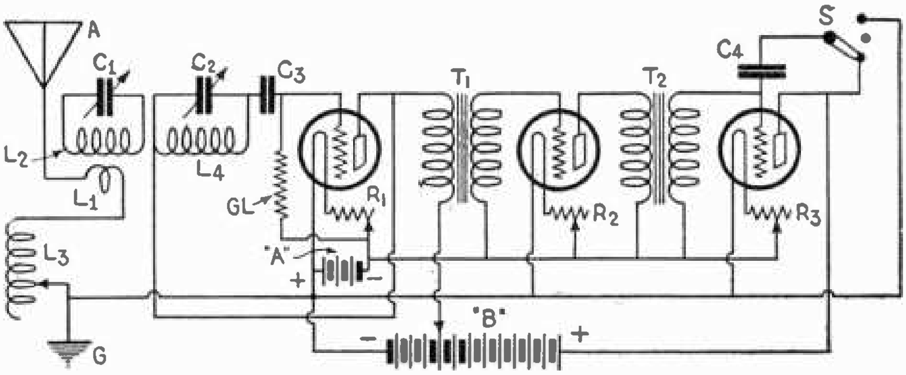


Fig. 1. Original 3 tube Cockaday Circuit.

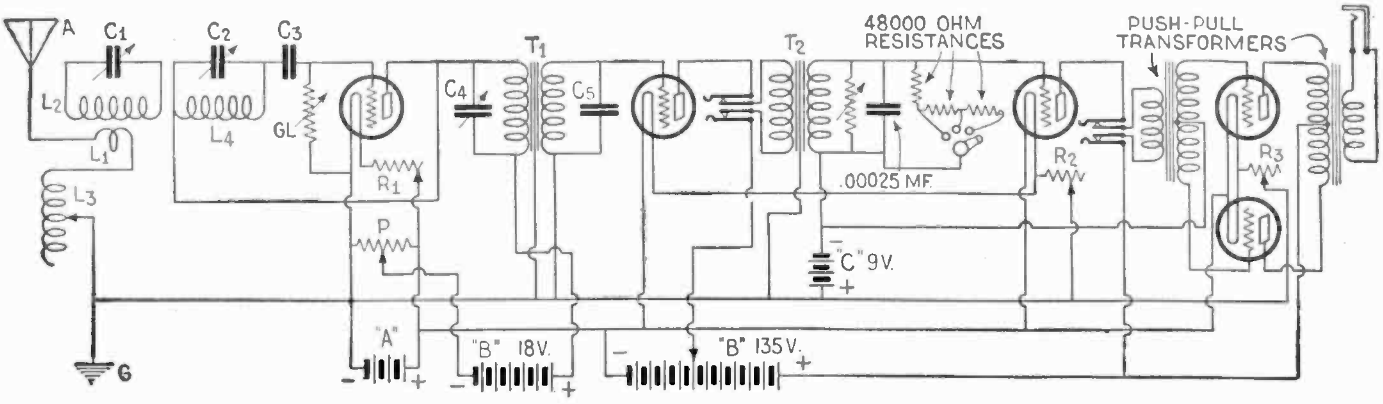

Fig. 2. Cockaday Circuit with push-pull amplifier.

Cockaday. It includes several radical features not found in the usual systems. Receivers using this circuit are generally made in three, four or five tube types. The chief value of this circuit lies in its extreme selectivity. It is usually referred to as a four circuit receiver, owing to the addition of a sensitizing circuit to the regular three circuit regenerative system. The diagram for the three tube receiver is given in Fig. 1. Here the primary or aerial tuning circuit is seen to have a single turn of wire, L1, wound around another coil L2, which is shunted by a variable condenser C1, thus forming a separate closed, tunable circuit, coupled very loosely with the antenna circuit. The primary, or antenna circuit, has in addition to the single turn, a bank wound coil L3 connected in the ground side of the open circuit and tapped to permit coarse tuning. Thus, the primary is coupled inductively to the separate closed circuit, which in turn is inductively coupled to the grid or secondary circuit containing a coil L4 shunted by the condenser C2, allowing tuning.

The tone of the music is varied by means of the novel arrangement using a condenser C4 connected to a three point switch. When the switch is placed in the center position the condenser is eliminated from the circuit and the wiring is standard. With the switch on the top tap, the grid of the tube is connected to the ground, thus by-passing a portion of the oscillations and giving a smooth soft tone with a certain loss of volume. With the switch arm on the bottom tap, the grid of the last tube is connected to the plate circuit, thus producing a different note due to the added grid-plate capacity. Coil L2 in the grid circuit is tuned by means of C1, which is a variable condenser of .0005 mfd. capacity.

A peculiarity of the circuit is that the length of the antenna has no bearing on the tuning. This is due to the *semi-aperiodic primary* and the fact that the sensitizing or pick-up coil is only one turn of wire, the inductance of which, compared to the whole inductance of the aerial circuit, is so small that any change in the over-all inductance has little, if any, effect.

This circuit, while originally having three tubes, has been arranged in conjunction with a standard *push-pull audio amplifier*, as shown in Fig. 2, making a five tube set with great power and possessing the characteristic of the original circuit with increased amplification. (See *Push-pull, Cockaday Coil* also *Regenerative Receiver*.)

COCKADAY COIL—The coil used in the *Cockaday circuits*. It comprises four windings, i.e. tapped primary, separate closed circuit coil, grid or secondary winding and a single turn looped around the closed circuit coil. (See *Cockaday Circuit*.)

CODE—Telegraph codes consist of characters formed by combinations of dots, dashes and spaces which represent letters, numerals, and punctuation marks. These characters are sent out by the radio operator with the aid of electrical impulses, and by using suitable receiving apparatus the receiving operator hears the incoming signal and is thus able to interpret the various combinations of dots and dashes and reproduce the original message. The Morse Code of characters came into general use in wire telegraphy shortly after the establishment of that means of communication. In this system, which is also called the "American Morse Code," some of the characters are made up with so-called spaces which are part of the group signal, and are necessary in distinguishing those characters. The International Morse code is a modified form of the American Morse code, and no spaces are used in the characters of the International Code. The International Morse Code is used all over the world for radio telegraphy, and for wire telegraphy in almost every country except the United States, Canada and parts of Australia. The American Morse, owing to the fact that there are fewer dashes in the characters, is about

Morse and Continental Codes.

5% more rapid than the International Morse. The American Morse and International (Continental) Codes are given herewith.

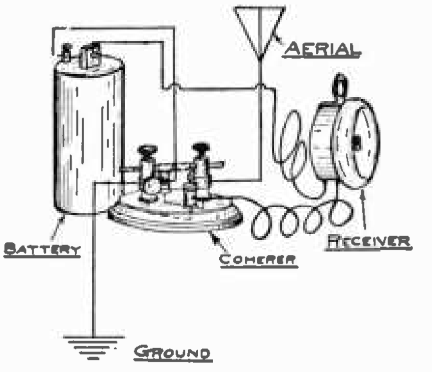
COEFFICIENT—In algebra, a number or multiplier of a *symbol.* Thus in the expression 5Y, the coefficient is 5. In electricity, and in its radio application, it is a number expressing the relation or ratio between quantities, one of the quantities generally being unity (1) as a basis or standard for the coefficients. For example, let us assume a copper wire is carrying an electric current, the *resistance* of the wire at 32 degrees Fahrenheit being one *ohm.* If we consider the resistance of the wire at 32 degrees to be unity, or one, then its resistance at any other temperature will be some number or coefficient times one.

To make this clearer, let us take the ratio of an inch to a foot. An inch is one-twelfth, or approximately .0833, of a foot. Any number of inches multiplied by this fraction will give another number in feet. Therefore we say that the coefficient, or multiplier, of an inch as compared to a foot is .0833. A coefficient is thus any number by which a quantity must be multiplied to give another quantity.

In radio the most common cases of coefficients are the following. The *coefficient of coupling* is the ratio between the *mutual inductance* (q.v.) (between the two coils, *primary* and *secondary*) and the square root of the product of the total *self-inductances* (q.v.) in the two circuits containing the coils. Similarly, the coefficient of amplification is the ratio of the effect produced with an *amplifier* (q.v.) to the effect produced without an amplifier. (See *Mutual Induction Coefficient,* also *Self-induction Coefficient.*)

COHEN, LOUIS, Ph. D.—Born in Russia, Dec. 16, 1876. Educated at Armour Institute of Technology, University of Chicago and Columbia University. Noted for his formulae and tables for the calculation of alternating current problems. He has written a book on the subject. Has evolved many formulas for the measurement of inductance and capacity. Has secured a number of patents on radio apparatus.

COHERER—A device formerly employed for detecting *radio waves.* In its original form it consisted of two metal rods separated by a narrow space in a glass tube and the gap between the rods filled with nickel and silver filings. It was found that when the *electromagnetic waves* or signals were passed through the coherer the particles of filings clung together and became *conductors.* Then by using some device such as the tapper hammer of an electric bell to strike the glass tube, again separating the particles after each signal, it was possible to keep the coherer constantly in a state of change between a *conductive* and a *non-conductive* condition, thus making the signals audible. There were many variations of this type of *detector,* which, however, is now obsolete. (See *Marconi Coherer.*)



Coherer used in radio receiving circuit.

COIL—A term having very broad application in electricity and radio. It may be used to designate any arrangement of a number of turns of wire, usually copper, and used for almost any purpose in the production of electric and magnetic effects or phenomena. The most common significance of a "coil" in radio is in reference to a number of turns of insulated wire wound on various forms and used for *tuning* (q.v.). The term *inductance coil* is generally used, although actually, any coil of wire will have inductance. Coils come in countless numbers and variety for many purposes. A coil may be used not alone for tuning—that is to adjust a receiver or transmitter to resonance with incoming or outgoing signals; it may be used to connect two circuits, in which case it is known as a *coupling coil;* it may be used with a *core* (q.v.) of iron wire, or laminated pieces, as a *choke coil* (q.v.) or it may be used in connection with *high frequency* apparatus, such as used by physicians. Coils are generally referred to by individual names indicating their construction or use. (See *Inductance, Tuning Coil, Vario-coupler, Choke Coil, Honey Comb Coil, Pancake Coil, Spider Web Coil, Lorenz Coil, Duo Lateral Coils.*)

COIL ANTENNA—Or Loop Aerial. An antenna (aerial) constructed by winding the wire around a square form. The coil (or loop) antenna, because of its comparatively small size, is often mounted on a frame work which may be rotated. If one end of the coil is pointed toward the broadcasting station, the antenna (aerial) will pick up its signals with maximum intensity, but if the coil is rotated from that position the signals from that station grow weaker, until when the plane of the loop is at right angles with the intercepted signals no sound will be obtained. It is a part of the radio compass used at sea. (See *Loop-Aerial.*)

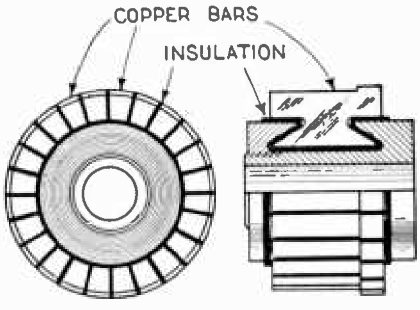
COLLECTOR RINGS—Insulated metal rings attached to the *armature* (q.v.) of an *alternator* (generator of alternating current) in such fashion that the alternating currents can be collected and communicated to the *brushes* without change, these rings are used to collect alternating current from that type of generator and brushes are used to collect direct current from a direct current generator.

COLLODION—A solution used by surgeons to cover slight abrasions or wounds, forming a protective coating similar to skin. It has been adapted to radio use as an insulating coating and is used as a binder on coils of various forms. It has been found more efficient than shellac for this purpose. A solution of pyroxylin or soluble guncotton in ether, with a certain amount of alcohol, depending on the purpose for which intended. When used as a coating for coils it serves as an insulator and also to hold the coils in place, but it should be sparingly applied.

COMBINATION DETECTOR—A detector composed of two different crystals in contact, instead of one crystal with a fine wire to search out the sensitive spots. Some combination detectors are composed of silicon and antimony; zincite and bornite; lenzite and cerusite, and zincite and chalcopyrite. These detectors all function without a battery and are simple to operate.

COMMON CONNECTIONS—A term often applied to a connection that joins several points. For example, in most radio receivers the binding posts for battery connections are arranged so that the "B—" and the "A+" or "A—" are connected to the same point. That is to say the post is a common connection for these leads. The term is also applied to a battery, as a *"B" battery,* which is used for both *detector* and *amplifier.* It is then known as a common "B" battery. The other method would, of course, be to use separate batteries for the detector and amplifier.

COMMUTATOR—In general electrical use, a device for reversing the direction of electric currents in a circuit. A *commutator* as used with a *generator* usually consists of a number of pieces called *segments,* mounted on a circular form but carefully insulated from each other. The illustration shows a common form. In the case of an ordinary motor, the commutator is employed to distribute the current to the windings and in a direct current generator it serves to furnish a direct current to the brushes although the current collected from the windings of the *armature* is alternating.



Front and side view of Commutator.

COMPASS, RADIO — See *Direction Finder, Goniometer,* also *Bellin-Tosi Direction Finder.*

COMPONENT—A part of the whole. In mechanics it is one of the parts of a stress or strain (mechanical force). In electricity, *component currents* are the several currents into which a single current may be assumed to be separated, so that if assumed to be acting together they would produce the equivalent effect of the actual current. Thus also, component *E. M. F.'s* (*electro-motive forces*) are understood as the several components into which any electro motive force may be divided. *Impedance* (q.v.) is said to consist of two components, the actual resistance and the apparent resistance present in the opposition offered to the flow of current termed the *reactance* (q.v.) by a circuit. For instance, the total current in the plate circuit of a vacuum tube responding to high *frequency grid voltages* may be considered as made up of two components, viz., a steady or constant current and a high frequency component superimposed on it.

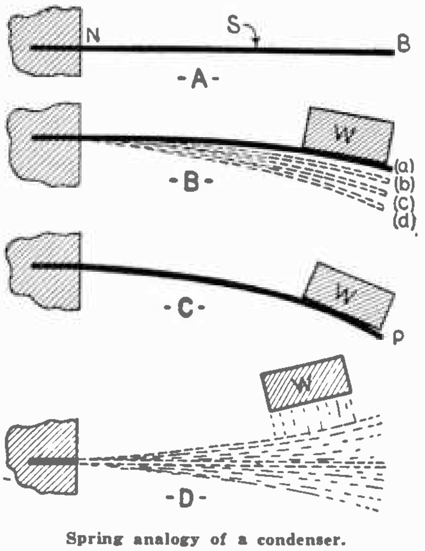
COMPRESSED AIR CONDENSER—A condenser which uses compressed air as the *dielectric* or insulating material between the plates. This type of condenser is used chiefly in transmitting circuits. (See *Condenser.*)

COMPOUND MAGNETS—A combination of several *permanent magnets.* (See *Magnets, Compound.*)

COMPOUND WOUND—A *dynamo* or *motor field magnet* wound with two *field windings,* one of which is connected in series, the other in parallel with the *armature* (q.v.).

CONDENSER—In electricity or radio practice a *condenser* consists of two or more conducting surfaces placed in relation to each other and separated by an insulating medium such as air, impregnated paper, mica, etc. The conducting surfaces are generally referred to as *plates* or *electrodes* (q.v.) and the insulating material is known as the *dielectric* (q.v.). Condensers are used in radio for a variety of purposes, their broad use being to allow tuning. In action, a condenser permits charges of electricity known as *electrostatic charges* (q.v.) to be stored up and released periodically, according to the frequency desired. They may also be used to exclude certain types of energy. (See *Condenser, By Pass,* also *Filter.*) The action of a condenser may be compared to that of a spring when placed under a mechanical strain. In the illustration Fig. 1A a flat spring S is shown in a normal position, NB. In 1B a weight W is placed on the surface of the spring. This weight will force the spring down from its normal position to one of the positions (a), (b), (c) or (d), according to the force exerted and the strength of the spring. If a heavier weight is then placed on the spring it will depress still further until we can imagine a point P in Fig. 1C at which the elasticity of the spring is used up and the opposition is such that it will no longer depress and comes to rest. When the weight is removed the spring will fly back into normal position, Fig. 1D, and in doing so will vibrate back and forth a number of times, thus producing, or rather, returning the energy that was stored in it during the moment of stress.

Considered as analagous to a *condenser,* in the above case the weight can be likened to the electrical charge applied to the condenser, the *resistance* of the spring may be considered somewhat similar to the *capacity* of the condenser, or the power returned on release of the spring may be regarded as the electrical power released by the condenser when the charging force is removed. The capacity of the condenser then will be seen as the ability to store up energy placed in it.



Spring analogy of a condenser.

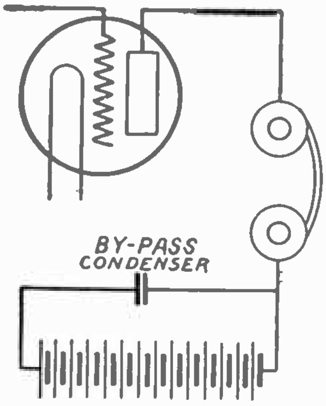
In the case of the spring, if too great a force is exerted, it may break down or as would actually happen, the elasticity would be lost. The same applies in the case of a condenser. If the charging force is too great, it may exceed the dielectric strength of the condenser and result in puncturing the insulating material between the plates. (See *Breaking Down of Dielectric.*) The energy obtainable from a charged condenser will be equal to the charge placed in it providing there is no leakage or other loss. In a well-designed condenser the leakage will be so negligible that it need not be taken into consideration.

The relation between the charge in a *condenser,* the *voltage* applied and the *capacity of the condenser* is expressed as $Q = C \times E$, where Q is the quantity of the charge in *coulombs,* E the potential in *volts* and C the capacity in *farads.* (See *Capacity, Condenser, Variable; Condenser Fixed; Condenser Transmitting,* also *Condenser Curves.*)

CONDENSER, AIR—See *Air Condenser.*

CONDENSER, ANTENNA—See *Aerial Tuning Condenser.*

CONDENSER, BY-PASS—A condenser, usually of the fixed (q.v.) type arranged in a circuit in such manner that currents of a certain frequency will pass freely around any obstructing object, as, for instance, a high resistance element necessary to the circuit. An example of the use of a condenser in this manner is shown in the case of a "B" battery where the battery has a high internal resistance. A fixed condenser is placed across the terminals of the battery without injury to it and offers a path of low resistance for the high frequency radio currents.



By-pass condenser across "B" battery.

CONDENSER CURVES—Curves showing the relation of variations in wavelength, frequency, and capacity with rotation of the dial of a variable condenser. Three types of condensers are shown here, the *compression,* Fig. 1, the *straight line capacity,* Fig. 2, and the *square law,* Fig. 3. In Fig. 1A is shown the relation of capacity and wavelength changes when the dial of a sample compression condenser was rotated. The condenser was shunted across a fixed coil. It will appear that the increase in capacity is gradual at the lower part of the range but increases very rapidly at the upper ranges. This is due mainly to the relation of the curvature of the upper plate to the lower plate as will be seen from the illustration, Fig. 1. These condensers are very satisfactory on about the lower two-thirds of their range, but through the remainder of their range a very slight adjustment of the knob causes an extremely large change in capacity, making them very difficult to handle near their maximum capacity. Fig. 2 shows the shape of the variable plates in the straight line capacity condenser and Fig. 2A illustrates the relation of wave-length and capacity changes with rotation of the dial. Here the capacity depends upon the overlapping area and is therefore proportional to the angle of rotation of the movable plates. The capacity curve appears as a practically straight line running diagonally across the chart. The wave-length, however, changes rapidly at the lower range and very gradually at the upper range as indicated by the wave-length curve. Fig.

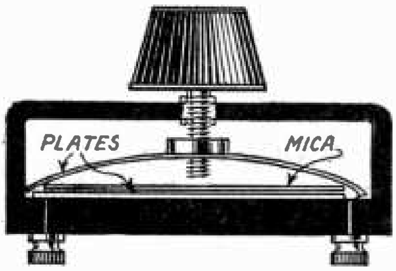


Fig. 1. Compression type condenser.

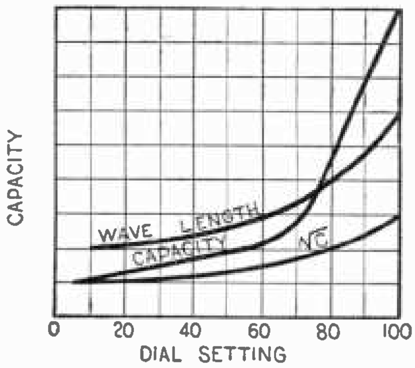

Fig. 1A. Curve for compression type condenser.

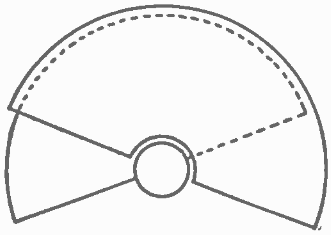

Fig. 2. Straight line condenser.

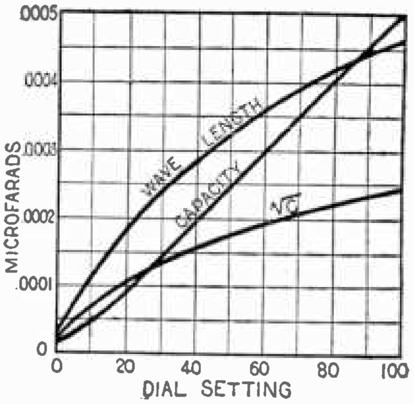

Fig. 2A. Curve for straight line condenser.

3 shows the shape and disposition of rotor and stator plates of a condenser so designed as to read directly in wavelength from the settings of the dial.

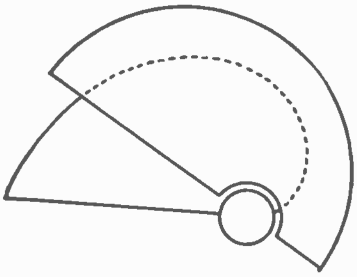

Fig. 3. Square law condenser.

This is known as a square law condenser, and the relational curves are shown in Fig. 3A. Here we find the wave-length curve a straight line and directly proportional to the angle through which the dial is turned. The line indicating the square root of the capacity √C is a straight line, and as the wavelength is the product of the square root of the capacity multiplied by a constant (varying with the individual condenser) the wavelength curve must also be a straight line.

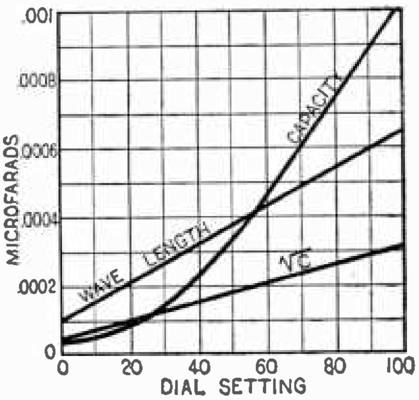

Fig. 3A. Curve for square law condenser.

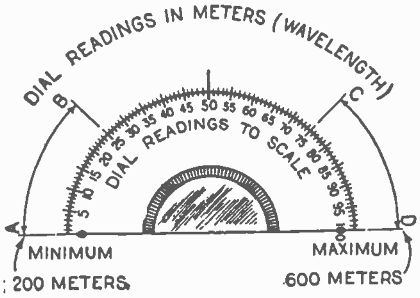

Fig. 3B. Showing effect of straight line condenser on dial reading.

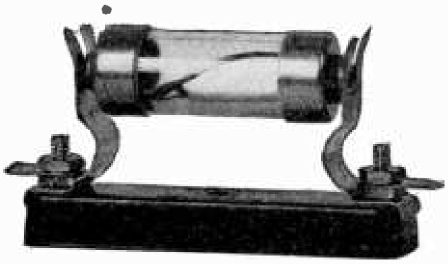
Such condensers are much used in wave meters (q.v.). Condensers are also made so that the frequency curve is a nearly straight line, varying more or less directly as the angle of rotation of the plates. Fig. 3B illustrates the result when an ordinary straight line capacity condenser is arranged with a dial calibrated directly in meters. It appears that the readings are bunched at the lower range (A to B) and spread out at the upper ranges (C to D). The reason for this can readily be seen by glancing at the curve Fig. 2A.

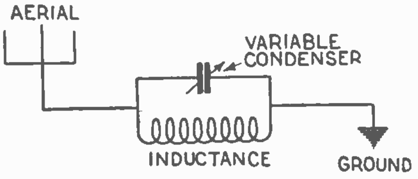
CONDENSER, FIXED—A *condenser* which has a fixed or constant capacity, allowing no variation of the value. (See *Condenser*, also *Condenser, By-Pass.*)

CONDENSER, GRID—A condenser, generally of low capacity, of the fixed or variable type, used in series with the grid of the *detector tube* to prevent excessive charges from affecting the *grid.* These condensers generally have a capacity between .00025 and .0005 *micro farads.* Due to the blocking action of these condensers, a high resistance, known as a *grid leak* (q.v.) is placed across the condenser or from the grid to filament, thus allowing the accumulated charges to leak off the grid of the tube in time for the grid to be free for the succeeding electric charge. The grid leak may be considered as a valve controlling the amount of energy that the detector can efficiently take care of without overload. (See *Grid Leak.*)



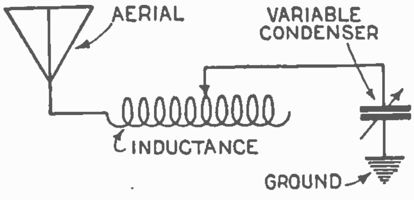
Grid leak and condenser.

CONDENSER, IN PARALLEL—A condenser arranged in a circuit in such manner that the current is divided between it and the other condenser or coil with which it is connected. The illustration shows a *variable condenser* connected in parallel with a coil, both placed in series between aerial and ground and forming a tuned primary or aerial circuit. (See *Parallel Connections.*)



Coil and condenser in parallel.

CONDENSER, IN SERIES—A condenser connected in a circuit with other condensers or coils in such manner as to form a continuous path, allowing the current to pass through each unit without dividing. The illustration shows a condenser connected in series with a *tuning coil,* aerial and ground, thus forming a tuned primary or aerial circuit. (See *Condenser, in Parallel,* also *Series Connections.*)



Coil and condenser in series.

CONDENSER, MICA—A condenser, usually of the fixed type, employing sheets of mica as the dielectric or insulating material between the plates. The condensers of small capacity used in receiving circuits are generally made with mica as a dielectric, but owing to its cost and thickness it is seldom used in low-power, high-capacity condensers. Mica is also used in condensers for high-power work such as transmitting, when the capacity is low. (See *Condenser.*)

CONDENSER, PHONE—A fixed condenser of comparatively low capacity used across the *telephone receivers* to allow a by-pass for a certain portion of the currents and thus prevent undue strain on the phones. (See *Condenser, By-Pass.*)

CONDENSER, TRANSMITTING—See *Condenser, Mica.*

CONDENSER, VARIABLE—Any condenser so arranged as to allow variation of its capacity. This may be accomplished in many ways, the usual method being to have the plates divided so that one series is movable with respect to the others, the capacity changing with the rotation of the variable plates. (See *Condenser.*)

CONDUCTANCE — Sometimes called the conductivity. The quality of a given conductor in virtue of which it facilitates the flow of an electric current. A *conductor* (q.v.) is a body having large *conductance* and an *insulator* (q.v.) is one having negligible conductance. *Conductance* is thus the opposite of *resistance.* The unit of conductance is the *mho,* the reciprocal of *ohm.* The symbol is obviously derived from ohm, reversed. It is the conductance of a column of mercury 106.3 cm. (centimeters) long, 1 square mm. (milimeter) in cross-sectional area and of a weight of 14.4521 grams.

CONDUCTIVE COUPLING—The association of one circuit with another by means of inductances (coils) mutual to both circuits.

CONDUCTIVITY, SPECIFIC—The reciprocal of Specific Resistance; being a standard of reference for comparing the conductances of different substances. (See *Specific Resistance, Conductance.*)

CONDUCTOR—Any substance that offers small *resistance* to the passage of electric currents may be termed a *conductor.* This term is the opposite of *insulator,* but there is actually no line of demarcation between the two, since any insulator will permit the passage of current when sufficiently high voltages are used. For all practical purposes, however, a conductor is considered as material that presents little difficulty to the passage of current. The most common conductor is copper, usually in the form of wire. An idea of the relative conductivity (power of carrying electric current possessed by various substances, pure copper being taken as standard) of various substances can be gained from the table following. The materials on the left are comparatively good conductors given in the order of their conductivity, while those on the right are poor conductors and generally used for resistances. (Note: A *resistance* is used to retard the flow of electricity without necessarily stopping it entirely, whereas an insulator is used to stop the passage of current.)

Silver
Copper
Brass
Gold
Aluminum
Zinc
Platinum
Iron
Nickel
Tin

German Silver
Platinum Silver
Manganin
Mercury
Graphite or carbon

There are, of course, many other substances that can be classed as good conductors, or as poor conductors, but the above are more generally known and used. It is a peculiar fact that while good conductors become less conductive as their temperature is raised, insulators lose a certain amount of their insulating properties as their temperature is raised. As too great current in a conductor will cause heat, and as explained above, cause lessening of conducting ability, it will be obvious that for the fullest efficiency a conductor will necessarily be arranged to carry the required current without undue heating. It is understood also that conductors in any part of a radio circuit should be carefully gauged as to size and the effective cross-section of the conductor determined, in order to offset the losses due to heating. It must not be assumed from the foregoing that the larger the wire the greater the efficiency—in fact a large wire is often less satisfactory than a small one in high frequency circuits.

When the conductor is to carry direct current the only consideration is to have the wire large enough to prevent heat losses and at the same time not be too bulky. Where the conductor is to carry *high-frequency* (q.v.) currents there are other factors to consider. High frequency currents are said to travel only on the outside of the wire (see *Skin Effect*) and therefore it is possible to use very fine wire for this purpose when the very low current values obtaining in reception are in question. A phenomenon that must be given attention, however, is that of *distributed capacity* (q.v.). (For more complete explanation of this subject see *Low-loss Coils*. See also *Bus bar*.)

CONNECTING UP or HOOKING UP—These general terms are used in radio to refer to the process of wiring a receiver or any particular part of a receiver or other circuit.

CONSTANT—A quantity or magnitude, which does not vary, derived from actual experiment, which is included as a factor in most formulas for the purpose of bringing theoretical calculations into agreement with experience. Constants are much used in radio calculations. As an illustration, different dielectric or insulating materials used in a condenser have different constants which must be taken into consideration when calculating the capacity of the *condenser*. Thus, as a dielectric, air at ordinary pressure is taken as the standard, the constant being stated as 1. Flint glass has a high dielectric value, its constant being stated as 10.10, other materials varying according to their comparison with air as a standard. (See *Dielectric*.)

CONSTANT CURRENT—An unvarying *current*. The term "constant" is applied to *voltage* when it is steady and unchanging, to *resistance* when it is fixed and unvarying, or to almost any value that does not change.

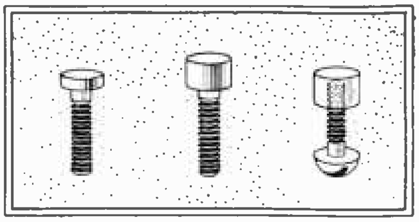
CONSUMPTION, CURRENT — The term usually employed to denote the current required or consumed by any part of an electrical circuit or by the circuit itself. A resistance in a circuit consumes a certain amount of energy because it dissipates it as heat energy. A filament in the case of a vacuum tube, requires a certain amount of current to heat it to brilliancy. If the filament thus requires one-quarter of an ampere we say its current consumption is one-quarter ampere. (See *Plate Consumption*.)

CONSUMPTION, PLATE—The current required to energize the plate of a vacuum tube. (See *Plate Consumption*.)

CONTACT BREAKER—A contrivance for quickly and automatically making or breaking an electrical circuit normally existing between two contacts. (See *Circuit Breaker*.)

CONTACT DETECTOR—A form of crystal detector in which a small wire, or "catwhisker," as it is called, makes contact with the crystal in the detector and acts as a *rectifier* of the *high frequency waves* received from the broadcasting station. (See *Crystal Detector—Theory of Operation*.)

CONTACT POINTS, or SWITCH POINTS—Generally refers to a small flat-headed machine screw used as a contact point for a *switch*. The illustration shows the types mostly used.



Various contact points.

Leads from various points of a tapped coil may be connected to the several contacts in order to permit variation of the *inductance*. A "contact point" may also mean any point in an electrical circuit at which contact is made to close the circuit.

CONTACT RECTIFIER—See *Contact Detector*.

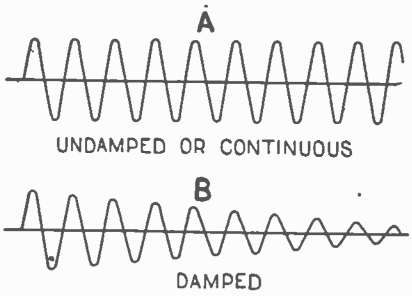
CONTACT RESISTANCE—When two connecting surfaces in a circuit carrying electrical energy do not make absolute or perfect contact, a certain amount of *resistance* (q.v.) results. In any part of a radio circuit where two wires or *conductors* are joined to form a circuit, it is essential that they make a positive contact. The wires used for connections in a radio receiver are generally soldered or fastened tightly by nuts or bolts, or machine screws in order to form a good contact. If this is not done, energy may be wasted, due to the resistance at the point of contact.

CONTINUOUS OSCILLATIONS—Each oscillation or vibration being of the same amplitude as the preceding one. (See *Sine wave*.)

C. W.—Abbreviation for continuous wave (q.v.).

CONTINUOUS DIRECT CURRENT—A *direct current* which flows steadily without interruption or reversal. The current supplied from a battery for radio use is continuous direct current, while that portion of the *high frequency alternating current* which is rectified by a *vacuum tube* detector is called *pulsating direct current*, as there is an interval of time between the rectified half of each incoming wave, due to the other half not being rectified. (See *Current, Pulsating Direct, Pulsating Current*, also *Rectification*.)

CONTINUOUS WAVES—Also called *Undamped* or *Sustained waves* and usually referred to as *C. W. Electromagnetic waves*, the separate oscillations (each vibration) of which are of constant or unvarying amplitude. In Fig. A a series of *oscillations* (q.v.) are shown. It will appear that one oscillation or *cycle* is of the same amplitude as the preceding one—the amplitude (q.v.) being considered as the height of the wave above the straight line representing time or its depth below that line. Each loop above the line or below it represents an *alteration* (q.v.) (the increase in current to maximum and back to minimum in either direction)—the loops above the line being considered as *positive alternations* and those below the line as *negative alternations*. Now it is evident from the sketch that each succeeding alternation has the same strength (amplitude) as that preceding it, and the same is true of the complete cycle, consisting of one alternation in each direction. Thus the waves are continuous, or constant, as far as amplitude is concerned. Now in Fig. B the amplitude is not constant—it decreases with each succeeding alternation and hence with each succeeding cycle (two alternations). After a comparatively few oscillations the current has decreased to zero, that is, the oscillations have died out completely. In this case the percentage of decrease in amplitude from one cycle to another is known as *decrement* or *damping*. Thus continuous waves may be considered as waves in which, with any train or group of oscillations, each succeeding oscillation has the same amplitude as that preceding it.



Series of undamped and damped waves.

CONTINUOUS WAVES—KEY MODULATED—Continuous waves (q.v.) which have been broken into dots and dashes of the telegraphic code by means of a *telegraphic key*, these signals being made audible at the receiving end by the use of an oscillating receiver.

CONTINUOUS WAVES—MODULATED AT AUDIO FREQUENCY—The process of variation of the frequency (vibration) of waves radiated by a broadcasting station in accordance with the sound waves is known as modulation. Frequencies from 10,000 down to about 32 are audible to the human ear and are known as audio frequencies. Hence continuous waves which are modulated at *audio frequencies* are waves which have been modulated (varied) by having the voice or music impressed on the *microphone* at the broadcasting station, which in turn causes the strength of the radiated electric wave to vary so as to correspond electrically to the sound vibrations at the microphone.

CONTINUOUS WAVE SIGNALS—See *Continuous Waves*.

CONTINUOUS WAVE TRANSMISSION—System of radio telegraphy using waves as described under "Continuous Waves."

CONVECTION CURRENTS—When a hot and a cold body are separated by a fluid which is free to circulate, heat is transferred from the hot to the cold body by currents of the fluid itself flowing from one to the other; similarly, all parts of a fluid which is being heated quickly come to approximately the same temperature. This transfer of heat by currents of the fluid itself is called "convection." In electricity "Convection Currents" are currents arising from the motion of charged particles thrown off in electrified streams, i.e., the flowing of charged air particles in streams from the pointed end of a highly electrified conductor, sometimes called "electric wind."

CONVENTIONAL—This term is much used in radio to denote a form established by custom. A conventional circuit for some particular purpose is understood as a circuit which has been generally used and which is generally considered as standard. Broadly, the most common form or use of anything. The conventional method of amplifying signals of *audio frequency* is by means of *audio frequency transformers*. Any other means is unconventional, although it may produce similar results.

CONVERSION FACTORS—A numerical factor which gives relation between the magnitude of a quantity expressed in terms of one system of units, and the same quantity expressed in terms of any other system of units. For example, the yard is regarded in the United States as 3600/3937 meter (a meter is approximately 39.37 inches). We say, therefore, that the conversion factor between the yard and the meter is 3600/3937 because any number of yards multiplied by this figure or factor will give the result in meters. (See *Capacity Conversion Factors.*)

CONVERTER—A term applied generally to any mechanical, electrical or electro-chemical device which will convert or change one form of energy to another. More specifically in electricity the term is used in reference to (1) a dynamotor designed with two *armatures*, mounted on one shaft, one being a motor armature driven by the original current, the other armature generates new current; this is also called a "motor-dynamo" and it can transform continuous (direct) current to higher or lower voltages, or, (2) a rotary electrical device used to change direct to alternating current or vice versa. (See *Rotary Converter.*)

COORDINATES—A thing of the same rank with another thing may be termed a coordinate. For example, lines by means of which the position of any point as of a curve may be defined with respect to certain fixed lines. In the illustration Fig. 1 lines known as axes of coordinates are shown. Such a system as this will be the basis for curves (q.v.) showing the relation between varying values. If we assume the horizontal line X as the axis of abscissas, all distances measured parallel to this line will be known as abscissas; distances measured parallel to the vertical line Y being referred to as ordinates. The line A-B is parallel to the axis of abscissas X and is therefore an abscissa. The line B-C is parallel to the axis of ordinates and is referred to as an ordinate. Now if we place a number of lines parallel to each axis (ordinates and abscissas) and assign to each of them a certain value, such as amperes, to each abscissa, and volts to each ordinate, a line can be drawn through a number of points to represent the various values of each quantity as related to the other. Thus, in Fig. 2 we have a purely hypothetical curve representing the assumed value of current in amperes under assumed voltages. In the example, the curve at point A shows approximately three amperes under a pressure of ten volts. This imaginary curve is, of course, shown merely for the purpose of illustrating the meaning of coordinates, ordinates, abscissa, etc. (See *Abscissa, Characteristic curve*, also *Graph.*)

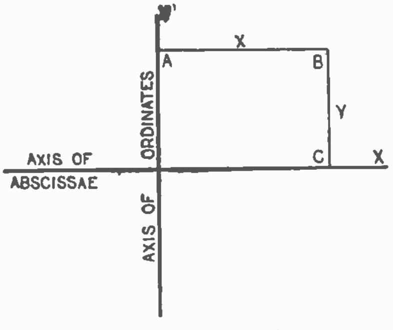


Fig. 1. Axis of coordinates.

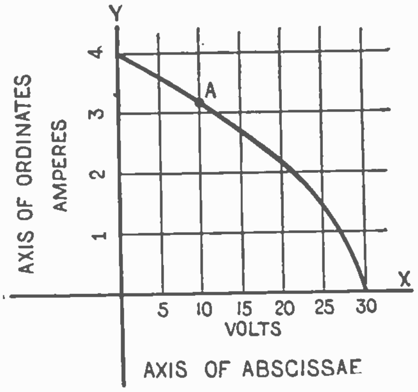

Fig. 2. Curve showing assumed value of current in amperes under assumed voltages.

COPPER PYRITES—Sometimes referred to as *Chalcopyrite*. It is used in radio reception as one of the elements of a *crystal rectifier* (detector) generally in conjunction with zincite or tellurium.

COPPER SULPHATE—A salt of copper. Also known as blue vitriol or copperas. A copper sulphate solution is sometimes used as a preservative for wooden aerial masts. It is used in certain forms of primary cells (devices for transforming chemical action into electric current) and also produces sulphuric acid when subjected to *electrolysis* (q.v.).

CORD, PHONE—The cord or flexible wire used to connect a *headset* (phone) or *loudspeaker* to the terminals of a receiver. Phone cord is usually copper tinsel wrapped around a cotton cord, the whole covered by braided silk or cotton threads. It cannot be used to carry high currents, but is efficient for the comparatively low currents flowing through the phone circuit of a radio receiver. Some phone cords are also formed of a number of fine copper wires covered with a suitable insulating material.

CORE—The central portion of a piece of certain electrical apparatus. Thus the center of a coil will be the *core*, irrespective of its nature, whether air or iron. The core of a *choke coil* (q.v.) is usually made of a bundle of soft iron wires or strips of iron. The core of the closed type is called a *laminated core*, being made up of laminations or layers of the core metal. (See *Choke or Choking Transformer, Closed Core.*)

CORE LOSSES—The losses due to the *stray currents* (q.v.) set up in an iron core while under the stress (strain) of a *magnetic field* (q.v.). Also losses due to *hysteresis* and *eddy-currents*. (See *Magnetic flux, Eddy current*, also *Hysteresis.*)

CORE TRANSFORMER (Iron)—A transformer having the wire wound over an *iron core*, the iron forming a path for the *magnetic lines of force*, as distinguished from a *transformer* in which there is no iron core—called *air core*. (See *Transformer.*)

CORONA—The Latin word meaning crown, originally applied to the crown shaped lights occurring in the *aurora borealis*. In electrical parlance it refers to the luminous discharge which occurs along high tension transmission lines or the aerial wires of a high power radio transmitting station. (See *Brush Discharge;* also *Corona Loss.*)

CORONA LOSS—The energy loss due to corona discharge. (See *Corona;* also *Brush Discharge.*)

CORRECTION FACTORS—A formula for the measurement of certain values is generally made by using certain conditions or types of apparatus as a standard. For example a formula for calculating the inductance of a coil is made by using a particular type and shape of coil as the standard. Therefore the formula will be essentially correct for this type of coil, assuming that its shape and other characteristics are the same. If, however, the nature of the coil to be tested differs from that of the standard coil in some way not covered by the formula, a system of correction must be used to adjust the formula to the particular case. Thus, the formula for inductance of coils takes into consideration the size of the wire or the number of turns, the length of the coil, its diameter and so on. However, it does not take into consideration the ratio between the length of the coil and its diameter. For this purpose a correction factor (necessary consideration) is needed to correct the result of the formula to fit the individual occasion. This correction factor is generally referred to as a *constant* (q.v.), its value being determined generally from a chart prepared to cover various ratios of length to diameter.

CORROSION—Chemical action which causes destruction of the surface of a metal. In the case of iron it is generally rust, corrosion of copper being due to oxidation, or perhaps the action of stray currents causing *electrolysis* (q.v.). This effect is very often noted in the case of an aerial wire where the wire is necessarily exposed to the action of the atmosphere, rain, etc. The effect is particularly important and undesirable where the lead in wire is joined to the aerial.

If the two wires are not soldered securely or at all, corrosion may set in, which will produce in time a high resistance connection and waste the valuable energy of the incoming signals. This is the main point of danger in an aerial system and the best protection is to solder the joint carefully. As a matter of fact the remainder of the wire may corrode to a considerable extent without disastrous effect. In the case of copper, the wire very quickly corrodes when exposed. For this reason insulated wire is sometimes used for the aerial. As the current received by an aerial travels only on the outer surface of the wire (see *Skin Effect*), and a corroded surface is not a particularly efficient conductor, there seems to be some basis for the use of insulated wire for this purpose. Another instance of corrosion is in a soldered joint within a receiving set. All soldered joints should be carefully wiped to remove any trace of *acid flux* (q.v.), which may remain to produce a destroying chemical effect on the wire and cause loss of energy. (See *Electrolysis*, also *High Resistance Joint.*)

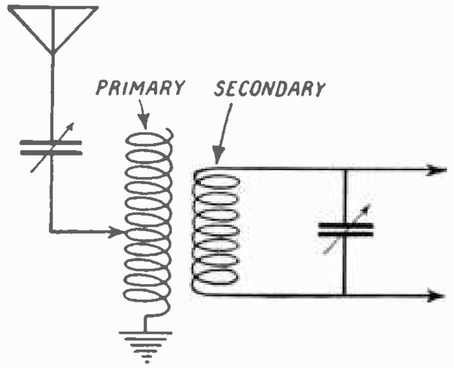
COULOMB—The practical unit for electrical quantity. It is defined as the quantity of electricity delivered by a current of one *ampere* flowing for one second. Therefore a *coulomb* of electricity will pass each second in a circuit having one *ohm* of resistance and a pressure of one *volt.* It is also used to express the quantity of electricity which a condenser having one *farad* of capacity will absorb when placed under a pressure of one volt. (See *Capacity, Electro-static, Volt, Ampere Hour, Practical Units, CGS Units.*)

COUNTER ELECTROMOTIVE FORCE—Commonly known as *Counter E. M. F.* It is an opposing electromotive force which tends to resist or act against the original electromotive force. It may be introduced in a circuit to prevent any fluctuation of the original force. (See *Back Electromotive Force*, also *Choke Coil.*)

COUNTERPOISE—A *counterpoise* is generally a second aerial suspended either below the main aerial or to one side of it. It is used more often in transmitting stations in place of the usual ground connection, but is occasionally also used in reception where it is impossible to obtain an efficient ground. (See *Aerial.*)

COUPLE, THERMO ELECTRIC—See *Thermo-Couple.*

COUPLED CIRCUITS—The term generally used to refer to circuits that are joined by *coupling.* (q.v.) In the illustration the *primary circuit* (the aerial ground and tuning devices) is coupled or joined to the *secondary circuit* by *inductive* coupling. That is to say, the signals impressed on the *primary circuit* are transferred to the *secondary circuit* by means of *inductive coupling;* when the lines of magnetic force around the primary coil cut the secondary coil, a voltage is set up in this coil which causes a current to flow in the secondary circuit, and it is then said the coils are "inductively coupled", there being no connecting wires between them. Signals might be transferred to the secondary circuit by any of several means, but in each case the method of joining the two for the purpose of effecting a transfer of energy is referred to as "coupling the circuits." (See *Coupling.*)



Circuit in which primary and secondary are joined by inductive coupling.

COUPLER—See "Coupler—(Loose)" and "Coupler—(Vario)".

COUPLER—(LOOSE)—A tuner used in a radio receiver, consisting of a primary and secondary coil so constructed that the secondary coil slides on rods in and out of the primary coil. When the secondary is entirely within the primary the coupling is said to be "tight," and as the secondary is withdrawn from the primary the coupling becomes "loose," depending upon the distance which the coils are separated.

COUPLER—(VARIO)—Form of tuner used in a radio receiver, having primary and secondary coils arranged in such a manner that the secondary rotates on a shaft within the primary. The degree of coupling is governed by the variation of the angle between the axes of the two coils.

COUPLING—The relation of one coil of wire carrying alternating currents to another in which energy is set up by the first coil. It is used to define the intimacy between the primary and secondary windings of various types of *oscillation transformers, couplers* and *tuning devices.* This transfer of energy may be produced in several ways, as by *inductive coupling, conductive coupling* or *electro-static coupling.* The more common method is to place the primary and secondary coils in close proximity and produce the energy in the secondary through induction. The illustration Fig. 1 shows a simple two slide tuning coil which is divided into a primary and secondary by *conductive* coupling. Here the transfer of energy from the aerial and ground, or primary circuit, to the secondary circuit (detector and phones) is accomplished with little loss of energy as the circuit is through wire conductors. This is also known as *direct coupling.* Now in Fig. 2 a simple form of *loose-coupler* is shown. This device is made in numerous forms, the principle of operation however, being the same in all cases. Here one coil, the secondary in this case, is made to fit into the larger coil which is the primary. The energy flowing in the primary coil induces or sets up a similar current in the secondary by reason of its proximity. The energy in the secondary, however, will not be as great as in the case of Fig. 1 where it is transferred directly through a wire conductor. The coupling shown in Fig. 2 will on the other hand, permit much closer adjustment to the desired signals.

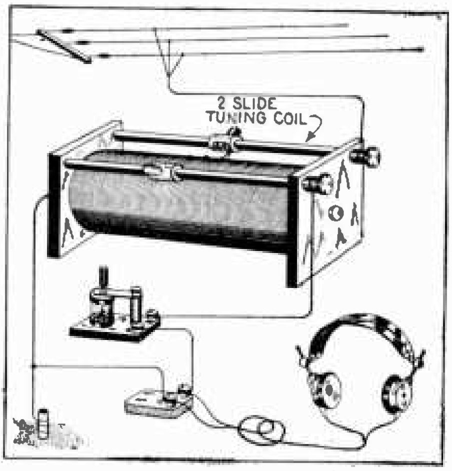


Fig. 1.—Two slide tuner divided into primary and secondary circuits by conductive coupling.

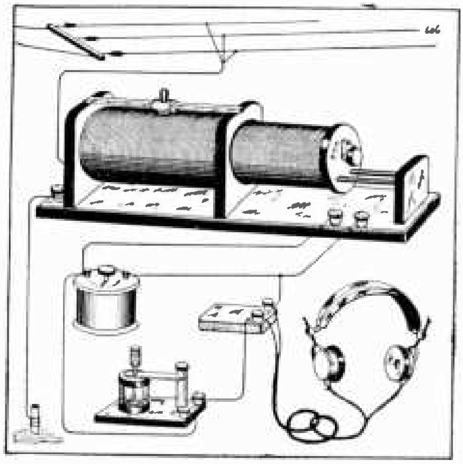

Fig. 2.—Circuit in which primary and secondary are inductively coupled by loose coupler.

The other method is known as *capacitive* or *electrostatic coupling.* This is shown in Fig. 3. Here the secondary coil is not in direct inductive relation to the primary, in fact it might well be almost any distance away were it not for the loss in efficiency due to long connections. The connection between the primary and secondary coils is by means of condensers. The transfer takes place through these and is determined by the setting of the condensers. It will appear that from a standpoint of maximum transfer of energy, the direct or *conductive coupling* system is best. The factor of tuning enters here however, and must be considered. In order to eliminate undesired signals the various systems of coupling are resorted to. It is known that *selectivity*—the ability to tune out undesired signals while receiving the desired signals—is often obtained only at the expense of a certain amount of energy or volume. It is a safe assumption therefore, that if there is any such thing as maximum efficiency in tuning apparatus, it must be a general term covering both selectivity and volume.

Coupling in its various forms is intended to refer not only to receiving circuits but to transmitting circuits as well. Its application in transmitting is covered under the heading *Spark transmission* (q.v.).

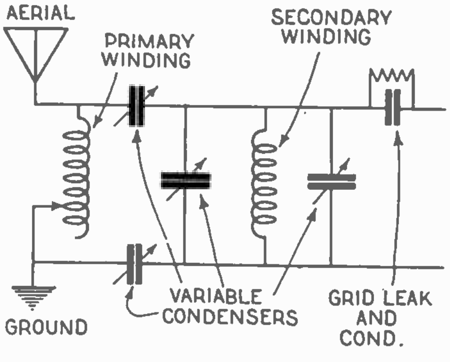

Fig. 3.—Electrostatic coupling between primary and secondary by means of variable condensers.

COUPLING COEFFICIENT — The closeness of *coupling* is specified by a quantity representing the ratio of the *mutual inductance* between two coils to the square root of the product of the two *self inductances.* In its practical sense coupling coefficient refers to the inductive relation of two coils. Coupling coefficient is defined as the ratio

$$\frac{Xm}{X.\ X_2}$$

Where Xm is the mutual or common reactance X is the total inductive or capacitive reactance in the primary circuit and X_2 the similar reactance in the secondary circuit. (See *Coupling, Mutual Inductance.*)

COUPLING, DEGREE OF—The extent of relationship between coupled circuits. In a great number of circuits the coupling is arranged so that it may be adjusted either close or loose, as the requirements of the reception may be. Variable coupling may be obtained either by varying the distance between the two coils of a *loose coupler*, or by changing the angle between the coils of a *variocoupler*. (See *Coupling.*)

COUPLING TRANSFORMER—(OSCILLATION TRANSFORMER) — This is the "tuner" of the transmitting circuit. It consists of primary and secondary windings usually of flat strips of copper, or copper ribbon, instead of wire, in order to reduce losses due to *skin effect* (q.v.). The primary coil receives the energy in the form of alternating currents from the generating device; these currents set up lines of force which interlink with the windings of the secondary coil connected in series with the antenna system, and in this manner the energy of the oscillation (alternating) current is transferred to the radiating system (aerial and ground) and thence into space. The purpose of the oscillation transformer is to produce a sharp wave which is readily tuned at the receiving end and causes a minimum of interference. The greater the distance between the primary and secondary coils the more sharp the wave becomes.

A device serving the same purpose in a receiving set, i.e. to enable the receiver to separate sharply the received signals, is sometimes called a receiving transformer, although commonly known as a tuner, coupler, vario-coupler, etc.

C. Q.—Abbreviation of inquiry made in code by a radio telegraph station desiring to communicate with another station. (See *Abbreviations.*)

C. Q. D.—The original Distress Signal (q.v.) established in 1904 by the Marconi Company. The origin of this signal is said to have developed from the use by telegraphers on land lines sending the C. Q. call when they wished everyone on their circuit to listen to the message being transmitted.

The signal C. Q. D. is now obsolete, having been replaced by S. O. S. at the International Radio Telegraph Convention held at Berlin, Germany, in July, 1908.

CRITICAL—A term often used in reference to the tuning qualities of a radio set, and, less frequently, to indicate a *vacuum tube* that *oscillates* too freely. If a receiving set is not critical in adjustment it is said to tune broadly, that is to say, not sharp in tuning. A critical set has a very narrow margin of control in tuning—the particular signals being receivable within only a very few points on either side of their true wave setting on the tuning dials. If a set is difficult to tune it is termed "too critical". This means that it tunes too sharply and it is difficult to get proper results, due to the possibility of passing by signals unnoticed when turning the dials. Obviously there is a middle point wherein a set may be selective and yet not too difficult to tune. If a vacuum tube goes into *self-oscillation* (q.v.) too readily it is said to be critical. This effect is not desired in a tube except in rare instances. (See *Resonance, Tuning, Broad, etc.*)

CRITICAL CURRENT—The current required to bring about some particular effect in an electrical circuit. In radio use, a common example is the exact amount of current needed by the filament of a vacuum tube to bring it close to the *oscillating point* (q.v.) without actually going into oscillation. (See *Critical.*)

CRITICAL POINT OF CURVE—The peak or point of maximum value in a curve showing the relation of any varying values. The illustration shows the curve indicating relation between voltage and signal strength in two types of vacuum tubes. The points marked "Peak" in each curve represent the critical points of the curves at which maximum audibility is obtained, any further increase in voltage not increasing the audibility. (See *Characteristic Curve*, also *Curve.*)

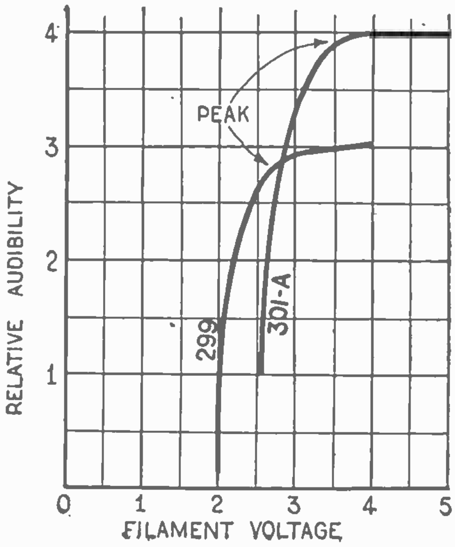

Illustration showing peaks or critical points of curve.

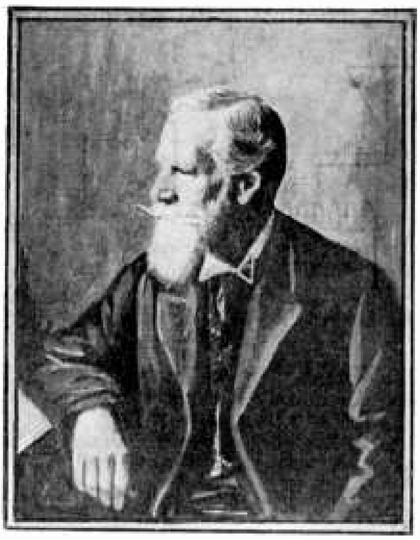
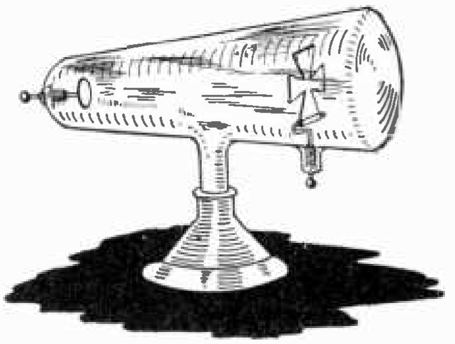
CROOKES, SIR WILLIAM (1832-1919) —English chemist and physicist. Born in London June 17th, 1832, Crookes was educated at the Royal College of Chemistry and afterwards became assistant in the meteorological department of the Radcliffe Observatory, Oxford. In 1855 he obtained a chemical post at Chester.



Sir William Crookes.

Crookes early began that series of brilliant researches which has left its mark on the scientific progress of the nineteenth century. In 1861 he isolated the new element *thallium*, during the investigation of the atomic weight of which he made the discovery of his *radiometer*. This led to his researches on the phenomena of electric discharges through highly exhausted tubes, or *Crookes tubes*. The illustration shows such a tube. When a current is passed through it. cathode particles travel along it. His discoveries on these phenomena led directly to the development by Sir J. J. Thomson of the now generally accepted *electron theory*. (q.v.) In 1883 he began his study of the rare earths, and in 1892 he forecast Radio telegraphy on the strength of Lodge's and Hughes' experiments.



Crookes' tube.

Knighted in 1897, Crookes was awarded the Royal medal in 1875, the Davy medal in 1880, and the Copley medal of the Royal Society in 1904, and the O.M., in 1910. He died in London, April 4th, 1919.

CRYSTAL—A general radio term for a mineral used as a *detector* (q.v.) of radio signals. The Physicist F. Braun noted in 1874 that certain pairs of crystals when arranged so that only a small area of surface was in contact, offered high resistance to the passage of currents in one direction while permitting them to pass readily in the other. This was really the birth of the crystal detector, although radio was not then developed. There are a great many different minerals that will act as detectors for radio signals, some of which operate with a wire, or other metallic contact, others which require a combination of minerals, one in contact with the other. There are also numerous *synthetic crystals* such as *carborundum*. Then again some of the more common natural crystals are subjected to treatment by heat, or other means, to change their nature or to make them more sensitive.

The following crystals are most used in radio reception: *galena, silicon, molybdenum, carborundum, zincite, bornite, chalcopyrite*, and *cerusite*. All of these are taken up under their respective headings. (See *Crystal Detector*, also *Combination Detector.*)

CRYSTAL DETECTOR—A combination of a *crystal rectifier* with contact and supports, used to detect *radio frequency oscillations*. Detectors of this nature are made in a great variety of styles, and use various kinds of crystals. In the more widespread form

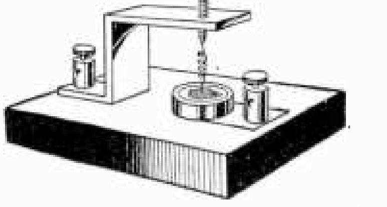


Fig. 1. Crystal detector using contact wire, or "cat-whisker."

the crystal detector consists of a crystal with rectifying properties, held in a cup or spring grip and arranged with a contact wire as shown in the illustration Fig. 1. This may be elaborated upon by supplying a series of flat springs to obtain very fine adjustment of the contact. Fig. 2. shows a combination detector, using two crystals, in contact with each other. This form has several advantages over the wire or *cat-whisker* (as the contact wire is called) type, chief among them the fact that it will withstand severe shocks without losing its adjustment. Fig. 3 illustrates a popular form of fixed crystal detector, in which the contact seldom requires adjustment. This type is of advantage providing it can be made sufficiently sensitive. (See *Carborundum, Vacuum Tube,* also *Crystal Receivers.*)

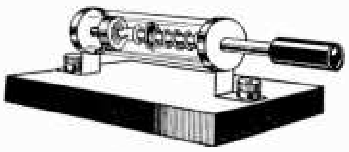

Fig. 2. Combination crystal detector.

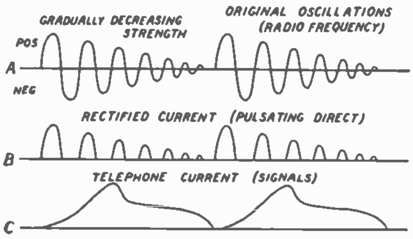
Fig. 3. Fixed crystal detector.

CRYSTAL DETECTOR—THEORY OF OPERATION—Theory of operation of a device used to detect radio waves, usually comprising a crystal in combination with a metallic contact, or, in some cases, two crystals arranged to rest against each other. In action this device serves to rectify the incoming signals, that is to say, it changes their nature from an alternating current to pulsating direct current. The incoming waves or signals consist of a series of alternations, the current flowing first in one direction, then reversing and flowing in the opposite direction along the circuit of the receiver. The changes of direction take place many times each second and would not be audible in the head phones in their original state. The crystal, as used in radio reception, has the peculiar property of furnishing a ready path for the flow of current in one direction while offering high resistance to its passage in the other. Now an *alternation* (q.v.) is a rise in current from minimum to maximum in one direction and back to minimum or zero, repeating the process in the other direction. Two of these alternations, one in a positive direction and the other in the negative direction constitute a *cycle.* (q.v.) If the crystal will permit the passage of current in one direction only, it is apparent that only half of each cycle can pass through; the other half of each cycle being lost or blocked out by the action of the crystal.

The illustration "A" gives a graphic representation of the *radio frequency oscillations* as they move over the aerial circuit. The curves above the line show the current in a positive direction while those below the line show it in the opposite or negative direction. If the signals or waves in this state were sent through a telephone receiver or head phone in a radio receiving set no sounds would be reproduced. Then again if the incoming oscillations were continuous, of unvarying strength, the rectified current would merely act on the diaphragm of the phone and hold it in a certain position as long as the signal persisted. This of course would not create any audible or intelligible sounds. If, however, the incoming oscillations were in the forms of groups or trains of waves, in any one of which the successive oscillations were less than the previous ones, the current would be rectified as shown in B and the result would be a series of pulses in the phone as indicated in C. These pulses would occur as often as the trains of oscillations occur (for more complete explanation of the difference between continuous and damped waves, see Damped Waves, also Continuous Waves). It will therefore appear that a *crystal detector* can only be used to receive *damped waves.* When the rectified portion of a damped wave train reaches the phones, the *diaphragm* is depressed and held until the train has died out, at which point the diaphragm is released until another train reaches it. This creates the audible signals and the number of trains occcurring each second will determine the number of depressions of the diaphragm and hence the pitch of the audible signals. (See *Crystal Receiver, Crystal Detectors,* also *Tickler.*)



Rectifying process of radio signals.

CRYSTAL RECEIVERS—A crystal receiver is the complete set of apparatus for receiving broadcast programs or *spark transmission* (signals), employing a crystal as the *detector* or *rectifier.* The set comprises a crystal detector, tuning device and phones, together with the usual aerial and ground arrangement. In its simplest form it may be merely a crystal detector, coil of wire and phones as in Fig. 1.

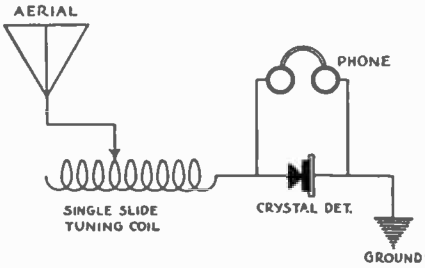


Fig. 1. Simple crystal set with single slide tuner.

Fig. 2 shows a more efficient form, using a two slide tuning coil. This method permits closer adjustment of the receiver to the particular signals desired. A still more efficient form is the *inductively coupled* type shown in Fig. 3. This method allows a very close adjustment and considerably reduces interference. The kind of detector to be used in any of the above types of receiver is immaterial as long as it is sufficiently sensitive. Such an arrangement as shown in Fig. 3 is very inexpensive to construct and when used within ten to twenty miles of the broadcasting station gives excellent results. A very simple arrangement for use with a crystal detector is shown in Fig. 4. This circuit uses a standard *variometer* and eliminates the necessity for a *condenser,* thus having only one control in addition to the adjustment of the crystal.

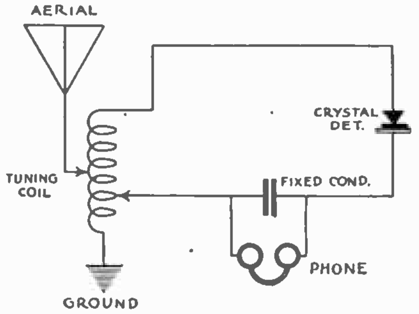

Fig. 2. Crystal receiver using double slide tuner.

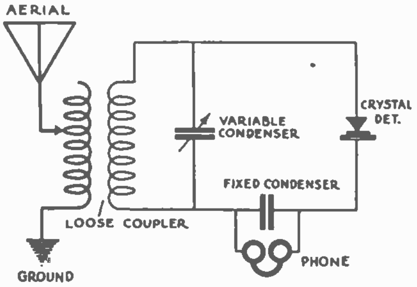

Fig. 3. Selective crystal receiver with loose coupler for tuning.

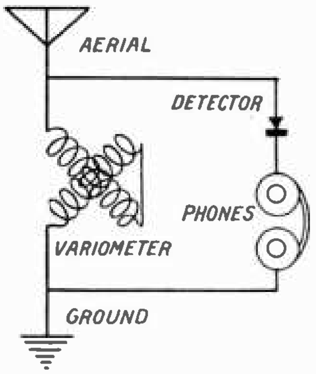

Fig. 4. A variometer is used as the tuning element in this crystal set.

CRYSTAL RECTIFIER—A device for changing an alternating current in a radio receiver into a pulsating direct current. This action is fully explained in "*Crystal Detectors (Theory of Operation).*"

CURRENT—A term used in electrical practise to signify the rate at which electricity flows from point to point in a circuit. The current in a circuit may be likened to the water flowing in a pipe. In this case the water would represent the electricity, the force or pressure represents the voltage, the pipe can be compared to the conductor or wire through which the electricity flows, and the current can be likened to the discharge from the pipe over a given period of time, that is the cubic feet of water per second. For practical purposes the unit of current is considered as the *Ampere.* This is the rate of flow of electricity when one *coulomb* (q.v.) passes a given point in the circuit each second. It will thus be apparent that while the ampere is often considered as the amount of current in a circuit, in reality it is the rate of flow of the electricity, the *coulomb* being the definite unit of quantity. Electric current is of course invisible. The only means of determining when there is current in a circuit is by observing its effect and it is always apparent by one or more of a number of effects. For example, if current is flowing in a wire or other conductor and a compass is placed near the conductor in such a position that the axis on which the needle revolves is parallel to the axis of the wire, the needle will be deflected. If the current reverses and flows in the opposite direction in the wire, the needle will be deflected in the opposite direction. The effect of current is also apparent by reason of the heat which it generates in passing through a wire conductor. If the wire is comparatively small and the current correspondingly large, the heat may be sufficient to be noticeable by placing the hand on the conductor. When the current is small, it can be detected by means of delicate instruments. This heating effect is made use of in various types of *ammeters*. The effect of current may also be noted in an incandescent lamp. In this case the current is made to flow through a fine wire inside a globe from which the air has been extracted, and the heat generated by the passing current causes the filament, or fine wire, to glow.

It is a well-known fact that heat causes expansion and this expansion of a fine wire is the principle on which one type of current measuring device operates.

Current is divided broadly into two divisions, *direct* and *alternating*. These two classes may again be separated into several further groups such as *high* and *low frequency alternating*, *continuous* and *pulsating*. Each phase or characteristic of current is taken up more in detail under its particular heading in this encyclopedia. (See *Current, Direction of Flow*, also *Current, Production of*.)

CURRENT, ALTERNATING—A current which does not flow steadily in one direction but changes its direction in the circuit periodically. (See *Alternating Current*.)

CURRENT CARRYING CAPACITY OF WIRE—The amount of current which a wire or other metallic conductor will carry without over-heating. Whenever current flows through a conductor, heat is generated. The amount of heat will be directly proportional to the resistance of the conductor and the square of the current in it. Now the resistance of a conductor depends on its cross-sectional area, length, and also its nature. It is therefore correct to state that the heating will depend on the amount of current flowing and the cross section and length of the wire. Obviously, a large wire will carry more current without over-heating, than will a small wire. Thus, it is necessary when choosing wire for a conductor to carry a certain amount of current, to select a wire of a cross section sufficient to carry the desired amount of current without undue heating.

The following formula for determining the current carrying capacity of various sizes and kinds of wire uses a certain factor T, which is the permissible rise in temperature above surrounding medium—such as air, earth or water. Where d is the diameter of the conductor in inches, T—the permissible temperature rise in degrees centigrade, N the resistance of conductor in ohms per mil-foot at final temperature, and I the current in amperes, then for solid conductors:

$I = \frac{K\sqrt{Td^3}}{r}$ and for stranded conductors: $I = 0.85\,K\frac{\sqrt{Td^3}}{r}$

K is a *constant* (q.v.) depending upon the condition of the surface of the wire and upon the amount of heat convection due to air currents. Values of the constant K for air differ according to different authorities from 800 to 1000, the former referring to still air and the latter to open air.

Table of current carrying capacities follows:

Wires and Cables, Insulated: Carrying Capacities, in Amperes, allowed by The Regulations of The National Board of Fire Underwriters for Interior Copper Conductors.

(For Aluminum 84 Per Cent of These Currents is allowed.)

Single Conductor Cables or Each Conductor of Multiple Conductor Cables.

CURRENT, CONVECTION—See *Convection Current*.

CURRENT, CRITICAL—See *Critical Current*.

CURRENT DENSITY—The number of amperes passing through a wire conductor per square inch of area of the conductor. For example, if a conductor is a wire or bar of copper having a cross section of one square inch and ten amperes are passed through it, the current density will be ten amperes per square inch.

CURRENT, DIRECT—Current that flows steadily, and only in one direction. (See *Direct Current*.)

CURRENT, DIRECTION OF FLOW (ASSUMED)—In electrical practice the *assumed direction of flow* of current is often referred to. This refers to the fact that direct current is assumed to flow from the *positive pole* of a battery, or other source of electrical energy, to the *negative pole* and thence back through the battery from negative to positive. This assumed action is shown in the illustration Fig. 1, where the arrows indicate the assumed direction of flow. Now while the current is stated as flowing from positive to negative outside the source, it is the generally accepted theory that the electron stream moves in the opposite direction, or from negative to positive. In other words, the current as we use the term, flows backward along the path of electrons. (See *Electron Flow*.) This reverse action of current and electrons is shown by the illustration Fig. 2 This apparent anomaly

can be likened to a salmon swimming up a rapid. The movement of electrons can be compared to that of the the water in the rapids and while the fish actually swim against the stream, and the electric current flows against the electron flow, the water and the electron stream nevertheless furnish the path of motion in each instance. The reason for the contradiction lies in the unfortunate arbitrary choice of positive and negative poles long before electrons were known. (See *Electron.*)

CURRENT, EDDY—See *Eddy Currents.*

CURRENT, HIGH FREQUENCY—A current that changes direction many times each second. In radio usage, currents having a frequency over ten thousand cycles per second are considered as *high frequency* or *radio frequency currents.* (See *Frequency, Radio Frequency* also *Low Frequency.*)

CURRENT, HIGH TENSION—Alternate term *High Pressure.* When the voltage, tension or pressure, in a circuit is comparatively low, the current is said to be a low pressure or *low tension current.* When the voltage is high, the current is said to be of high tension or pressure. Thus, as applied to radio usage, a dry cell or storage battery giving, respectively, one and a half and six volts for a certain type, are said to produce low tension or low pressure current. A "B" battery (q. v.) giving from 22½ to 45 volts (the usual value) furnishes *high tension* or *high pressure current.* While there is not a very great difference in voltage between a small "B" battery and an "A" type storage battery, the ratio of voltage to current in a "B" battery is far greater than in the ordinary case of the "A" battery and this must be taken into consideration. In general electrical practice the terms are not so arbitrary, and high tension currents might be taken as those above a pressure of several thousand volts.

CURRENT, LOW FREQUENCY—An alternating current that changes its direction of flow a comparatively few times per second. In commercial electrical work any frequency up to about 500 cycles per second is considered as low frequency current. In radio phraseology *audio frequency* (q.v.) currents are termed low frequency. For ordinary radio practice low frequency may be considered as any frequency below about 10,000 cycles. (See *Oscillation* also *Oscillatory current.*)

CURRENT, OSCILLATORY—See *Oscillatory Current.*

CURRENT, PRIMARY—A current which flows directly from its source, such as a cell or generator. The current obtained from any source through a direct conductive circuit is termed a primary current. (See *Secondary Current,* also *Induced Current.*)

CURRENT, NATURE OF ELECTRIC—As explained under the heading *Current,* electric current is manifest or understood by its effects. It may be apparent through the production of heat or light, by producing mechanical action such as required to operate a bell or move an electric motor, or, again, by producing chemical changes (See *Electrolysis*), and still further in its disastrous effects on the human body when the current has sufficient intensity. Without any actual or visible form of manifestation it can best be understood from the *electron* basis. It will be understood that an *electron* (q.v.) small as it is, contains a charge of electricity. When a sufficient number of electrons are in motion in a conductor (Note: current consists of electrons in motion) the current becomes large enough to be measured. As an instance of this fact a current of one ampere intensity (one coulomb per second) requires that about 10^{19} electrons flow past a given point in the circuit each second. When the electrons are not progressing along a conductor, no current flows in the circuit. If no current is being carried by the conductor, the electrons may move about, but they do not progress along the conductor.

CURRENT, PRODUCTION OF ELECTRIC—An electric current is produced in a conductor by applying an *electro-motive force* (voltage) at points of the conductor or by maintaining a difference of *potential* (q.v.) between two points. In the first example we can assume a metal ring or closed coil of wire through which a magnet is pushed or perhaps in the core of which a magnet is being excited, or in the general sense any complete circuit through which the number of magnetic lines of force are being varied. In the second instance the difference of potential may be due to a *primary cell* (q.v.). Thus, the first case can be understood as referring to any mechanical means of producing current, such as *generators.* The other general method is by use of a *voltaic cell,* that is, by chemical action. There are four important methods of producing an *electro-motive force.* The first is by friction, the apparatus used in this connection being termed a static machine; the second is by chemical action, as a primary or secondary cell; third, by mechanical motion, i.e., *dynamos* and *generators,* and fourth, by thermal action—known as a *thermo-junction* which is the wiring of two unlike metals in a conductory circuit so that by heating one of the points of joining an electric current will be set up in the circuit. (See *Static Electricity, Generator, Thermo Couple,* also *Current and Electro-Motive Force.*)

CURRENT, PULSATING DIRECT—When an alternating current is rectified by means of any device which permits current to pass only in one direction, the resultant current will move only in one direction, hence it is known as a *direct current·* but unless both negative and positive halves of the *cycle* (q.v.) are rectified or changed to direct current, the resultant current will appear as a series of pulses in one direction. The most common application of this is found in the case of a *crystal rectifier,* or *detector* as used for receiving radio signals or broadcasting.

Diagram showing how crystal detector converts alternating high frequency current into pulsating direct current.

When the incoming waves, or high frequency *oscillations* (Q.v.), are impressed on the detector, due to its peculiar properties they can only pass through it in one direction. In other words, granting that the incoming signal, or current, reverses its direction a great many times each second, it will be obvious that at any instant in the *cycle* (q.v.) current is moving in a certain definite direction, as from positive to negative, or vice versa, as stated, due to the peculiar properties of the detector the incoming signal current can only pass through the detector when the current is flowing in the correct direction. This means that only half of the *wave* (q.v.) is passed through and rectified. The result is a series of direct current surges through the balance of the circuit, each surge of current being followed by a space or time interval while the opposite half of the *cycle* or opposite *alternation* (q.v.) is blocked by the uni-directional nature of the crystal. These surges are then audible in the *head phones,* as they will actuate the *diaphragm* (q.v.) whereas a high frequency alternating current such as the original impulse from the broadcasting station would be inaudible. For a more complete explanation of this action see Rectifying action of crystal detector. (See also, *Rectifier, Full Wave Rectification and Rectifying Tube.*)
